Columnar Papilloma.—I have once met with this form of growth in the nasal fossæ in a lady past sixty. It sprung from the roof of the nasal cavity, and formed a mass blocking the nostrils and projecting into each orbit laterally. Much relief was obtained for a time by removing the projecting part of the tumor by avulsion with polyus forceps, but the growth soon returned. A second operation was performed, but death took place on the third day from septic meningitis. The post-mortem examination showed that the cribriform plate had been absorbed by the pressure of the growth, which had come directly in contact with the dura mater. The cause of death was a small rent in the membrane. The tumor was papillary in structure, and covered with non-ciliated columnar epithelium. Sections of the growth under the microscope closely resembled those of papillary growth from the rectum. The effect produced by the growth on the surrounding parts seemed merely the result of pressure and not of infiltration, consequently the growth may be regarded rather as a papilloma than a columnar epithelioma.

In **FRONTAL SINUSES**, though rarely, are occasionally the seat of disease. Abscess may form here, with much pain and expansion, and possibly carries its way to the anterior wall, attended by the local signs of inflammation and by larger or concomitant inflammation of the membranes of the brain. In such circumstances it may be proper for the Surgeon to remove by a small trephine the anterior wall of the sinus, and thus give exit to the retained pus. In other instances, again, the anterior wall of the sinus may be necrosed and perforated, the aperture being felt under a puffy tumor of the scalp. Here also the trephine is required. Distention with serous fluid also has been described as having occurred in some cases. There are a few cases recorded in surgical writings of **Polypi** springing from these sinuses, and passing their way down into the nose after producing expansion of it and much inconvenience. Here likewise, the propriety of trephining and so extracting the morbid mass would have to be considered.

DISEASES OF THE CHEEKS.

The chief diseases met with in the cheeks are, **Naevi** (p. 96), **Atheromatous Cysts** (vol. i. p. 941), **Subcutaneous Strumous Abscesses** (vol. i. p. 943), **Primary Syphilitic Sores** (vol. i. p. 1014), **Tertiary Syphilitic Ulcers** (vol. i. p. 1068), **Lupus** (vol. i. p. 1063), **Epithelioma** (vol. i. p. 990), and **Adenoid Ulcer** (vol. ii. p. 39). The symptoms and treatment of all these lesions have already been described. On the inner surface of the cheek **strumous cysts**, which can easily be dissected out from the inside, are not uncommon. **Epithelioma** also is not rare. Malignant tumors affecting the whole thickness of the cheek can seldom be operated on with any advantage.

Salivary Fistula.—One of the most troublesome surgical affections situated on the cheek is **Salivary Fistula**, occurring in consequence of injury, or, at operation, by which the parotid gland or duct has been opened,

so as to cause a trickling of saliva through the external aperture made into it. The flow of saliva in these cases is always to a great extent and often entirely intermittent, ceasing in the interval between meals and becoming very abundant during mastication.

The *Treatment* is by no means satisfactory, the attempt at union of the opening in the cheek being frustrated by the escape of saliva through it. If the fistula be very small and recent, the electric cautery may be employed with success; or the external aperture touched from time to time with a pointed stick of nitrate of silver. Should these means fail, the fistula having become chronic, operative measures will be required. The closure of an old salivary fistula in the cheek is a very troublesome matter. In these cases the Sténonian duct appears to be obstructed or partially closed; and it is useless to attempt to occlude the opening in the cheek until a proper aperture for the escape of the saliva has been made into the mouth, the escape of a few drops of saliva through the fistulous opening rendering the attempt to close it completely nugatory. The plan of treatment which I have found to answer best is a modification of Desault's. It consists in passing a small hydrocele trocar into the fistula in the cheek, pushing this obliquely forwards and inwards into the mouth, as nearly as possible in the direction of the parotid duct, withdrawing the stilet, and then passing a small silk seton through the canula, so as to bring one end out of the mouth, and the other through the fistula in the cheek. The canula is then withdrawn, and the seton tied loosely. It should be left in for about three weeks, so as to establish a sinus into the mouth. It is then to be cut and withdrawn, and the sinus in the mouth kept patent by the daily introduction of a probe, by leaving a small piece of gum catheter in it, or, if it show much disposition to close, by the introduction of a laminaria tent. In this way the saliva is diverted from the external opening and made to flow into the mouth. The external aperture in the cheek may now be closed by touching its edges with a pointed stick of nitrate of silver or the galvanic cautery; or, if large, they may be pared and stitched together.

DISEASES OF THE LIPS.

Congenital Malformation of the Lips is of common occurrence. *Congenital Contraction*, or even complete closure of the orifice of the mouth, has been met with at birth; such a condition must be remedied, according to circumstances, by the skill of the Surgeon. The opposite condition is also occasionally observed, the opening of the mouth extending on one side too far into the cheek, constituting the condition known as *Macrostoma*. It must be remedied by a plastic operation. By far the most common malformation, however, is the condition termed *Harelip*, which will be noticed in detail in the chapter on the Plastic Surgery of the Face and Mouth.

Hypertrophy to a great extent occasionally occurs in either or in both lips. It is especially common in the upper lip in scrofulous children, forming the condition known as "strumous lip." It is often of an edematous character, being kept up by the irritation of fissures or cracks; if so, these must be cured, when the size of the lip will gradually diminish. Sometimes, however, it becomes permanent, continuing after the cure of the fissure; in these circumstances it may be necessary to excise an elliptical portion of the mucous membrane of the lip in a horizontal direction, and then to bring the edges together by means of sutures or pins.

Ulceration is not unfrequently met with on the prolabium, frequently of a simple character, though chronic. It is often dependent on a disordered state of the digestive organs. It will commonly yield to the application of

nitrate of silver, to proper constitutional treatment, having for its object the improvement of the digestion, and in very chronic cases to the administration of the preparations of arsenic.

Primary Syphilitic Sores, communicated by kissing, are by no means uncommon on the lips. Their peculiar character has been already described (vol. i. p. 1044).

Cysts and Erectile Tumors.—The lips may be the seat of cysts and erectile tumors, requiring extirpation by the knife or ligature. In dealing with these, the Surgeon must be guided by the circumstances of the individual case; but he should, if possible, avoid cutting through the whole thickness of the lip; and, if compelled to do so, he must act as will be described in speaking of cancer of this region. (See next page.) These growths most frequently occur on the lower lip.

Cysts are usually small and transparent, with thin walls, containing a glairy straw-colored fluid. These should always be dissected out; mere excision of a portion of the wall being followed by recurrence of the disease.

Nævi of the lip are usually of an active character, and may either be excised, if of moderate extent and implicating the whole thickness of the lip; or, if of large size and projecting from the mucous surface, they may be safely ligatured (p. 98). I have had under my care several cases of *Nævus* of the upper lip, implicating the whole substance of the part, and have successfully removed them by the repeated application of potassa cum calce.

Warty Growths are common on the lip, and are apt after existing some time to become epitheliomatous. Sometimes crusts of epithelium, forming horn like projections, are developed on the surface. They are best treated by early removal, no local application being of much use, and the danger of their becoming malignant being very considerable.

Epithelioma.—The structure of epithelioma has been so fully described at p. 390, vol. i., that it need not detain us here. The accompanying cut (Fig. 660), is a good illustration of the microscopic characters usually presented by it in the face and lips.

Epithelioma of the lip commences either as a warty growth, which gradually ulcerates, or as an indurated crack or fissure, the edges of which have a tendency to spread. The submaxillary lymphatic glands tend to become early involved; and the disease may eventually prove fatal by the pain, exhaustion, and constitutional irritation thus induced. Lip-epithelioma almost invariably occurs in men, and in the lower lip—I have never met with a case affecting the lower lip of a woman. It is met with after the middle period of life. Of twenty consecutive cases in which I have operated, and of which I have notes, thirteen were above sixty, and six between fifty and sixty years of age; in one case only did the disease occur under thirty. This disease is at first entirely local, often being induced by some irritation, as by a rugged broken tooth, or by smoking a clay-pipe; and when removed it does not, I believe, very commonly recur. At least, of the very many patients that have been operated upon at University College Hospital, I have known but few to return with a recurrence of the disease; I cannot,

Fig. 660.—Section of an Epithelioma of the Face, showing the Epithelial Cells penetrating into the substance of the true Skin.

therefore, but come to the conclusion that the operation for epithelioma of the lower lip frequently rids the patient permanently of his disease.

When return does take place, it is not always in the cicatrix or in the adjacent glands. I have seen recurrence at the angle of the mouth and inside the cheek of the side opposite to that on which the primary disease had declared itself and been removed, and this not till three or four years after the operation. In these cases the tumor was probably a fresh primary growth.

When the glands are enlarged, the advisability of operating will depend upon the extent of the glandular implication. It must be remembered that the internal organs are affected in epithelioma only in exceptional cases, and thus we may hope occasionally to cure the patient permanently even after implication of the lymphatic glands. If merely the submaxillary lymphatic

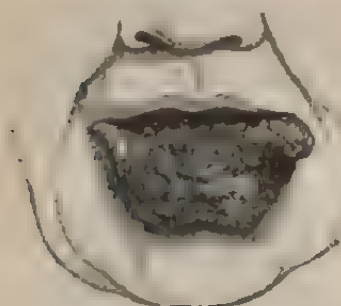

Fig. 661 Extensive Warty Epithelioma of the Lip.

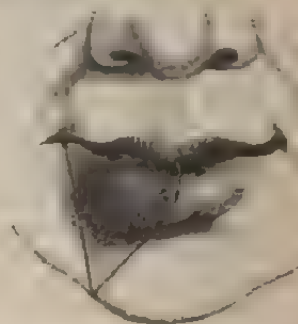

Fig. 662. — Lines of Incision for Removing V-shaped Piece of Lip.

glands are enlarged, they should be fully exposed by a curved incision carried from near the symphysis to the level of the hyoid bone and back to the edge of the sterno-mastoid. The facial artery and vein will probably be divided; and sometimes it is necessary to remove the submaxillary gland, which may be implicated by extension from the neighboring lymphatic

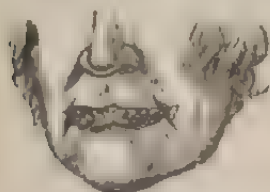

Fig. 663. — Epithelioma of Lower Lip. Lines of Incision.

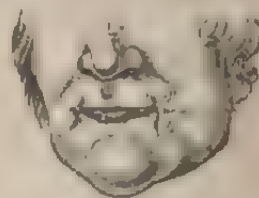

Fig. 664. — Lip after Removal of Epithelioma.

glands. A gland must be sought for, also, between the genio-hyoid muscles. If enlarged glands can be felt beneath the sterno-mastoid, it is better not to operate, as these can seldom be safely removed owing to their adhesion to the carotid sheath.

If the glands are extensively adherent to the skin, then no operation should be attempted.

Operation. — When once the true nature of the disease has been ascertained, the operation should be performed with as little delay as possible; but, before it is done, it is well that any very prominent or broken tooth should be removed, and the tartar cleaned away from the incisors. The

operation requires to be somewhat modified, according to the situation and extent of the affection (Fig. 663). If this be tolerably limited, a V shaped cut extending widely round it, and carried sufficiently low to include any incised prolongation of the absorbents, should be practised; the edges of the cut should then be brought together by two harelip pins with a twisted suture, as in the case of a simple harelip. When the disease occupies a considerable longitudinal extent, but does not dip down very deeply, a slice of the lip should be shaved off, including the whole of the morbid structure;

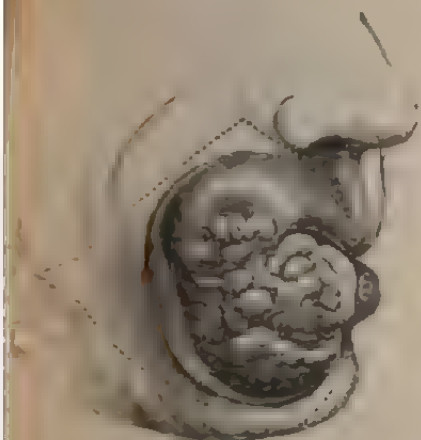

Fig. 663 — Extensive Epithelioma of the Lip. Lines of Incision.

Fig. 666 — Epithelioma of Lower Lip involving Jaw, successfully removed. Heath.

and it is often surprising, in these circumstances, to observe how the tissues of the lip will speedily rise to their natural level, thus preventing any permanent deformity from being left (Fig. 664). In some cases the disease escapes a square surface, and then it is necessary to excise a portion of the lip when this is done, a considerable gap is left, requiring to be filled by the plastic operation of the kind that will be considered in a subsequent chapter, which may be most conveniently done at the time when the excision is performed. When the disease occurs at the angle of the mouth, it assumes a more intractable character than when affecting the free part of the lip. The same operation—that of free excision—may be applied to it here as in the former case, but with less prospect of success. Should the disease be as extensive as in Fig. 665, the lines of incision must be so planned as completely to surround and to isolate it.

Heath has very successfully extended this operation to cases in which the cancer of the lip had invaded the gum, and had involved the lower jaw, by removing a portion of the implicated bone, together with the disease, in the best parts. Fig. 666 gives a good idea of the cases to which this operation is applicable.

DISEASES OF THE PAROTID GLAND.

Mumps or Parotitis is an acute specific disease, the local manifestation of which is inflammation of the parotid and sometimes of the other salivary glands. It is common in children, though it not unfrequently occurs in

adults. It is highly infectious, and frequently epidemic; and, as in the other acute specific diseases, one attack generally protects the patient from the disease for the rest of his life. It has an incubative period of from two weeks to twenty-two days, but three weeks is the most common time. It commences usually with some febrile disturbance and malaise lasting about twenty-four hours, but this may be wanting. At the end of that time one parotid gland becomes swollen, stiff, and painful; the swelling continues to increase till about the fourth day, at which time it reaches from the zygoma to the angle of the jaw. The swollen *sacra parotidis* can usually be clearly felt over the masseter and forms a valuable diagnostic sign, distinguishing parotitis from inflammation of the lymphatic glands behind the jaw. When the swelling is at its height, mastication is extremely painful. There is usually elevation of temperature, reaching 102° F. or 103° F. When one gland begins to subside that on the opposite side usually begins to swell and runs the same course, but occasionally both glands swell simultaneously. Suppuration rarely, if ever, takes place, unless it be in the lymphatic glands of the neighborhood. As the parotid affection subsides, but sometimes simultaneously with it, inflammation of the testicle in the male or the breast, labia, or ovary in the female may take place. These so-called metastases are very rare in children. The orchitis is frequently followed by partial or complete atrophy of the testicle, but fortunately, as the disease severely affects both sides, sterility rarely results. Inflammation of the membranes of the brain has been said to have been met with as a complication of mumps.

The *Treatment* of this affection is simple. If it be severe, the application of hot fomentations and the administration of salines, and when the affection is on the decline, frictions with camphorated oil, will hasten its resolution. The orchitis must be treated with hot fomentations and rest.

Tumors—Tumors of the parotid gland itself are not so frequent as morbid growths situated upon it or in its vicinity. The tumors met with in this

region may be simple or malignant. The simple tumors met with in this region most frequently present a peculiar structure rarely met with in any other part of the body. They consist of mixed cartilage, fibrous tissue, and mucous tissue, to which is often added glandular tissue, imperfectly resembling the structure of a racemose gland. When small, they are firm, and somewhat elastic to the feel, smooth or slightly lobulated on the surface and freely movable on the parts beneath. As they increase in size fluctuating areas become perceptible, often projecting above the rest of the growth. These may be actual cysts containing a glairy fluid formed by mucous softening of the cartilage or they may be due to the presence of a mass of gelatinous tissue, presenting

Fig. 667.—Tumor of Parotid, too Deeply Seated for Removal.

under the microscope the typical branched cells and mucous intercellular substance of a myxoma. These tumors grow slowly, often taking many years to reach the size of a walnut, but at any time they may take on active growth and reach a large size in a comparatively short time, becoming even as large as a cocoanut; the skin covering them then becomes thin but not adherent, and not unfrequently a network of veins covers the mass. These

growths frequently send prolongations under the ramus of the lower jaw, and then occupy the whole of the space between its angle and the mastoid process; when firmly bound down, they involve the bloodvessels and nerves in this important region, coming into relation with the styloid process and its muscles, with the internal as well as the external carotid, and even pressing upon the pharynx and projecting into the fauces, as was the case with the patient from whom the annexed cut (Fig. 667) was taken. In such cases as these the deep relations of the tumor are so intricate, important, and extensive, that no operation for its removal can be undertaken, and the patient eventually dies, usually in consequence of disturbance of the cerebral circu-

Fig. 668.—Simple Tumor of Parotid.

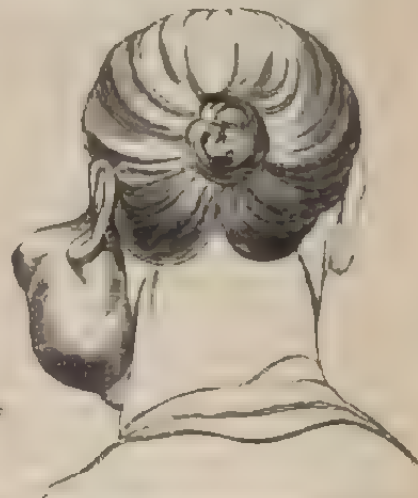

Fig. 669.—Simple Tumor of Parotid: Back View

lation, or of compression of the pharynx and larynx; or the skin may at last become adherent and give way, profuse hemorrhage afterwards taking place from the ulcerating tumor. In consequence of the large size that these tumors may attain, they have a tendency to produce atrophy of the parotid, and often, by interfering with the cerebral circulation, occasion various congestive symptoms about the brain. Besides the ordinary "parotid tumor" pure cartilaginous growths are not uncommon, and more rarely pure fibromata and myxomata are met with. Cysts, except as secondary formations in solid tumors, are very rare.

Malignant Tumors of the parotid are of moderately frequent occurrence. They are most commonly soft glandular cancers (encephaloid), but scirrhus has been met with in this situation. They spring from the gland itself and not from the structures superficial to it as is the case with the simple growths. They present the ordinary rapid growth of such tumors; they are from the first fixed and deeply seated, and early implicate the skin.

Spindle-celled and round-celled sarcomata are occasionally met with in this region, springing from the bones or fasciæ. They grow rapidly and implicate the surrounding parts, and as a rule force their way into the pharynx. The distinction between these and the true cancers cannot always be made during life.

Diagnosis.—It is of great importance to effect the diagnosis between the non-malignant and the malignant varieties of tumors in the parotid region,

In the *simple tumors* there is always mobility; and, although the attachment may be deep, the skin is not involved to any extent. The outline of the mass is usually well defined, square, and somewhat lobulated. The progress of the growth is very slow, often occupying many years before it attains any considerable bulk, as in the annexed cuts (Figs. 668, 669), representing a tumor of sixteen years' standing which I excised. In the *malignant growths* there is no mobility, but the mass is solidly fixed; its outline is ill-defined, the skin soon assumes a reddish purple color, is brawny, and presents the usual characters indicative of subjacent malignant action. When these tumors are *encephaloid*, they grow with considerable rapidity, feel soft and papery, and are rounded and ill-defined in their outline, especially under the ear and by the ramus of the jaw.

The lymphatic gland, which lies just in front of the neck of the lower jaw, and those superficial to the parotid, when chronically enlarged, may then closely resemble a simple parotid tumor. Their mobility is usually less than that of the simple parotid tumor, and they are slightly tender when pressed upon, and it is very seldom that a single gland is affected. Occasionally, however, it may be impossible to make a certain diagnosis till the tumor is removed.

Treatment.—In the treatment of these tumors, extirpation is necessarily the only course that can be adopted; and this should certainly not be attempted if the disease be malignant; for, as it would be impossible to remove its deeper attachments, the growth to a certainty would speedily return. Even if the disease be of a simple character, care must be taken that every lobule and prolongation be extirpated; for, if any be left, however small, it will without doubt become the nucleus of a new tumor. In removing tumors in this situation, the superficial incisions should be free, and either longitudinal or crucial, so that the whole mass may be fairly exposed. It is not wise to remove integument, however redundant this may appear to be, unless it have undergone infiltration, incorporation with the tumor, or change of structure; and even then as little as possible should be taken away. The fibrous or aponeurotic investments of the tumor must be fairly opened, and the edge of the knife must then be directed against it, and the dissection carried on from below upwards, or from behind forwards, so that one division of the bloodvessels supplying it may be sufficient. After the tumor has been well loosened by the division of investing tissue and structures, and it is surprising how movable it often becomes after this has been done, though it may previously appear to have incorporated somewhat solidly with the subjacent tissues, it should be taken hold of by the hand or a large double hook, and drawn well forwards whilst the deep dissection is being carried on. In prosecuting this, the Surgeon must particularly guard against wounding the temporo-maxillary artery and the facial nerve, which are especially exposed to injury. In some cases the division of these cannot be avoided, as they are incorporated in the mass that is undergoing removal. The hemorrhage will then of course be abundant, but may usually be immediately arrested by the ligature of the divided artery; in fact, in most cases the bleeding is profuse, owing to the unavoidable section of nutrient vessels and of large subcutaneous veins, but may generally be readily arrested by ligature and pressure. In most instances, however, by keeping the edge of the knife carefully against the tumor, and by drawing it well forward, so as to loosen it in its areolar bed at each stroke of the scalpel, removal of the morbid mass may be effected without the division of any important vessel or nerve. It is of more consequence to avoid a wound of the parotid duct, or of the chief branches of the plexus arterius, than even of the temporo-maxillary artery; as incurable paralysis of the face would result from such an

injury. Injury to this nerve is best avoided by dissecting out the tumor by incisions parallel to its main trunk and chief branches, and especially by drawing the mass well forward, and directing the knife towards it.

If the tumor, though non-malignant, have been allowed to attain an enormous size, developing at its deeper attachments as well as superficially, with large lobes lying behind and under the ramus of the jaw, in close relation with the pharynx, the internal carotid, and jugular vein, it will not be prudent to attempt its removal.

Excision of the Parotid Gland itself is occasionally spoken of, but is very rarely done. I believe that in most cases in which it is stated that complete removal of this gland has been accomplished, tumors overlying and compressing it have been mistaken for it. Godlee, in one case in University College Hospital, completely removed the gland for an infiltrating growth. The operation was tedious and difficult, and the facial nerve and carotid artery were necessarily divided. The wound healed well, but the growth returned and ultimately proved fatal.

DISEASES OF THE NECK.

Congenital Fistulæ in the Neck or Branchial Fistulæ are of very rare occurrence. They arise from imperfect closure of one of the branchial clefts, most commonly the lowest (see Fig. 365, vol. i. p. 938.). The fistula opens on the skin near the sternal origin of the sterno-mastoid. It is lined with mucous membrane and discharges a small quantity of mucous fluid. A fine probe can usually be passed a considerable distance upwards towards the hyoid bone, and, in rare cases, can be made to enter the pharynx. Similar congenital fistulæ have been met with in the middle line of the neck. As they cause no inconvenience, they are better left alone as it is impossible to close the whole track, and obliteration of the orifice would probably be followed by the dilatation of the remainder into a cyst.

Cystic Tumors in the Neck.—Six varieties of cysts are met with in the neck: 1, the congenital multilocular cysts or cystic hygroma; 2, unilocular serous cysts or hydrocele of the neck; 3, blood-cysts; 4, deep atheromatous cysts; 5, burian cysts; and, 6, true hydatid cysts.

1. The **Congenital Multilocular Cysts or Cystic Hygromata** are usually situated in the middle line in the subcutaneous tissue in front of the trachea, where they may attain a good size. Their supposed origin and their structure have been already described (vol. i. p. 939.) If not too large or too deeply attached, they may be removed.

2. The **Unilocular Serous Cyst or Hydrocele of the Neck** is of somewhat doubtful origin, but they are usually supposed to arise in spaces left by the imperfect closure of the branchial clefts. These tumors were accurately described by Maunoir and Phillips. They may be congenital, but more commonly appear in children or early adult life. The cyst is usually situated in the posterior inferior triangle, but has been met with also in front of the sterno-mastoid between that muscle and the jaw, forming a rounded tumor, smooth, tense, and elastic, and filled with a yellow or chocolate-colored serous fluid. It may attain so large a size as to interfere with deglutition and respiration. The largest I have seen was of the size of an orange. The skin covering this tumor is not discolored, in some cases of natural thickness, in others thin and expanded, so as to give a bladder-like appearance to the growth.

The *Treatment* of this tumor consists in tapping, when complete collapse of the cyst takes place; it however soon fills again. A permanent cure may be effected by injection with iodine, or by passing a seton across. It is

usually impossible to dissect it out owing to the depth of its attachments and the thinness of its wall.

3. **Blood-cyst or Hæmatocele of the Neck.**—This may be merely one of the cysts just described into which hemorrhage has accidentally taken place. The true blood-cysts, however, are much more serious; when punctured pure blood escapes, sometimes almost arterial in tint, and even if the cyst be emptied it speedily fills again. They have been met with in close connection with the great vessels of the neck. Their origin is not certainly known, but some have supposed them to originate from a cyst-like dilatation of one of the large veins of the neck. In others no communication has been found with any large vessels, but the lining membrane was highly vascular. The *Treatment* consists in puncturing the cyst with a fine trocar and injecting iodine or perchloride of iron. If the cyst could be partially emptied by pressure, showing communication with a large vein, this would evidently not be justifiable. Gay has successfully dissected one out, which lay in close contact with the carotid sheath.

4. **Deep Atheromatous Cysts** are very rare. They are of congenital origin, and arise from inclusion of a fold of skin during closure of the branchial clefts (vol. i. p. 938). Their most common situations are below the jaw, in the middle line pushing upwards beneath the tongue and along the anterior border of the sterno-mastoid. The only *Treatment* consists in dissecting them out. The operation may be very difficult, owing to the relations of the cyst-wall to the large vessels and other important parts.

5. **The Bursal Cysts** occur in the middle line about the hyoid bone and the front of the larynx. They have already been described with diseases of bursæ (p. 480).

6. **True Hydatid Cysts** sometimes form in the neck. A woman was under my care at the Hospital for a hydatid tumor of the liver, which I tapped; seven years afterwards she presented herself with a thin-walled elastic semi-transparent tumor in the posterior interior triangle of the neck, about the size of an orange. This I tapped, and found it to contain clear serous fluid with the remains of echinococci. In another case, that of a lad aged about 18, otherwise healthy, I removed a hydatid tumor as large as a shadow from the nape of the neck, where it was deeply seated under the trapezius, growing apparently from the substance of the complexus or splenius capitis muscles, and lying close upon the cervical spine and the occipital bone.

Solid Tumors of the Neck—Fatty tumors and the various forms of sarcoma, may occur in the subcutaneous tissue and fascia of the neck as elsewhere, but they present nothing special. The neck is the favorite seat of lymphadenoma, the tumors in this situation often reaching an enormous size, so as to endanger life by their pressure. In the submaxillary region, tumors are occasionally met with similar in character to the parotid tumor already described. The submaxillary gland itself is rarely the seat of disease.

Tumors in these situations may occasionally attain a considerable size, and if beneath the fascia, may extend deeply. In some cases when the integuments and superficial structures covering the growth are divided, it may be isolated with sufficient facility, its fixity being in a great measure due to its being bound down by the investing fascia rather than to its having contracted deep adhesions. Occasionally, though rarely, a slow-growing simple tumor develops deeply in the anterior triangle of the neck, lying between the sterno-mastoid, the trachea, and the pharynx, possibly even under the carotid sheath, with the artery pushed on one side, or even running over the anterior convexity of the growth. In such cases, the question of removal requires to be approached with the utmost caution. If the tumor be movable above the vessels, it may generally be taken out; if it lie below the

sheath, even though not fixed to the spine, its extirpation is not practicable. Before determining upon the removal of a tumor situated in one of the triangles of the neck, it is indeed always very necessary that a diagnosis of its nature be effected, and that some opinion be formed of the probable extent of its deep attachments.

The first point to ascertain is whether it be simple or malignant. If simple, it will usually have been many years in growing; it will be hard but not stony, lobulated or somewhat square-shaped; the patient's general health being good. It will generally be found to be movable, though not perhaps to any great extent, and will present no sign of incorporation with neighboring structures. If it be superficial, the fibres of the platysma will not appear to spread over it, and the sterno-mastoid muscle may be traced to one side of or below it. In such circumstances, removal of the tumor may be undertaken by any Surgeon possessing a fair share of anatomical knowledge and manual skill, with every prospect of success. But if the tumor be of stony hardness, have implicated the skin, and be immovable, the whole head being moved on any attempt at drawing it aside, if it be ill-defined under the jaw and ear, or rapidly growing, soft and pulpy to the feel, deeply seated under the angle of the jaw, evidently below the platysma and deep fascia of the neck, and possibly beneath the sterno-mastoid, then no attempt at extirpation should be undertaken, as the mass could either not be removed with safety, or, if it were by any possibility extirpated, the already existing contamination of the neighboring parts would certainly lead to a speedy recurrence of the disease.

In removing *submaxillary tumors*, a free superficial incision nearly parallel to the margin of the lower jaw, but below this, will usually allow ready extirpation of the mass. In these operations the facial artery is generally sufficiently under cover of the bone to escape injury, but there may be, and usually is, free venous hemorrhage.

Congenital Tumor or Induration of the Sterno-mastoid.—These terms are applied to a diffuse thickening and induration of the sterno-mastoid, affecting especially its lower and sternal part, occasionally met with in infants. It is observed either at birth or shortly after. It disappears after a few weeks or months without any special treatment. Its nature is somewhat uncertain; it has been attributed to injury during birth, especially in cases of breech-presentation; Bryant considers it inflammatory; Holmes is inclined to regard it as a congenital hypertrophy; and by others, it has been referred to syphilis. In a case recorded by F. Taylor, in which the swelling was examined after death, it was found to be due to a new growth of fibrous tissue between the bundles of muscular fibres. The child was syphilitic, and the case was also one of breech-presentation at birth.

Diffuse Cellulitis of the Neck. Ludwig's Angina has been described in vol. i. at p. 894.

DISEASES OF THE THYROID GLAND.

The thyroid gland is subject to various simple chronic enlargements, which commonly go by the name of *Bronchocoele* or *Goitre*. The thyroid gland is composed of closed vesicles, lined by a single layer of cubical epithelium, containing a clear albuminous fluid. The vesicles are held together by areolar tissue, supporting numerous vessels of considerable size. Virchow has shown that all forms of bronchocoele commence by a true hypertrophy of the gland-substance, but as the enlargement progresses, one or other of the constituent elements of the gland may increase out of proportion to the others. If all the constituents continue to increase equally, the simple bronchocoele results; if the contents of the vesicles accumulate, unduly dis-

tending the cavities, the disease assumes the form known as cystic bronchocele. Very commonly there is a great increase of the fibrous tissue, forming the *Fibrous Bronchocele*, and occasionally great dilatation of the vessels takes place with simple hypertrophy of the remaining structures of the gland, forming the *Pulsating Bronchocele*. Secondary changes also may modify the structure of the tumor. Of these the most common is a substitution of a gelatinous colloid material for the albuminous fluid normally found in the vesicles of the gland. Calcification also is common both in the walls of the cysts in cystic bronchocele, and in the masses of fibrous tissue in the fibrous goitre.

The CAUSES of bronchocele have been much discussed, both professionally and popularly. The most generally received belief is, that the disease is directly occasioned by some impurity in, or peculiarity of, the water that the patients drink; and it has been supposed that water coming through chalk or limestone is particularly apt to occasion bronchocele in this country, and that water resulting from melted snow is its occasioning cause in Switzerland. But these ideas are groundless. Hard water is drunk largely in the country in districts where no bronchocele occurs, and snow water is never used in Switzerland; spring-water of the purest kind only being drunk. It would appear that air and locality have much more to do with the occurrence of bronchocele than water. In mountainous countries the disease occurs almost entirely amongst the inhabitants of valleys, where the air is moist and stagnant; the inhabitants, especially of valleys that run north and south, into which the sun does not penetrate readily, or for many hours in the day, which are always in the shade of neighboring and overhanging mountains are especially prone to it. This is well known to be the case in Switzerland, where the disease is endemic; so also in large towns, it occurs chiefly amongst the poor who live in cellars and kitchens, or damp, ill-ventilated streets and courts. When it is met with in the richer classes, it is found mainly amongst children and young people shut up in school-rooms or devoted to a sedentary and indoor life, unnatural and prejudicial. It is rarely, if ever, met with amongst those who lead open-air and active lives. Bad food and low living no doubt conduce to it. The tendency is probably hereditary in some cases, when associated with idiocy, constituting that wretched condition "cretinism"; it undoubtedly is so. Every race of men is liable to bronchocele, and it occurs in all latitudes from the Arctic region to the tropics. Thus Frankland found bronchocele amongst the inhabitants of the polar regions, and Mungo Park amongst those of the interior of Africa. In this country it is most common in Derbyshire, and has consequently received the name of "*Derbyshire neck*." It is most frequent amongst women.

SYMPTOMS AND VARIETIES. Simple Hypertrophy.—The thyroid gland may be simply hypertrophied, and may then attain a considerable size. It forms a smooth rounded tumor, maintaining more or less accurately the form of the normal gland, though frequently the enlargement on one side is greater than that on the other. It is soft and elastic to the feel, and moves up and down with the trachea during deglutition. In the majority of instances in England, the tumor is of but very moderate size, terminating at first as a mere fulness and uniform rounded enlargement of the isthmus, until perhaps, by the pressure of the growth confined between the sternomastoid muscle and under the deep fascia of the neck, the voice becomes croaking and harsh, and respiration and deglutition seriously affected. It is seldom that the bronchocele distorts the structures of the neck to one side, but this may happen. Thus I have seen the larynx and trachea pushed completely over to the left, forming a long convexity in that direction.

whilst the carotid sheath on the right side was thrust behind the sternomastoid muscle.

There is a remarkable connection between tumors of the thyroid gland of this kind, and a general anæmic condition of the system. In London nothing is more common than to find a certain degree of bronchocele in pale and bloodless women and girls; indeed, so frequent is the coincidence that it is impossible not to regard it in the light of cause and effect.

The immense lobulated tumors hanging from the forepart of the neck, which are met with in various districts of this country and of the Continent, more especially in the valleys of the Alps, in which the disease is and has been epidemic for ages,¹ usually belong to the fibrous variety of bronchocele.

Fibrous Bronchocele.—This form commences as simple hypertrophy, but as the tumor increases in size it loses its soft elastic feel and becomes dense and indurated; at the same time its form often changes, becoming more irregular and lobulated. The pressure-effects of the fibrous bronchocele are more severe than those of the simple form, owing to the greater density of its structure. Respiration may be greatly impeded, at first only during exertion, but, when the growth reaches a considerable size, during rest also. Occasionally the tumor may extend below under the sternum, and the pressure-signs then become more serious. Deglutition is seldom seriously interfered with.

Cystic Bronchocele is due to the development of cysts in the substance of the enlarged gland. These cysts may be single or multiple. When single or of large size, as in Fig 670, they usually contain clear serous fluid. When multiple, they are filled with colloid substance, or with a fluid that presents the ordinary characters of altered blood, being dark, grumous, or like coffee-grounds, and have often cauliflower-like excrescences projecting into their interior.

Pulsating Bronchocele is occasionally met with. The pulsation, which is eccentric and distensible, is synchronous with the heart's action, and evidently due to the vascular character of the tumor itself. This form of bronchocele is sometimes conjoined with the cystic. When it is confined to one lobe only, care must be taken not to confound the beatings with those of carotid aneurism; a mistake which I have known to occur. The diagnosis of the two affections has been adverted to at p. 191, vol. ii.

TREATMENT.—The treatment of bronchocele must vary according to the size and character of the tumor, and the constitutional condition associated with it. When small, and associated with anæmia, and of comparatively recent formation, it is best treated by improving the general condition of the patient. This may be done in various ways—by the administration of good food; by change of air from a low and damp to an elevated and dry and healthy situation. The change to a higher and drier and more airy locality has been much insisted on by those who have studied the disease in those valleys of Switzerland in which it is endemic; and establishments have been erected several thousand feet above the level of the sea, on mountain-tops, with the view of curing patients thus affected. Guggenbühl has been particularly successful in these endeavors. In towns, the patient, if living on the basement floor, should be moved to the upper story, if possible, and should be encouraged

¹ Quis tumidum Guttur mimatur in Alpibus?

in habits of outdoor rather than of sedentary or indoor occupations. Besides these hygienic measures, which are of the first importance, the disease may be treated medically by the administration of iron, especially the iodine internally, and the external application of iodine or of iodide of lead ointment. Indeed, in the soft bronchocele occurring in anæmic females, iron is of the utmost service, and acts almost as a specific.

In bronchoceles of large size, hard, and unconnected with anæmia, the chief reliance is to be placed on the free and continuous use of iodine internally as well as externally. The iodide of potassium is the best form in which to give the iodine internally. The quantity of this medicine should be gradually increased, until from 20 to 30 grains are given three times a day either alone, in milk, or in combination with some preparation of iron; the iodide is probably the best. But iron is very necessary in all the anæmic forms of the disease. Iodide of lead and compound iodine ointment may be used with advantage. It has been recommended by Mount that the balsam of mercury ointment (16 grs. to the ounce) should be well rubbed in for several days; and then, the tumor being covered with it, the patient should be exposed to the strong heat of a mid-day summer sun. This method of treatment, which is said to have been extremely successful in India, has not been tried in this country to a sufficient extent to enable an opinion to be formed of its merits. In some instances pressure has been of use, especially in conjunction with the iodine injections; though it is not so easy to apply this means, and no considerable degree of it can be borne, on account of the increased difficulty of respiration that is thus occasioned. In fact, the compression exercised upon the tumor by the sternomastoid muscles in some of these cases is so considerable that it becomes necessary to divide its tendon subcutaneously, in order to relieve the trachea from the constriction to which it is subjected. When the tumor is chiefly cystic, the fluid contents may be drawn off by tapping, and an endeavor may be made to cause the cyst to close by inducing inflammation in them by the injection of tincture of iodine. The fluid that flows from the cyst is often darkly stained with blood, and occasionally pure blood may escape in considerable quantities from the puncture. Morell Mackenzie advises the injection of the cyst with perchloride of iron to check the flow of blood that often takes place from the cyst wall. He recommends that the cyst be tapped with a trocar and canula; after the fluid has escaped, a solution of perchloride of iron (5 grs. $\frac{1}{2}$ of water) is injected; the canula is then plugged and left in till suppuration is established, after which it may be withdrawn and a drainage-tube substituted. When bronchocele is very large, and very chronic, its absorption cannot, I think, be expected to be brought about by these or any other means, and the question then arises as to the propriety of having recourse to operative interference. The introduction of a seton across the tumor is occasionally attended by beneficial results. This operation, however, is not unaccompanied by danger; a patient in the neighborhood of London, to whom it was being performed some years ago, lost his life by the entrance of air into a vein which was accidentally punctured at the root of the neck.

Injection of Tincture of Iodine into the substance of the gland is recommended by Billroth in cases of simple hypertrophy. In fibrous bronchoceles he does not advise it, as they are often permeated by very large blood-vessels. The iodine is injected by means of an ordinary hypodermic syringe, about ten minims being thrown in at a time. The operation may be repeated twice or three times a week, according to the effect.

Injection of Perchloride of Iron, by means of the syringe figured at p. 563, vol. II., might be of service in some cases of very vascular and pulsating bronchocele; but it is not without the special danger of forming a pou

the circulation, and rapidly fatal embolism may follow its use. A fatal accident of this kind has in fact been recorded. In one instance of pulsating bronchocele in which I employed it, although much local inflammation and deep-seated suppuration were induced by it, the patient was in the end materially benefited.

Ligature of the Thyroid Arteries has been practised by some Surgeons, with, it is stated, a certain degree of success. The difficulties and danger of the operation, the uncertainty of its results, and the readiness with which the arterial supply would be forwarded to the tumor from other sources, have caused it to be but little resorted to by Surgeons of the present day. In one case of pulsating bronchocele in which I had recourse to this treatment, no benefit resulted from it.

Excision of the Thyroid Body.—Roux, Warren, Greene, and others, have successfully extirpated large bronchoceles, but these operations must be looked upon as altogether the exception in the treatment of the disease; and instances are certainly not often met with in this country in which a Surgeon would think it proper to undertake so serious a procedure for an affection that is not necessarily mortal. Cases, however, occasionally occur in which, from pressure on the trachea, oesophagus, and jugular vein, the dyspnoea is so excessive, the dysphagia and vertigo so serious, that there is no escape from death except by the removal of the tumor. Of all the methods for the removal of enlarged thyroid gland, P. H. Watson's operation is probably the safest in execution, and most satisfactory in results. It is done as follows: A free incision is made in the mesial line from the upper to the lower end of the tumor, the fascia being as freely opened as the skin; but the delicate fascia, investment of the thyroid gland, which is a prolongation of the sheath of the thyroid vessels, should be left intact. The vessels on each side of the tumor, superior and inferior thyroid, are then to be securely ligatured with their sheath, by passing an aneurism-needle round this, and tying it with a suture. It is of the first importance that the vessels be tied in and not cut through their sheathing envelope; for, as Watson truly observes, if this be not done, they will be found to be so fragile as to risk being cut through by the operation. After ligature of the four sets of supplying vessels, the areolar capsule of the thyroid should be opened by being scratched through in the mesial line, and the mass removed with care and delicacy, all attachments being divided by blunt pointed scissors. The principal danger, besides the hemorrhage, would probably consist in the adhesion of the tumor to the coats of the vessels, more particularly the internal jugular vein. In one case referred to by W. Greene, this vessel was wounded.

Professor Kocher, of Bern, living in a goitrous country, has probably performed the operation of excision of bronchocele more frequently than any other surgeon. He has also been enabled to study the effects of the operation on the after health of the patients, and his observations in this respect are of interest alike to the physiologist, the surgeon, and the pathologist. His operations may, indeed, be regarded as physiological experiments on the use of the thyroid body, on which they throw much light; and as pathological researches into the nature of that remarkable disease first described by Sir W. Will. "Myxœdema"—in which atrophy of the thyroid is an important characteristic.

Kocher has partially or wholly excised the thyroid body in 101 cases; of these he was able to trace the after-conditions in 28 cases of partial, and in 18 cases of total extirpation of this organ. In none of the cases of partial extirpation was any deterioration of general health noticeable. Of the 18 cases of total extirpation, in two only was there no change for the worse with regard to the general health, and it was most remarkable, that in one of these

cases a vicarious hypertrophy of a small accessory thyroid body had taken place, whilst in the other a return of the goitre had made its appearance.

In all the remaining 16 cases of total extirpation, more or less marked signs of derangement of general health were manifest. This derangement was of a progressive character, being more noticeable in the oldest, least or in the more recent cases that had been operated on. Professor Kocher describes the symptoms that manifested themselves as occurring in the following order. Some time after leaving the hospital a sense of fatigue, lassitude and weariness was experienced in the limbs, with dragging pains in the arms and legs. A sensation of coldness soon was superadded, especially in the hands and feet, which parts in the winter became bluish-red and cold chills blains making their appearance. The mental activity decreased, thought and speech became slow. The movements generally were sluggish, but there was no impairment of the mental powers. Swelling of the body, but more especially of the face, now began to take place. The eyelids became thickened and somewhat transparent, and the expression of the countenance idiotic. Hands, face, and abdomen swelled. The skin lost its elasticity and became dry. The hair fell off. In more developed cases anæmia occurred. In those cases in which the growth of the body was incomplete, this was retarded in a very marked manner. In some instances dysphagia, headache and giddiness were met with.

These symptoms, it will be observed, are identical with those of "myxœdema;" not one is absent that is met with in that disease, not one is added. The only explanation that can be given of the identity of the symptoms following total extirpation of the thyroid body as described by Kocher with those of myxœdema, as described by Gull and Ord, is that the one pathological condition common to both, viz., absence of the thyroid body is the cause of the symptoms.

Excision of the Isthmus of the thyroid has been recommended by Tillaux as a means of cure in certain cases of bronchocœle, the effect of the operation being to lead to atrophy of the enlarged lateral lobes of the thyroid. Tillaux in Paris, and Sydney Jones in this country, have practised the operation successfully in several cases. The operation consists in exposing the isthmus by a median incision, passing a double ligature through it at each end, tying them tightly, and then excising the intervening portion. S. Jones advises that the wound should be well drained. The results appear to have been very satisfactory, but the principle on which it is obtained is certainly very obscure.

Acute Bronchocœle is a very different disease from the chronic form. It is of rare occurrence, but has been met with both sporadically and epidemically, and in young subjects. In this form of the affection the thyroid gland undergoes rapid enlargement, attaining to the size of the fist or larger in the course of a few days or weeks. Both lobes and the isthmus become affected. Owing to the rapid enlargement of the thyroid body, the fascia of the neck covering it does not stretch with sufficient rapidity; and the consequence is that the subjacent parts, as the trachea, become compressed, so that more dyspnoea sets in, and death from asphyxia may result in the course of a few days or weeks. It is difficult in these cases to know how to save the patient, for tracheotomy by the ordinary methods may be impracticable, owing to the manner in which the tumor dips down behind the sternum. In such cases tapping the tumor in different places, and the division of the fascia of the neck covering it, may give relief, and afford time for the action of remedies. If this fails and death is imminent from asphyxia, two courses only are open to the surgeon, either the isthmus must be divided accurately in the middle line, Paquelin's red-hot knife being used to limit the hemorrhage, or the

larynx may be opened, the cricoid cartilage being divided and a long canula or a catheter be passed downwards past the obstruction. The latter method has been successfully adopted by König, who has invented a special canula for such cases. In his case the tube had to be passed nearly five inches downwards before air entered freely through it.

Exophthalmic Goitre, Graves's Disease.—In practice we not uncommonly observe a triple clinical combination, of anæmia, exophthalmos, and bronchocele; and the connection of these has been commented on by Graves, Basedow, Sichel, White Cooper, Aran, Begbie, and numerous other practitioners. Exophthalmic goitre is almost exclusively met with in women in young adult life. It commences with anæmia and some menstrual disturbance. These are accompanied by palpitation and irregular action of the heart; often with considerable breathlessness. Enlargement of the thyroid gland soon follows, which may assume the form of the pulsating bronchocele. At the same time that this gland enlarges, protrusion of the eyeballs becomes a marked symptom. In extreme cases the exophthalmos may be so great that the lids cannot properly cover the eyeballs, and inflammation of the conjunctiva and cornea may result; except from this cause, however, there is no affection of vision. The disease may steadily increase and death take place from some intercurrent disease or general wasting, more rarely from pressure of the enlarged gland on the trachea. In other cases the symptoms may gradually subside and the patient recover. The exact nature of the disease is unknown. Shingleton Smith has described changes in the cervical sympathetic ganglia, which he is inclined to regard as the cause of the disease. The ganglia showed an increase of connective tissue with atrophy of the ganglionic cells.

The treatment consists in rest, the administration of iron and aloetic purgatives.

Malignant Tumors of the Thyroid Body.—Kaufman, in 1879, published a paper in which he recorded 30 cases, partly his own and partly collected, of malignant tumor of the thyroid body; of these 23 were carcinoma, and 7 sarcoma. In every case the malignant tumor originated in a gland already affected by chronic bronchocele. The tumors usually affected one lobe only, but in a few cases the whole gland was implicated. The cancerous tumors were characterized by rapid growth, infiltration of neighboring structures, and early infection of the lymphatic glands and internal organs. In six cases, secondary tumors formed in the bones. The tumor was in all cases soft in consistence, and microscopic examination showed that the morbid growth commenced by proliferation of the normal cells of the gland, the new cells first filling the spaces and then burrowing into the surrounding parts in columns. The cells were in most cases polygonal, but in one the spaces were lined with cylindrical epithelium.

The sarcomata were round-celled, spindle-celled, and mixed. In one case the growth perforated the trachea, and in all secondary tumors appeared, in three cases in the lymphatic glands.

A special form of malignant tumor of the thyroid body has been met with in a few recorded cases in which the secondary tumors closely resembled the normal thyroid body in structure. These were first described by Cohnheim, and cases have been recorded by Morris, Warrington Howard, and Neumann. In all these the lymphatic glands were affected, and pulsating growths appeared in the bones.

The thyroid body is also sometimes implicated by malignant sarcomata springing from the structures in its neighborhood, and by epithelioma of the œsophagus or larynx. It is very rarely the seat of secondary malignant growths.

CHAPTER LVI.

DISEASES OF THE JAWS AND THEIR APPENDAGES

DISEASES OF THE GUMS AND ALVEOLAR PROCESSES.

Abscess of the Gums, Alveolar Abscess or Gumboil, is of very frequent occurrence, from the irritation of decayed teeth. The common gumboil forms at the edge of the gum and is quite superficial; it is at once relieved by puncturing it with a lancet. A more troublesome form of alveolar abscess is that which develops in connection with the fang of a tooth, usually carious but occasionally apparently healthy. The pus forms at the extremity of the fang, the alveolus being absorbed around it, so that a small abscess cavity is hollowed out deep in the bone. The pus may find its way out along the tooth, pointing at the margin of the gum, but not unfrequently, especially in the molar or bicuspid teeth it perforates the compact tissue of the jaw-bone and forms an abscess deeply seated below the reflection of the mucous membrane from the gum to the lip or cheek. This is accompanied by considerable swelling of the face and severe pain. The nature of the swelling is recognized by its being firmly fixed to the jaw. By a free and early incision and extraction of the diseased tooth the pus may be let out into the mouth and immediate relief obtained, but not uncommonly in the lower jaw the abscess opens externally near the angle and a troublesome sinus may be left, which refuses to heal until the affected tooth is removed. In the upper jaw the pus may burrow beneath the palate, forming an abscess in the roof of the mouth which occasionally leads to necrosis of a portion of the bone. To prevent this such abscesses should be opened early and the diseased tooth immediately extracted.

Spongy Gums, sometimes accompanied by ulceration, may occur as the result of scurvy, or from the administration of mercury. If the condition be due to scurvy, it is quickly relieved by attention to diet, fresh fruit and vegetables being freely supplied. The mouth may be washed at the same time with an alum-gargle. Such cases are not uncommon among the female poor of large cities whose food consists chiefly of bread and tea. In mercurial salivation a strong alum-gargle will be found the best remedy.

In scrofulous ill-fed children a *spongy condition of the gums with ulceration* and fetor of the breath is sometimes met with. The ulcers are covered on the surface with a gray slough. The cause of the condition is often obscure. It must be treated by tonics, cod-liver oil and iron, and by chloride of potash, administered internally to very young children, or used as a gargle when possible.

Inflammation of the gums during teething must be relieved by lancing.

Simple Hypertrophy of the Gums, in the form of a pendulous fringed out-growth overlapping the teeth is occasionally met with in young children. The cause of the condition is uncertain, but it is remarkable that the children in all recorded cases were deficient in intellect. In a case of this kind under my care I freely removed the growth with the scalpel and scissors. It was found to consist of the ordinary structure of the gums, with fine fibrous stroma containing much gland-tissue; the papillae on the surface were very large, and covered by unusually thick epithelium. At the time of the opera-

tion the child was 24 years of age. Five years afterwards the late John Murray exhibited this patient and his younger brother and sister at the Medico-Chirurgical Society (Trans. vol. lvi.). The growth had returned and the two younger children were similarly affected. They were all the subjects of tumors of the skin of the nature of molluscum fibrosum and peculiar enlargements of the fingers and toes, and were all of weak intellect. No cause could be found for the disease beyond the fact that the parents were first cousins. C. Heath recommends in such cases that the alveolar border should be removed with the growth.

Epulis is a tumor springing from the periosteum and edge of the alveolus, and implicating the osseous walls of the sockets; it grows up between and loosens the neighboring teeth, which it displaces and envelops in its structure. It is of two kinds; *simple* and *malignant*. The *Simple Epulis* is a fibrous tumor; the term *Malignant Epulis* is applied to a myeloid tumor springing from the alveolar border of the jaw, and it is sometimes extended to epithelioma of the gum.

Simple Epulis is most frequently met with in the lower jaw (Fig. 671). I have, however, seen several instances of its springing from the alveolar border of the upper jaw (Fig. 672). It appears to be occasioned chiefly by

Fig. 671.—Epulis of Lower Jaw.

Fig. 672.—Epulis of Upper Jaw, hanging down so as to overlap the Lower Jaw.

the irritation of decayed stumps, and hence occurs more frequently in connection with the molar than with the incisor teeth. Although this disease has occasionally been seen in children, it seldom occurs before the adult age, and may be developed even up to an advanced period of life. It is seen as often among females as males. A fibrous epulis appears as a red, smooth, and lobulated tumor, at first hard and semi-elastic, like the ordinary structure of the gum, but after a time ulcerating on the surface, with a purulent or sanguinous discharge. The fibrous epulis springs from the periosteum, and sometimes contains spicula of bone. It is covered by a thin layer of mucous membrane.

Treatment of simple fibrous epulis consists in the removal of the whole of the mass. If it be very small and superficial, the growth alone may be removed and the surface from which it springs scraped with a gouge. By this means it may occasionally be cured, but more commonly, as it evinces a great tendency to reproduction, it must not be simply shaved off but the portion of the alveolar border from which it springs must be removed as

well; unless this be done, the growth will to a certainty be reproduced. In all ordinary cases of simple epulis, the removal may be done from the inside of the mouth without the necessity of making any incisions through the cheek. In very large masses of epulis extending towards the ramus it may be necessary either to carry an incision from the angle of the mouth downwards and outwards, or to dissect up the cheek from the bone, and thus expose the disease fully. In performing the operation, the first thing to be done is to extract a tooth on each side of the tumor; a cut must then be made with a saw through the alveoli of the teeth that have been removed, down to a level with the base of the growth. In doing this, care must be taken not to cut too near the remaining teeth, lest the alveoli be opened and their support lost. If the tumor be large, it may be necessary to saw deeper, but the base of the lower jaw should, whenever practicable, be left intact in whole of its substance not being sawn through, so that, though a considerable portion of bone be removed, yet the length of the jaw may be preserved. For this purpose Hey's saw should not be used, as it is a twirling instrument, difficult to manage in this situation; but a straight and stiff hand saw, with as deep a blade as the mouth will conveniently admit, will be found most useful (Fig. 680). The epulis, included between two vertical cuts may now, if small, be removed with cross-cutting forceps, and the bleeding stopped by placing a plug in the wound and compressing it against the teeth of the upper jaw by means of a bandage passed under the chin. If the epulis be large, a horizontal cut should be made along the bone about midway between the alveolus and the base, by means of Hey's saw; and, after the bone has been penetrated to a sufficient depth, the blade of the cross-cutting forceps may be fixed in this cut, and the diseased part then removed. Should there be a spouting dental artery, it may be necessary to apply a red-hot wire or the perchloride of iron, in order to arrest its bleeding. The cut surface will speedily granulate; and the cavity fills up with fibrous tissue. The operation for the removal of epulis is a very safe one. Of 28 cases collected by Hutchinson from different London Hospitals, only one was fatal, from pyæmia.

Malignant Epulis.—By this term is commonly meant a myeloid sarcoma of the alveolar border, but it is occasionally extended to epithelioma of the gum.

Myeloid Sarcoma of the Alveolar Border forms a soft purplish, very vascular tumor, growing rapidly and speedily recurring after removal, unless the incisions are carried widely beyond the growth. It occurs principally, as far as my observation goes, in males advanced in life. These tumors require the same operation as the simple epulis; and, as much hemorrhage usually follows their removal, a red-hot iron must be applied to the bleeding surface. If a malignant epulis be very large, it may be necessary to remove a portion of the whole thickness of the bone, through an external incision, as will be described in the section on *Excision of the Lower Jaw*.

Epithelioma of the Gum is not common. It presents the ordinary characters of epithelial cancer. It is distinguished from myeloid sarcoma by its flat surface, its early ulceration, the everted edge of the ulcer, and its comparatively slight tendency to fungate. In the later stages the neighbouring lymphatic glands become enlarged. In the lower jaw when the growth penetrates the compact bone, it extends widely in the cancellous tissue. In the upper jaw it may invade the antrum, and completely fill the cavity. The treatment is to remove the growth freely with a considerable portion of the bone on each side of it. In the upper jaw, if the growth fills the antrum, it may be necessary to remove the whole or a great part of the upper maxilla.

Necrosis of the Jaw is commonly the effect of blows, of salivation by mercury, of syphilis, of fever, or of exposure to the fumes of phosphorus. I have, however, seen the disease occur idiopathically in otherwise healthy subjects, without any assignable cause. In this way I have seen the whole of the alveolar process of the upper jaw exfoliate in a young lady, otherwise perfectly healthy; and I have several times had occasion to remove large portions of the lower jaw—in one case more than half of the bone—for necrosis that could not be referred to any of the causes mentioned above, or indeed to any assignable reason. The disease begins with deeply seated pain resembling inveterate toothache, which nothing will allay; the gums become swollen; the teeth are loosened, and eventually drop out. Before they do so, however, pus usually wells up through the alveoli. Abscesses form inside the mouth and under the angles of the jaw, having fistulous openings through which bare bone is reached by the probe. The general health suffers greatly, more so than in necrosis generally, doubtless in consequence of the patient swallowing some of the pus from the dead bone.

Necrosis of the jaws, arising from the inhalations of the fumes of phosphorus during the manufacture of lucifer matches, first noticed by Lörinser, at Vienna, has been especially described by Von Bibra and Geist, who had abundant opportunities of observing the disease at the large manufactories at Nuremberg. This **Lucifer match disease** was some years ago very frequent, but, in consequence of the adoption of precautionary measures, is now much more rarely met with. It consists in necrosis of the jaws, and is attended by the symptoms above described, but in a more severe degree and an acute form. The affected bone undergoes a remarkable change, assuming the porous aspect and gray color of dirty pumice-stone. Both jaws are equally liable to be affected; but commonly one only at a time is diseased; the whole of the bone may die and be separated. Thus of 51 cases observed by Von Bibra, both jaws were affected in five instances only—the upper alone in 21 cases, the lower in 25. According to Langenbeck, the local disease is preceded in many instances by general symptoms of phosphorus-poisoning; and there is a considerable amount of bony deposit from periostitis, enclosing the necrosed bone. It has been believed that workmen having sound teeth are not easily if at all influenced by the fumes, and that the phosphorus acts through carious teeth; but Langenbeck has observed that the teeth have been sound in cases of the disease.

The *diagnosis* of necrosis of the lower jaw, is usually unaccompanied by any difficulty. In the upper jaw, especially when limited to the palatal process, it may resemble epithelioma in the raised and everted edges of the ulcer in the hard palate and the spongy feel communicated to the probe by the dead bone.

Treatment.—The treatment of necrosis of the jaws presents nothing special. The removal of the sequestra should be effected as far as practicable through the interior of the mouth, by free incisions through the gums.

In the *upper* jaw, where the necrosis seldom extends beyond the alveolar border or the palatal process, this may always readily be done.

In the *lower* jaw, the question as to whether the dead bone should be extracted through the inside of the mouth, or by incision from without through the cheek, will be determined partly by the position of the sinuses and partly by the situation and extent of the bone affected. This may in a great measure be ascertained by the situation of the sinuses leading down to it. If these be in the cheek, or in the side of the neck, or under the angle of the jaw, it is usually an indication that, if the whole of the corresponding ramus or body of the bone be not involved, the posterior and outer parts are certainly affected; and, in these circumstances, extraction of the seque-

trum is best effected by opening up the sinuses parallel to the line of the jaw, and removing the necrosed bone in the usual way. The incision for this purpose need not usually be very extensive. If the operation be delayed, in accordance with those principles that guide us in the management of necrosed bone generally, until the sequestrum is quite loose, it may usually be readily extracted, in whole or in pieces, through an opening that will leave but a small cicatrix. By such operations as these, the whole of the lower jaw has been extracted piecemeal at intervals in a state of necrosis, first on one and then on the other side. Carnochan has removed the whole of the necrosed lower jaw at one operation, disarticulating first one and then the other condyle in the usual way.

If, however, there be no external abscess or sinus—if the gum have been loosened and perforated, with a ragged portion of sequestrum projecting through it into the cavity of the mouth, then no external incisions will be required, but the dead bone may be readily removed from within the mouth. Large portions of the jaw may thus be removed. I have taken away the whole of the ramus with its processes, entirely through the gums, without any external incision; and, in a negro, the whole of the bone in a state of necrosis has thus been removed in separate pieces, by Perry, through one side of the mouth.

Reproduction of the Jaw after Removal.—The amount of regeneration of bone will depend greatly upon the state of the periosteum before the removal of the sequestra. If this be healthy, and if new bone have already formed

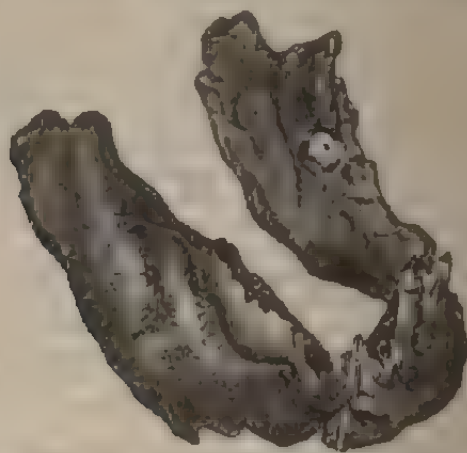

Fig. 673.—Wood's Case of Phosphorus necrosis of entire Lower Jaw.

prior to operation, a very perfect reproduction of the portions of jaw removed may take place; in fact, complete reproduction of the whole of the lower jaw, body, rami, and epiphyses, though in a somewhat rudimentary and imperfect form may follow its removal for phosphorus necrosis. In the museum of the Bellevue Hospital, New York, Wood showed me two specimens of the necrosed lower jaw, removed by him for phosphorus disease from a girl about 19 (Fig. 673). She died of brain-disease three years after the operation; and in the same collection is her cranium with a reproduced lower jaw, consisting of an entire semicircle of bone, about 1½ in. in depth, with all the epiphyses. This unique and most interesting case has already been described, and the regenerated bone figured (Fig. 668).

it the periosteum must have been preserved entire, and thus led to the reproduction of the bone. Should no new bone have formed before the operation, a dense fibroid cicatricial structure will replace the lost bone.

DISEASES OF THE ANTRUM AND UPPER JAW.

Our present knowledge of the operative procedures necessary for the removal of diseases of the jaws, is due chiefly to the labors of Gensoul, of Lizars, and of Liston. Sir W. Fergusson greatly distinguished himself in this field of surgery, and simplified and extended it much in its operative department; and C. Heath has made important contributions to its literature. O'Shaughnessy also, who has had many opportunities of witnessing these affections amongst the natives of India, has added much to our acquaintance with their pathology and treatment.

The various large and irregular cavities that lie amongst the bones of the face may become the seat of disease, primarily originating either in the mucous membrane by which they are lined, or in the osseous structures that compose their walls. In this way the frontal sinuses, the ethmoidal and sphenoidal cells, and the antrum, may either be seats of chronic inflammation of their mucous linings, with more or less profuse muco-purulent discharge; or the mucous membrane may take on more serious organic disease. Thus epithelioma may develop in it, and after distending the cavity in which it originally formed, may thin and destroy its osseous walls; and, thus passing outwards into other situations about the face and the base of the skull, where it is freed from the pressure of surrounding bone, it may take upon itself greatly increased development, blocking up mucous canals, as the nose and the lachrymal sac and ducts, displacing the eye, and producing great disfigurement of the side of the face. These secondary outgrowths, from the rapidity of their unrestrained development, and the amount of deformity and distress which they occasion, may readily be mistaken for the primary disease, the real starting-point of which will often be found in a deeper and more limited locality. The bones constituting the walls of these facial cavities, or the periosteum covering them, may also become the original seats of morbid growths, more particularly of enchondroma, and myeloid spindle-celled or round-celled sarcoma. These run a similar course to the growths originating in the mucous membranes.

Suppuration in the Antrum.—Suppuration may take place in the antrum; it is usually excited by caries of one of the teeth, the fangs of which come in close relation with the cavity, viz., the first and second molar, the bicuspid, and the canine. It occasionally arises from injury. It is usually accompanied at first by deep-seated aching, throbbing, or lancinating pain in the face. The pus as it forms will sometimes overflow, as it were, into the nostril through the aperture into the middle fossa, and then may keep up constant irritation, with much fœtor in the nostrils. When this takes place the patient is conscious of an unpleasant smell, but according to Heath this is not perceptible to other people as it is in ozæna. In other cases, it drains through the socket of a tooth into the mouth; and in other instances again, but much less commonly, its exit being prevented, it gives rise to enlargement of the cheek, the soft parts of which become brawny and inflamed, and the bones expanded, so that at last they are thinned to such an extent that, as in dropsy of the cavity, they crackle when pressed upon. Any portion of the wall of the cavity—the orbital, buccal, palatal, or nasal—may thus be expanded and fluctuation be felt through it; and, the lachrymal duct being commonly obstructed, the eye on the affected side becomes watery. In some cases abscess of the antrum has been followed by loss of sight in

the eye of the same side. Temporary blindness is not uncommon when the floor of the orbit is raised by the pus.

Treatment.—The treatment of this condition consists in the extraction of any carious tooth seated in the neighborhood of the antrum; or, if the teeth be all sound, in the removal of the second molar, the fangs of which come into close relation to, and frequently perforate the bottom of, the cavity. In this way an exit may be given to the matter; but as it will not discharge itself sufficiently freely, the antrum must be opened through the alveolus, or through the canine fossa under the cheek, provided it be much expanded in this situation, so that its cavity can be easily reached. The perforation into the antrum may readily be made, or the socket of the tooth enlarged, by means of one of the forms of antrum-perforator here represented (Figs. 674, 675, 676), or a carpenter's gimlet, as recommended by Fergusson. As the

Fig. 674.

Fig. 675.

Fig. 676.

Various forms of Antrum-perforator.

matter drains away, the cavity will gradually contract, and the deformity thus be removed. It is well not to attempt to perforate in the site of teeth that have been extracted for some time, as here the bone becomes unduly consolidated, and the attempt to reach the cavity is consequently likely to fail. The matter that is discharged is often very offensive, or it may be thick and pasty from the absorption of its watery parts. After the aperture has been made, the cavity should be syringed out with tepid water, and the shape of the cheek gradually restored by pressure.

Cysts of the Antrum or Dropsy of the Antrum.—In this disease the antrum becomes slowly distended with a fluid, in some cases glairy and mucous in character, like the contents of a ranula or ganglion, in others thin, brownish, and serous, containing cholesterine. It was formerly believed that this condition was in some instances at least due to obstruction of the aperture leading from the antrum to the nose, but it is now generally acknowledged that in all cases it results from the formation of a cystic tumor springing from the mucous membrane lining the cavity. In such cases the accumulation of fluid may after a time cause expansion and thinning of the osseous

walls of the cavity. The cheek is rendered round and prominent—a painless indolent semielastic tumor forming in it and protruding it outwards, and giving rise to the egg-shell or parchment-like crackling on pressure (Fig. 677). The floor of the orbit or the roof of the mouth may be caused to bulge, and the nasal cavity may be encroached upon.

Treatment.—The operation of "catheterizing the antrum," founded on an erroneous idea as to the nature of the disease, was formerly recommended, but was never attended by any benefit to the patient. The only efficient treatment consists in opening the antrum from without: this is done without incising the lips or wounding the face, by thrusting a trocar and canula into the most thinned and expanded part of the tumor under the cheek; or, if necessary, by dissecting up the cheek from the gum, and thus making an opening into the cavity of the antrum with a strong pair of scissors or a perforator, through its most expanded and thinnest part, so as to allow the discharge to escape freely. In order to prevent a reaccumulation of the fluid, it will be better to cut away a small portion of the thin and expanded wall of the antrum, and thus to establish a permanent aperture in it, through which it must be syringed out daily with some antiseptic solution, such as Condy's fluid, until all discharge ceases. The best instrument for this purpose is that recommended by Heath, consisting of a common Eustachian catheter, to which an India-rubber ball is fitted to contain the fluid to be injected.

Polypus of the Antrum.—Mucous polypi are occasionally met with in the antrum, but they give rise to no symptoms unless they reach a size sufficient to cause distention of the cavity. They then most commonly cause absorption of the inner wall and project into the nasal cavity, from which they have been successfully removed by forceps.

Dentigerous Cysts.—These may, according to Christopher Heath, occur in either jaw. They arise in connection with teeth which from some cause have been retained in the jaw. They are almost invariably connected with the permanent teeth. Tomes believes that they arise from the excessive formation around a retained tooth of a fluid which is normally found after the complete development of the enamel, between it and the soft tissues investing it. The tooth is not unfrequently found to be inverted. The cysts may occur at any age, but are most common in young adults. In the upper jaw they may form cysts in the antrum. In the lower jaw, they form prominent isolated tumors. They have been mistaken for solid tumors, and the jaw has in consequence been partially removed. Occasionally they may suppurate. Heath mentions also *dentinal tumors*, i.e., irregular masses of dentine growing from a tooth and forming tumors of the jaw; but they seem very rare. The treatment consists in cutting away a part of the wall of the cyst and removing the retained tooth. The subsequent treatment is the same as that of cyst of the antrum.

SOLID TUMORS of various kinds may take their origin from the superior maxilla or its immediate neighborhood. Generally by the time the case comes under observation, it is impossible to say with certainty in what part or tissue it took its origin—whether it began in the upper jaw, or spread into

Fig. 677.—Cystic Tumor of Antrum.

it from contiguous structures. The following are the chief tumors met with in this region.

Fibroma.—This is not uncommon springing from the periosteum, and either filling the antrum or projecting from the alveolar border. It grows slowly, and has no tendency to infect the surrounding tissues, but when springing from the antrum it causes gradual absorption of the surrounding bone, and forces its way into the neighboring sinuses and cavities, or projects forwards on the face, sometimes forming a tumor of considerable size.

Enchondroma.—Pure enchondroma is uncommon; its general mode of growth, and the appearance it gives rise to are similar to those of fibroma.

Osteoma.—Bony growths are occasionally met with filling the antrum and causing a projection forwards on the cheek. They are composed of tissue having the normal structure of bone, and somewhat denser in structure than ordinary cancellous tissue. They increase slowly and painlessly. A case of this kind occurring in a young woman, aged 25, was recently in University College Hospital, under the care of C. Heath. It formed a considerable projection on the face, and had been growing for ten years. Pedunculated growths have been met with growing from the outer surface of the bone, and still more rarely ivory-like tumors have been found in the same situation.

Vascular Tumors.—Liston removed a tumor from the maxillary region, which in section presented the appearance of erectile tissue. The specimen is now in the Museum of University College. The section closely resembles that of the corpus cavernosum penis.

Sarcomata of various kinds are of frequent occurrence in the upper jaw, originating in the maxilla itself, or in the surrounding bones. Spindle-celled and round-celled sarcoma, in some cases undergoing partial ossification, and in others developing into cartilage, are the varieties chiefly met with. They form soft, rapidly growing tumors, often implicating the surrounding parts and pushing into the neighboring cavities from an early period. They are extremely vascular, so much so that in rare cases they pulsate distinctly. When they project into the nose they form polypoid masses, bleeding readily and obstructing the fossæ. If they spring from behind the maxilla, they not unfrequently penetrate the cranial cavity, either from the orbit or by means of the foramina in the base of the skull. Myeloid sarcoma occurs in young adult life chiefly in the alveolar border of the bone. In other parts it is extremely rare.

Epithelioma is far from uncommon. It may, as before stated, spring from the gum and penetrate the antrum, or it may originate in the mucous membrane of the antrum or nasal fossæ. It forms a soft, rapidly growing tumor, infiltrating the surrounding parts. It very early spreads into the irregular cavities in the neighborhood of the upper jaw, and thus is very apt to recur after apparently complete removal. The form most commonly met with is the squamous epithelioma spreading from the hard palate or gum, but columnar or tubular epithelioma originating in the antrum or in the nasal fossæ is also met with.

Situation and Symptoms of Tumors in the Region of the Upper Jaw.—Sarcomatous tumors occasionally spring from the surface of the malar bone, pushing forward the cheek, spreading into the mouth, and involving, with greater or less rapidity, according to their malignancy, the soft structures of the face, and occasionally the lymphatic glands under the jaw. They are usually rapid in growth, soft and elastic to the feel, irregular in outline, and only secondarily implicate the superior maxilla and the neighboring cavities.

The various growths that are connected with, or spring from, the periosteum or mucous membrane of the antrum, in growing gradually expand

and dilate the walls of the cavity, pressing the bones outwards, thinning them, and giving rise to a considerable outward projection of one side of the face, the anterior surface of the superior maxilla being the part that usually yields to the outward pressure. The tumor thus formed is generally smooth, round, or oval, slightly lobed, perhaps, more especially if fibrous, and has in many cases a tendency to hang downwards, so as to overlap the lower jaw to a certain extent. As it grows, it encroaches more or less upon the structures lying in the vicinity of the antrum. Thus, it pushes down the palate, causing considerable swelling in the roof of the mouth; displaces the alveolar processes and teeth, giving rise to irregularity in their outline, and tending to project into and occupy the alveolus. It may encroach upon the orbit, occasioning epiphora, impairment of vision, and displacement of the eyeball. As the tumor enlarges, it obstructs the nasal cavity, and, stretching back into the pharynx, interferes with respiration and deglutition, and sometimes occasions severe epistaxis. When it is of a malignant character obstruction of the nasal fossa will be found to be one of its earliest signs leading to the suspicion of nasal polypus; but the true and more serious nature of the disease will be revealed by the integuments becoming indurated, the gums implicated, and, perhaps, the submaxillary lymphatic glands enlarged.

Diagnosis.—In the diagnosis of these tumors growing in the upper jaw, there are three principal points to be attended to: 1, to distinguish the growth from fluid accumulation; 2, to determine whether it be simple or malignant; and, 3, to ascertain its primary seat.

1. In making the diagnosis from *fluid accumulation in the antrum*, the history of the case, and the uniform enlargement of the cavity without outward projection beyond any part of its walls, the elasticity, and even fluctuation, that may, after a time, be detected, more particularly towards the outer side of the swelling, and at the junction of the mucous membrane of the cheek and the gum, will enable the Surgeon to determine that it is a fluid. But in many cases that is not sufficient; and it becomes necessary to make an exploratory puncture by means of the perforator, through one or other of the more thinned and expanded parts already indicated. This should never be omitted in cases of doubt; for it has happened even to a Surgeon as Gienoul that, after making incisions through the cheek with the view of extirpating the tumor, the bones were found to be expanded by an antral abscess, and that, consequently, the operation had been undertaken unnecessarily.

2. In determining whether the growth be *simple or malignant*, the Surgeon will experience much difficulty, so long as it is confined to the cavity of the antrum, but when once it has perforated and passed beyond its walls, this point is easily solved. Yet, even whilst the tumor is still confined within the antrum, much light may be thrown upon its nature by attention to the rapidity of its growth; the greater this is, the more reason there is to suspect that it is malignant. Too much importance, however, must not be attached to this sign, for though, as a general rule, fibrous, cartilaginous, and bony tumors may increase less rapidly than the malignant, yet they may attain a very great bulk in a short space of time. The age of the patient is of comparatively little value in the diagnosis. I think, however, that, as a general rule, simple tumors more frequently occur in the young, whilst the malignant forms of the affection are more commonly met with at the middle or advanced periods of life. It is of much importance, in a diagnostic point of view to examine the condition of the submaxillary glands. When the disease is malignant, they often become enlarged and indurated at an early period. In a case under my care, the malignant character of a tumor,

whilst still in the antrum, was determined by the fact of there being a long chain of indurated lymphatic glands lying under the angle of the lower jaw, where they had become secondarily affected by absorption, before the bone had been perforated by the growth. It must be remembered, however, that many of the sarcomata which run an essentially malignant course, infiltrating surrounding parts and recurring in internal organs, may at no time affect the lymphatic glands. When once a malignant tumor has passed beyond the cavity of the antrum, and is thus relieved from the pressure of its walls, it grows with great rapidity, and, where it can be felt under the skin, is perceived to be soft and elastic. Insinuating itself extensively amongst the bones of the face and skull, it creeps through the foramina and fissures, and encroaches greatly on the nasal cavity and orbit; its early protrusion into these cavities is especially characteristic of malignancy. It implicates the integuments of the cheek, with an inflammatory edema, and the soft structures within the mouth, and throws out sprouting masses in these several situations, which present all the characters of the true malignant fungus.

3. A point of very great importance in relation to operative interference is to determine the *primary seat of the tumor*; whether it spring from the cavity of the antrum, from the malar bone, or from behind the superior maxilla in the pterygo-maxillary fossa. When it springs from the *interior of the antrum*, the buccal, orbital, nasal, or palatal walls of that cavity are expanded, and the line of teeth is rendered irregular. When the tumor primarily springs from the *malar bone* (Fig. 678), it pushes forward the cheek into a somewhat conical prominence, and dips down into the mouth between the gums and the soft structures of the face. It does not involve the palate, or alter the line of the teeth; but rather spreads over the bones, and involves the covering soft parts by continuity of tissue, without any definite anatomical disposition. As the tumor increases in size, it will implicate the anterior wall of the antrum, and thus secondarily projects into that cavity.

Fig. 678.—Malignant Disease of Malar Bone not suitable for operation.

When the disease develops primarily *behind the superior maxilla*, between it and the great ala or the pterygoid process of the sphenoid, the upper jaw-bone is simply pushed bodily forwards, there being little, if any, deformity in its outline, the line of teeth not being displaced, nor the walls of the antrum—palatal, nasal, or orbital—expanded. Yet it must be borne in mind that the difficulty of diagnosis is greatly increased by the fact that a tumor, though not originating in the antrum, may find its way at an early period of its growth into this cavity, or may pass into the orbit through the sphenomaxillary fissure, and may make its way forwards amongst the bones of the face, partly by creeping through, and partly by absorbing and displacing them.

Treatment.—In the treatment of tumor of the upper jaw and antrum, nothing can be done except to extirpate the growth; and it is consequently of great importance to distinguish those forms of the disease in which an operation can be undertaken with safety, and with a fair chance of success, from those in which none should be performed. The points to be considered are: 1, whether the tumor is benign or malignant; 2, if it be benign, whether

grows from the antrum or springs from behind the superior maxilla; or, if it is malignant, whether it has passed the boundaries of the antrum. When the tumor, springing from the antrum, is of a simple character, the antrum should be removed, together with the whole of the superior maxilla; the tumor, whatever size it has attained, being generally encapsuled, and the bones expanded and absorbed around it; so that it is well bounded, and does not implicate neighboring parts. Here, as Liston justly observes, no rubbing or grubbing operations, but free excision of the whole mass, should be performed. When the tumor springs from the spheno-maxillary or pterygo-maxillary fossa, pushing the bones of the side of the face forwards, an operation should not be lightly undertaken, as it is doubtful, in many cases, whether the Surgeon can interfere with any prospect of success. Should, however, the tumor be simple, the patient's health be good, and an operation be deemed expedient, the tumor can be reached only by excising the upper jaw when it may either be removed attached to that bone, or it may be extirpated from the cavity in which it lies behind it. Such an operation, implicating as it does the base of the skull, may be followed by death from shock to the nervous centres, as I saw happen in a patient of Liston's thus operated upon; or, involving the internal maxillary artery, may be attended by very profuse and troublesome hemorrhage. When once a malignant growth of this part has passed beyond the osseous boundaries of the antrum, the question of removal becomes very complicated. In reference to this point, I think that it may be stated generally that, if the cheek be freely movable over the tumor, and the submaxillary glands unaffected, the operation may be resorted to with. But, if it have advanced so far as to implicate the soft structures of the cheek, with enlargement of the submaxillary glands, it is neither wise nor prudent to interfere with it by operation: as infiltration will have taken place more widely than the knife can reach, and speedy recurrence must of necessity ensue. So long as it is contained within this cavity where, indeed, it is often impossible to ascertain, until after removal, the true nature of the affection, it may be excised provided the glands in the neck be not greatly enlarged. If they be much implicated, even though the walls of the antrum be not perforated, it is wrong to interfere, as a cure by operative procedure would be hopeless. Whenever the soft structures of the cheek are involved so as to require partial excision with the tumor, no operation should be performed; as it cannot be completely extirpated, and will speedily recur in the cicatrix. When the upper jaw on both sides is affected, as sometimes though rarely, has happened, it is clear that the tumor cannot be removed.

Fig. 679.—Malignant Tumor of the Upper Jaw, involving the whole of the Bones of the Face, not admitting of operation.

OPERATIONS ON THE UPPER JAW.—The operations that have been practised for the removal of tumors springing from the upper jaw are of three kinds. They consist of:

1. *Scraping out of the Tumor*; 2. *Partial Excision of the Superior Maxilla*; and 3. *Complete Removal with or without the Malar Bone*.

For operations on the upper jaw, the Surgeon will require strong cutting forceps, and two or three narrow-bladed saws, with handles set at different angles, and having movable backs (Fig. 680).

1. **Scooping out the Tumor.**—The practice of scooping out tumors of the antrum, after turning up the cheek from the anterior surface of the superior maxilla, is one on the propriety of which there is a difference of opinion among Surgeons. Liston, whose experience in these diseases was in his day unrivalled, denounced all "grubbing" operations; and Syme strongly disapproved of the practice.

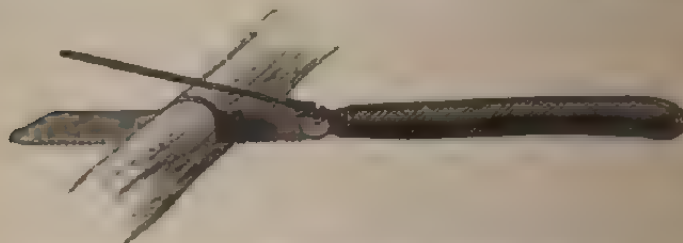

Fig. 680.—Saw with Movable Back, for Operations on the Jaws

But other Surgeons, whose views on the subject are entitled to the highest respect, advocate and practise this proceeding. For my own part, I look upon the practice as unscientific in principle and disastrous in its results. It is applicable only to the softer kinds of tumors, and these are chiefly sarcomata. Now I hold it to be impossible by gouging, scooping, chiselling, or scraping, to extirpate these completely from any bone in which they may be developed. It is impossible in this way fairly to go beyond the limits of the disease into healthy structures. Tumors that appear and feel sound, are in reality infiltrated; and hence speedy recurrence takes place. This has happened in every case in which I have seen this operation practised; and the recurrent is worse in all its features—more rapid, more luxuriant, more malignant—than the primary disease. In fact,

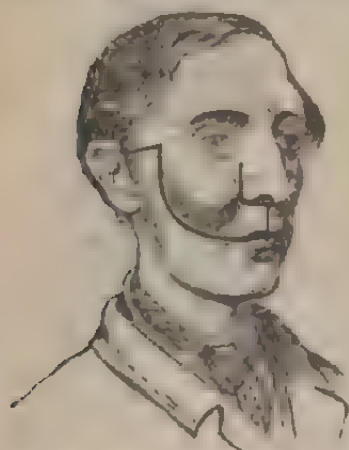

Fig. 681.—Lines of Incision in Liston's Operation for Excision of Upper Jaw.

there is no reason why, in operations on the jaws, we should depart from that principle which is found necessary in operations on other parts for the removal of malignant growths, of being guided in the extent of the removal by the anatomical boundaries of the part affected, and not by the apparent extent of diseased structure. It seems to me to be as reasonable to scoop a navel or a malignant tumor out of the head of the tibia instead of amputating the affected bone, as it is to scrape it out of the antrum, instead of extirpating the superior maxilla.

2. **Partial Excision of the Superior Maxilla.**—Although I do not consider the scooping away of the tumor from the antrum to be a proper or surgical procedure, I would not advocate the removal of more of the bones of the face than is absolutely necessary for the complete extirpation of the disease, more especially when that is not malignant. The disease may be limited either to the upper or to the lower part of the superior maxilla. In these cases, the practice of Sir W. Fergusson has led to great advances in our method of removing such disease

with the least possible disfigurement and the least loss of bone. With regard to the external incisions in these cases, Fergusson has shown that they often need to be but very limited; all that is necessary being a cut from the angle of the mouth upwards and outwards through the cheek, or, in other cases, a slit through the upper lip in the mesial line, the knife being carried along the side of the columna into the nostril. By these simple incisions, the distinguished Surgeon has shown, sufficient relaxation of parts can be obtained for the excision of the greater part of the superior maxillary bone.

In some cases, the malar bone and floor of the orbit will be found to be sound. When this happens, they should both be left; and with this view, after the cheek has been incised, as just described, a deep horizontal groove should be made with a narrow straight-backed saw below the orbit, directly across from the nasal process of the maxillary to the edge of the malar bone. The forceps should now be applied so as to cut downwards and outwards from the end of this incision, and thus to sever the connection between the superior maxilla and the malar bone. They are then to cut along the groove that has been traced horizontally with the saw, one blade cutting from the nares along this; and, lastly, the alveolus and hard palate have to be divided. This is best done after the extraction of one of the central incisors, by passing a narrow-bladed saw into the anterior nares and cutting down through the alveolus; the remainder of the section being completed with the forceps. Or the proceeding may be reversed, and the cut made from the mouth up towards the nasal cavity. Should the disease implicate chiefly the upper orbital and nasal portions of the bone, leaving the cheek and roof of the mouth sound, another modification of the operation may be undertaken by carrying the knife from the nasal process down the side of the nose and from the nostril across the cheek, dissecting up the flap thus formed. The palpebral ligament must then be cut through, and the fat of the orbit pushed upwards and held on one side with a copper spatula, which at the same time protects the eye from injury. The nasal process of the superior maxillary bone is then cut through from the lower and inner part of the orbit into the nose; the saw is carried from the anterior nares across the superior maxilla above its alveolar process and from the outer end of this a perpendicular cut is carried upwards into the orbit towards its outer angle so as to extend backwards into the sphenomaxillary fissure. The cutting-pliers are then carried along these lines of incision so as to loosen the bone completely and the detached portion is then lifted out by means of a curved periosteal elevator.

3 Complete Excision of the Upper Jaw.—The operation of excision of the whole of the upper jaw, together with the malar bone, for tumor of the osseous system, was first proposed by Lizars in 1826; though Gensoul, of Lyons, was the first Surgeon by whom the operation was actually performed, in May, 1829. Since then, it has been repeatedly practised; and the names of Liston and of Fergusson are inseparably connected with it, for the skill with which they have devised, and the boldness with which they have carried out the various steps of its performance.

The patient should be placed in a recumbent position with the head and shoulders well raised by pillows, opposite a good light. The Surgeon stands at first on the same side as the bone to be removed, but during the sawing he will find it convenient to stand always on the right side, returning to the left, if that be the affected side, during the final stages of the operation. Hemorrhage during the operation is one of the chief difficulties, not only on account of the actual loss of blood that may take place, but from the risk of asphyxia from the blood finding its way into the larynx. In order to prevent this accident the throat must be frequently wiped out

during the operation with sponges fixed upon proper holders. Annandale has recommended that the operation should be done with the patient's head hanging over the end of the table, so that any blood that runs backwards may accumulate in the upper part of the pharynx, whence it can be removed from time to time with a sponge. This position, however, tends to aggravate the hemorrhage, and is not to be recommended when the tumor is very vascular. It will often be found useful to plug the posterior nares with a good-sized sponge passed behind the soft palate in the way already described, before commencing the operation. This tends to push the soft palate forwards, and may embarrass the breathing. Should this happen, a large tube of some kind, such as a lithotomy tube, may be passed between the root of the tongue and the soft palate, through which respiration can be readily carried on. During the operation a good-sized sponge, attached to a piece of string, may be placed in the mouth on the side on which the operation is being performed, care being taken to leave a sufficient space for the passage of air in respiration. It must be remembered, that the patient does not require the whole mouth to breathe through, and if it be carefully managed, a great part of the cavity may be filled with a sponge during the operation. In this way, in ordinary cases, this operation may be performed without a drop of blood passing down the throat. If the tumor be very large and vascular, and much hemorrhage is expected, it may be advisable to adopt more efficient means to prevent the risk of asphyxia. This danger may be entirely avoided by the method devised by Trendelenburg, and adopted by Langenbeck, in cases of operation about the jaws, palate, or pharynx, in which serious hemorrhage is anticipated. The patient having been placed under the influence

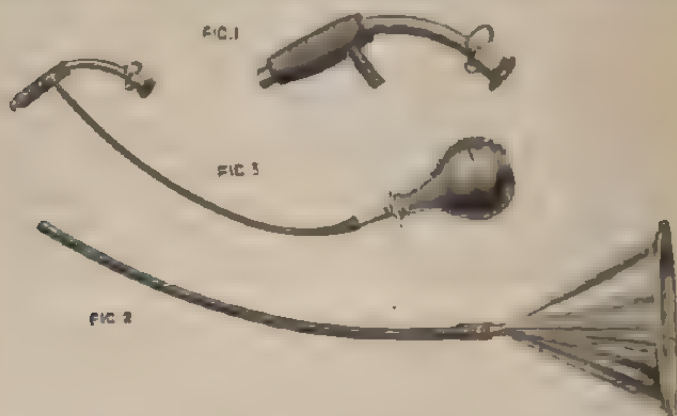

Fig. 682 — Trendelenburg's Trachea-tampon.

- 1 The Trachea tube and Collar slightly inflated. 2. The Inhaling Funnel.
3. The Inflating Bottle attached to the Collar on Trachea-tube.

of chloroform, tracheotomy is performed in the usual way above the thyroid body. A trachea-tube fitted with a hollow India-rubber collar (Fig. 682, 1) is then introduced, and the inhalation of the anæsthetic vapor carried on through it by attaching, by means of an India-rubber tube, a funnel containing a sponge (Fig. 682, 2). When the surgeon is about to commence his operation, the collar is inflated by means of the India-rubber ball attached (Fig. 682, 3); the effect being to close the trachea round the tube, and thus to cut off all possibility of blood finding its way down the larynx

into the bronchi and air-cells. After the operation is completed, the "trachea-tube" is removed, and an ordinary trachea-tube is substituted and retained as long as it may be thought necessary. If this apparatus be not at hand, the desired result may be equally well obtained by performing a preliminary laryngotomy and then plugging the pharynx with a large sponge, which can be withdrawn as soon as the operation is over. Macewen has recently suggested, that instead of opening the larynx or trachea a tube should be passed from the mouth through the glottis and the pharynx, the upper opening of the glottis being then plugged with a sponge. This he has successfully done in several cases. The tube should be of gum elastic, and should correspond to about a No. 10 or 12 English catheter. It is passed by introducing the finger into the mouth and depressing the epiglottis on the tongue, and so guiding the tube over the back of the finger into the larynx. (The patient's head should be thrown somewhat backwards while the tube is being passed).

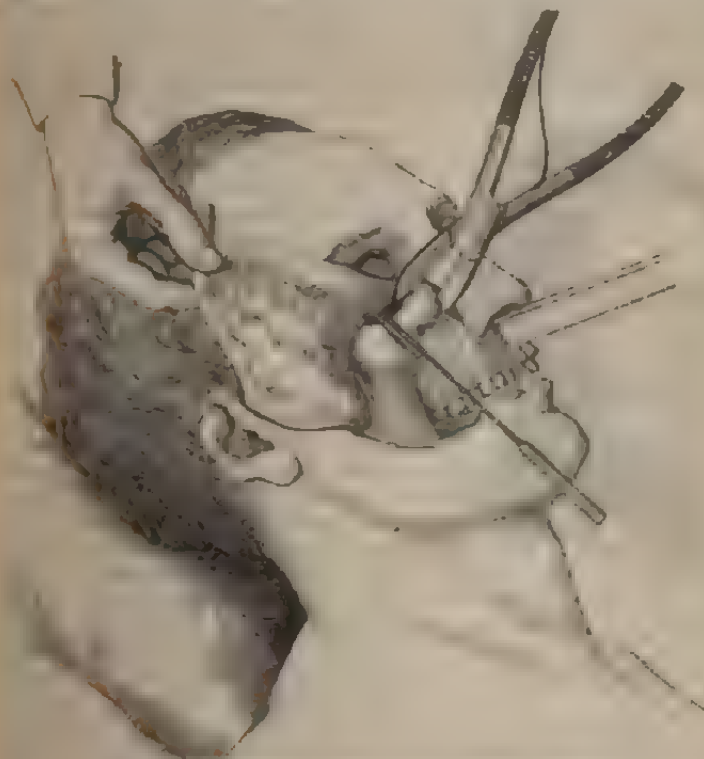

Fig. 683 — Excision of Upper Jaw by Liston's Method.

In order to diminish the loss of blood as far as possible, the facial artery must be compressed during the early incisions, and all bleeding vessels must be seized in forceps immediately they are divided.

The parts to be removed must be fairly exposed by raising a flap from the cheek. This may be fashioned in various ways (see Figs. 684, 685, 686). The following, which is the method adopted by Liston, will occasionally be found to be convenient where the tumor is very large (Fig. 684):

In the first stage, the central incisor tooth on the diseased side having

been extracted, the point of a bistoury is entered opposite the external angular process of the frontal bone, and carried with a semicircular sweep to the angle of the mouth. From the upper end of this incision, a cut about one inch in length may be carried along the zygoma. Another incision is made from the nasal process of the superior maxillary bone, down to the side of the nose, round the ala, which it detaches, and through the centre of the upper lip into the mouth. The flap thus formed is dissected upwards until the margin of the orbit is reached (Fig. 683); the soft parts are then carefully separated from the floor of this cavity, and drawn upwards by a curved copper spatula, which protects them and the globe of the eye.

Or the line of incision by external flap (Fig. 684) may be adopted in the following way. The point of the knife is entered opposite the inner angle of the eye, and carried down the side of the nose, round the ala, and through the centre of the upper lip. Another incision is now made in a horizontal direction below the orbit, by entering the point of the knife where the first incision commenced, and carrying it directly outwards in the line of junction of the lower eyelid with the cheek, along the edge of the orbit as far as the zygoma. The flap thus formed is thrown outwards. This line of incision has the great advantage over the one represented in Fig. 681, that the arteries

and nerves of the face are cut near their terminations, and not through their large branches. This line of incision, to which C. Henth gives the preference, is most suitable to all tumors of ordinary size.

The next step in the operation consists in the division of the bones. This is best done with a jaw saw and strong cutting pliers. The central incisor tooth is first extracted on the side on which the jaw is to be removed. The jaw saw (Fig. 680) is then pushed into the nostril parallel to the hard palate. Its point must not be directed upwards for fear of injuring the cribriform plate. The saw is then carried through the alveolar border and the palatal process of the superior maxilla and palatal bones, cutting through the alveolus of the incisor that has been extracted. No incision must be made with a knife through the soft structures of the hard palate, as they are divided round and with less hemorrhage by the saw. Care must be taken not to saw so far as to enter the soft palate. A smaller saw is then

Fig. 684.—Line of Incision in Excision of the Upper Jaw by External Flap.

taken, and the nasal process divided at the level of the lower margin of the orbit, so that the posterior extremity of the incision shall correspond to the line of the articulation between the superior maxillary and the ethmoid bones. The saw is then carried through the malar bone in such a direction as to reach the anterior extremity of the sphenomaxillary fissure. If the tumor implicates the malar bone extensively, the zygoma must be divided and another saw cut carried from the sphenomaxillary fissure through the frontal process of the malar bone.

The cutting pliers are now applied first to the malar bone and next to the nasal process. One blade of the bone forceps, the flat side being directed to the sound bone, is then put into the nose, the other in the mouth in the line of the saw-cut already made. As the blades are closed the wedge is

action of the forceps forces the bone outwards and fractures its posterior attachments. Unless the bony structures are extensively destroyed by the tumor, the line of fracture runs across the ascending process of the palate bone and the middle part of the two pterygoid plates, the articulation between the superior maxillary and the palate bone, and between the tuberosity of the palate bone and the pterygoid plates being too firm to yield. The bone being now completely separated from its osseous attachments, the Surgeon seizes it in the "lion forceps" with his left hand and wrenches it downwards and outwards, while he cuts away the soft palate from its attachment to the bone, care being taken not to cut it through vertically. If at this stage the superior maxillary nerve is seen, it must be cut through. The parts of the pterygoid muscles attached to the portions of the pterygoid plates that are removed can be torn through with a little help from the scalpel or scissors. If the bone is too much broken up by the tumor to be held by the lion forceps, it can usually be drawn forwards by the fingers. As soon as the bone comes out, a dry sponge must be forced into the cavity to arrest hemorrhage, while the mouth and fauces are cleared of blood, and the patient, who at this stage has often partly regained consciousness, is again brought under the influence of the anæsthetic. Hemorrhage from the terminal branches of the internal maxillary must then be arrested by the actual cautery, or, if possible, by ligature. When all bleeding has ceased, the whole cavity must be carefully examined, and any remaining fragments of the growth must be removed either with scissors or with Paquelin's cautery. If the whole growth is undoubtedly removed, the cavity is then touched with a solution of chloride of zinc (gr. 40 to $\bar{3}$), care being taken that none of the fluid passes down the throat. It should then be sprinkled with iodoform in crystals, and the cheek flap laid down. If there is any doubt about the complete removal of the growth, Heath recommends that some strips of lint spread with chloride of zinc paste should be laid in the cavity. Some pieces of dry lint may be placed over these to prevent any of the paste finding its way into the throat. The flap must be retained *in situ* by strong metallic sutures or harelip pins through the lip, and by finer sutures of catgut, horse-hair, or silk, along the other lines of incision. However much the skin may have been stretched and thinned, none should be removed unless it has been actually incorporated in, or infiltrated by the tumor. The after-treatment consists in syringing the cavity out daily with Condy's fluid and water, and sprinkling the raw surface with a little iodoform by means of a camel's hair pencil. There is nothing so efficient as iodoform in the prevention of decomposition in these cases, and by its use the danger of septic poisoning or septic pneumonia is greatly diminished. After cicatrization is complete, the patient is fitted with a proper obturator, and the deformity resulting is far less than might have been anticipated.

Results.—The result of operations for the removal of the upper jaw is very satisfactory, so far as the operation itself is concerned. Though most serious, the operation is not very dangerous. Of 17 consecutive cases collected by Hutchinson as having been practised in the London Hospitals, it was successful in 14; and of 16 cases (10 of total and 6 of partial removal) done by Esmarch, 13 were successful (viz., 8 of the former and 5 of the latter). So far as recurrence of the disease is concerned, all will depend on the nature of the tumor, and the extent of the operation. If the disease be malignant or even myeloid, speedy recurrence will certainly ensue if partial excision or scooping be practised. Nothing, indeed, can be more disastrous than the result of partial operations in these cases. Even though the whole maxilla be excised, the incisions being carried wide of the disease, recurrence is the almost invariable rule, though the more complete operation

secures longer immunity. The liability to recurrence is remarkable in these cases, when we consider how isolated the upper jaw is, being bounded on three sides by the cavities of the mouth, nose, and orbit, and how completely it can be excised. It is, I believe, mainly due to two causes—early implication of the soft parts, and extension of the mischief through the fissures and sinuses behind the bone. These recurrent malignant growths, after removal of the primary tumor, do not admit of extirpation.

When the tumor is benign, the result is most satisfactory, and the cure usually complete.

Tumors that spring from behind the Superior Maxilla have already been adverted to in speaking of naso-pharyngeal tumors (p. 574), and in discussing the diagnosis of tumors of the upper jaw (p. 577). They may grow from the sphenoid bone, or from some of the deep cavities lying between it, the palate bones, and the ethmoid, constituting various forms of naso-pharyngeal, palatine, or naso-palatine polypi. Formerly these tumors were either left untouched, or were extirpated together with the superior maxilla or after its removal. Of late years various operations have been devised without the necessity of removing that bone, which is either turned up, down, or on one side. The best operation on the whole for their removal is **Langenbeck's Osteoplastic Section of the Superior Maxilla**, with displacement of that bone. The first operation was performed in 1859. Up to 1877, Langenbeck had performed it 13 times, with 10 complete cures and 3 deaths. It has been performed in Germany also by Esmarch, Wagner, Simon, Nussbaum, and Billroth. The last two performed it for removal of the superior maxillary nerve for neuralgia. In America it has been performed twice by Cheever. In one case, it was done for removal of a tumor growing from the body of the sphenoid bone; the tumor recurred, and the operation was repeated at the end of eleven months, with perfect success. In the other case, both bones were displaced at the same operation; but the patient died on the fifth day of "prostration with excitement." In Langenbeck's first operation, the incision was made from the middle of the nasal eminence of the frontal bone towards the right, over the nasal process of the superior maxilla and downwards to the ala of the nose. The edge of the wound were dissected up so as to expose the whole nasal process and the nasal bone, the periosteum remaining untouched. The cartilaginous portion of the nose was separated from its bony attachments. The nasal bone was then cut through with bone-forceps, close to the septum, and upwards as far as the frontal bone; by a second cut the nasal process of the superior maxillary was divided into the antrum. The cut ended where the nasal process of the superior maxillary bone forms the lower border of the orbit. The upper part of the nasal process of the superior maxillary and the nasal bone were then prized up and were turned on to the forehead, being still attached by periosteum and mucous membrane. The nose was then fully opened, and the polypus was removed. The bones were then replaced and supported in position by a plug of charpie. The wound healed readily, and there was no exfoliation of bone. Langenbeck's second operation was undertaken for a tumor springing from behind the superior maxillary bone in the pterygo-maxillary fossa. Two incisions were made; the first began at the insertion of the ala nasi and ran along the lower border of the malar bone, describing an arch with the convexity downwards and terminating at the middle of the zygoma; the second began at the nasal notch of the frontal bone, and, following the lower margin of the orbit, crossed the frontal process of the superior maxillary bone, and joined the lower incision at its outer extremity. The soft parts were not dissected up. The lower incision was then carried to the bone, and the masseter dissected from its attachment to the malar bone. By depressing the lower jaw so as to remove

the zygomatic process out of the way, the finger could be forced in front of the anterior border of the temporal muscle into the spheno-maxillary fossa, which was dilated by the tumor, into the nose through the spheno-palatine foramen. A narrow saw was now passed along the finger—its point being supported by the forefinger of the left hand introduced into the nostril—and a cut was made directly forwards through the ascending process of the palate bone and the body of the superior maxillary bone, across the cavity of the antrum, parallel to the hard palate and immediately above it, terminating at the anterior nares. The upper incision was now deepened, and the soft parts were raised from the floor of the orbit and from the angle between the zygoma and the malar bone; and, the saw being again introduced, a cut was made through the malar bone into the spheno-maxillary fissure, and thence across the floor of the orbit as far as the lachrymal bone. The wedge-shaped piece of the superior maxillary bone included between these cuts was now attached only by its connections with the nasal and frontal bones, and by the soft parts covering it, which were untouched. By introducing an elevator into the cut in the malar bone, the whole piece was lifted up, bending upon its attachment to the nasal and frontal bones as upon a hinge, until it was completely turned inwards and upwards over the opposite side of the face. The tumor, which was found to have extensive connections in the pterygo-maxillary region, was now removed. The bone was then replaced, and the wound closed. On the sixth day, the greater part of the wound was healed; on the nineteenth the wound had completely healed, and no mobility could be felt in the bone.

Ollivier and Lawrence's operations, which are adapted specially to tumors of the nasal fossa, have been already described.

DISEASES OF THE LOWER JAW.

Abscess in the Lower Jaw.—Chronic abscesses, causing "expansion of the bone," have been met with in the lower jaw. They may arise in connection with the fang of a diseased tooth, or from suppuration of a dentigerous cyst. If the shell of bone surrounding the pus be very dense, they may resemble solid tumors. Their treatment presents nothing peculiar.

Acute Suppurative Periostitis is occasionally met with in the lower jaw. It probably is dependent on carious teeth, but the immediate cause seems usually to be exposure to cold, such as riding in a train facing an open window. The disease is characterized by rapid swelling, with tension and redness of the skin. A large abscess quickly forms, surrounding the bone, usually limited to one side, about the angle. The swelling extends downwards into the neck, and tends to point externally. On opening the abscess a large part of the bone can be felt bare and denuded of its periosteum. If the pus be let out early, free drainage provided, and decomposition prevented, no necrosis may take place. It is usually necessary to make the incision externally, as the pus extends too far in the neck to allow of sufficient drainage being provided from within the mouth.

Necrosis of the Lower Jaw has been already described (p. 571).

Tumors of the Lower Jaw—The lower jaw is a common seat of tumors. *Simple Epulis*, *Myeloid Sarcoma* of the alveolar border, *Epithelioma* of the alveolar border, and *Dentigerous Cysts*, have been already described with tumors of the alveolar borders and of the upper maxilla; they are, however, all more common in the lower jaw than in the upper.

Cysts of the Lower Jaw.—*Single cysts*, containing a glairy or mucous fluid in which cholesterol crystals are often seen, are not uncommon in the lower jaw. They cause a painless, slow enlargement of a limited portion of

the bone. At first the fluid is surrounded by a solid bony wall, through which no fluctuation can be felt, and in this stage they have been mistaken for solid tumors. As the wall becomes thinner, fluctuation and egg-shell crackling can be felt. They originate in connection with a tooth, but their mode of origin is not very clear. Sometimes in extracting a painful tooth a small cyst, seldom more than a quarter of an inch in diameter, is found attached to a fang. These cysts are developed beneath the periosteum of the fang, and hence have been termed *periosteal cysts*. Tomes believes they are of inflammatory origin, and the fact that their contents have the appearance of inspissated pus bears out the view. Whether the single cysts are of a similar origin is not certain.

Multilocular cysts, which have also been described under the names of *cystic sarcoma*, *adenoma*, and *fibro-cystic tumors* of the jaw, although occasionally met with in the upper jaw, are infinitely more common in the lower. These tumors are of slow growth, but may reach a great size: they are composed of cysts varying in size, and having more or less solid matter between them. The walls of the cysts are sometimes thin and membranous, sometimes composed of tissue, appearing to the naked eye as fibrous tissue, while in other cases bony lamellæ enter largely into their composition, so that on pressure they occasionally communicate the semi-crepitant sensation peculiar to cystic expansions of osseous structures. The fluid contained in these cysts is viscid, and usually semi-transparent, yellowish or bloody. Most commonly these tumors run a simple course but occasionally they have been known to recur after removal and infect surrounding parts. The origin of these cysts formed the subject of a most interesting lecture delivered by F. S. Eve at the Royal College of Surgeons. He confirmed the fact already noted by several observers, that the solid part of these tumors is composed of irregular, branching columns of small round epithelial cells resembling those in the deeper layers of the epithelium of the gum, and surrounded by a fibrous stroma. In some cases the cells at the circumference were columnar. The cysts are formed by colloid degeneration of the epithelial cells. Eve believes that he has demonstrated that the columns of cells are formed by an ingrowth of the epithelium of the gum, and that the starting-point of the disease is often the irritation caused by a diseased tooth. Falkson and Bryk, on the contrary, believe that in some cases at least these cysts have their origin in a persistence of a portion of the epithelium forming the enamel organ of the developing teeth. They found their opinion upon the resemblance of the epithelium cells and the contents of the smaller spaces to those observed in the enamel organ. The question of the origin of the tumors cannot be considered to be finally determined. That they are in some way connected with the teeth is highly probable, as they always start from the neighborhood of the alveolar border.

Fibromata and Chondromata are met with in the lower jaw, and spring either from the periosteum or from the centre of the bone. They resemble similar growths elsewhere, and present nothing peculiar.

Osteomata of both forms, the cancellous and ivory exostosis, are met with in the lower jaw; it is in fact one of the most common seats of the latter affection.

Odontoma.—This is not properly a tumor of the jaw, but it is most conveniently mentioned here, as closely simulating disease of the bone. An odontoma is the result of some peculiar modification in the growth of a tooth, resulting in the formation of an irregular mass of dental tissues of no definite shape. Tomes describes one removed by Sir W. Fergusson as being "composed of enamel, dentine, and bone derived from calcification of remnants of the dentine pulp, thrown together without any definite arrangement."

According to Heath, only 8 cases have been recorded, all in the lower jaw. The tumor can be removed if its nature is recognized without taking away any of the jaw-bone. Outgrowths from the fangs of fully developed teeth composed of dentine and cement are not uncommon, forming the so-called warty teeth, but these are seldom of sufficient size to be of any surgical interest.

Sarcomata of various kinds form a considerable proportion of tumors of the lower jaw. Myeloid, spindle-celled, and round-celled sarcomata are all met with. The first is always central, the last two may be periosteal or central. Chondrifying or ossifying sarcomata are occasionally met with. The myeloid tumor usually runs a simple course, the other forms are frequently malignant. The mode of growth of these tumors and the symptoms they give rise to are the same as in other parts.

Diagnosis.—In the lower, as in the upper jaw, it is of great importance to distinguish the simple from the malignant affections; as in the latter form of disease an operation is sometimes not advisable, the soft tissues around the bone being implicated to such an extent as not to admit of removal, and consequently not of the full and complete extirpation of the disease. The malignant tumors may generally be readily detected by the rapidity of their growth, by their pulpy or elastic character, and by infiltration of neighboring parts, with early adhesion to the skin and implication of the glands below the jaw.

Treatment.—The treatment of tumors of the lower jaw depends in a great measure upon the character of the growth. In single cysts of moderate size, with thin walls and but little solid tissue around the cysts, the best mode of treatment consists in cutting down through the gum on the expanded portion of bone, opening the cyst by means of the antrum-perforator, small trephine, or cutting pliers, according to its size and the thickness of its walls, letting out the contained fluid; and then, by introducing a plug of lint causing the cavity to granulate from the bottom, and gradually to contract. When the cysts are so large that they have destroyed the integrity of the bone, or when they are associated with a large quantity of solid tissue, as in the true multilocular cysts, excision of the diseased bone must be practised. This, also, is the only plan of treatment that can be had recourse to in other growths in this bone.

Excision of the Lower Jaw.—The operation of excision of a portion of the lower jaw for tumor of that bone was first performed by Deadrick, of Tennessee, in 1810, and not, as is generally but erroneously supposed, by Dupuytren. As the growths for which this operation is performed are usually situated between the symphysis and the angle of the bone, seldom extending beyond the middle line, the operation is generally limited to one side of the face. In some instances, however, the tumor may encroach so far that it may be necessary to remove more than the half of the bone; and in other cases, again, though of very rare occurrence, the whole of the bone has been disarticulated.

When the tumor is of moderate size, and is situated about midway between the symphysis and angle of the jaw, it may be reached by making a semilunar incision of sufficient length under the lower edge of the bone, and carrying the anterior extremity of it well forward upon the chin, but not dividing the lower lip, if it can be avoided, nor cutting into the angle of the mouth; then dissecting up the flap thus formed, and carrying the knife cautiously along the inner side of the jaw, so as to detach the mucous membrane of the mouth and the mylohyoid muscle to a sufficient extent. In doing this, the hemorrhage is often very profuse; the bleeding from the facial artery is particularly forcible, the blood being thrown in a larger and stronger jet than

would seem possible from the size of the vessel. The hemorrhage should be at once controlled by the application of ligatures to both ends of the bleeding artery, and to any other points from which it is abundant. Unless this is done, the after-steps of the operation will be rendered much more obscure and difficult. One of the teeth on each side of the tumor having been previously drawn, the jaw must now be deeply notched through their axile or interdental base with a narrow strong-backed saw, and cut through with pliers, or completely divided with the saw. After the fragment of diseased bone, with the attached tumor, has been removed, and all bleeding vessels have been secured, the flap of cheek should be laid down smoothly, and retained nearly by means of harelip pins. Occasionally the dental artery in the cut jaw gives trouble; the hemorrhage from this source may be checked by the application of a piece of solid perchloride of iron, or by touching it with an actual cautery. The patient must at first be fed with slops, which should be sucked in through a tube. At a later period, when cicatrization is well advanced, the teeth should be tied together with strong silver wire; or a silver cap should be fitted upon the teeth of the two portions of bone that are left, and attached by an elastic spring to another silver cap put on those of the upper jaw, so as to prevent the displacement that would otherwise occur in the smaller fragment. Union takes place after a time by fibrous tissue, which becomes sufficiently dense to make the jaw strong and useful.

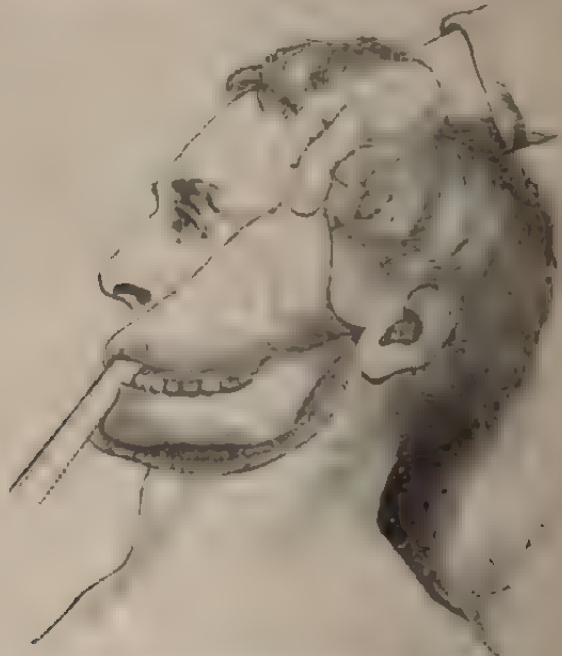

Fig. 685.—Excision of Lower Jaw. Soft Parts Raised.

In those cases in which the tumor *encroaches upon the angle and near the jaw*, it is usually better to remove the bone at the articulation on the affected side; for, if the articular end including the coronoid process be left, it will be displaced forwards and upwards by the action of the *temporalis* and *external pterygoid* muscles, and be a source of much inconvenience and irritation to the patient, not compensated by any corresponding utility. In the

case, the removal of one lateral half of the jaw will consequently be required, and the operation may be performed in the following way. The patient's head must be allowed to fall a little backwards so that the chin may be well raised from the chest. An incision is then made, commencing near the symphysis, passing along the under surface of the body of the jaw as far as the angle and then upwards at the posterior border of the ramus as far as the level of the lobule of the ear. If the tumor be very large, it may be necessary to make an incision upwards towards the lip from the anterior end of that just mentioned or even to divide the lip completely, but this should be avoided if possible. The facial artery and vein are wounded in the first incision and must be at once secured. The flap is then raised and the mucous membrane divided along its reflection from the cheek. If the tumor is simple, this may be partly done with a periosteal elevator, the periosteum being saved where it can be safely taken from over the tumor. The knife is then carried behind the jaw in front of the tumor, separating the mylohyoid and dividing the mucous membrane in the floor of the mouth, care being taken not to cut away the geniohyoid and geniohyoglossus muscles, unless the situation of the tumor is such that this cannot be avoided. If these muscles are necessarily divided, a thick ligature should be passed through the end of the tongue, which must be drawn forwards by an assistant, lest it fall backwards into the

Fig. 656.—Excision of Lower Jaw. Disarticulation of Condyle.

pharynx and thus threaten or even occasion suffocation, as has happened to surgeons of eminence both in France and in America. The jaw having been elevated on both sides in front of the tumor, the incisor tooth must be drawn at the point where it is intended to divide the bone, and the saw Fig. 680 applied. The section should be completed with the saw, as if the bone-forceps be used a jagged edge will probably be left. The jaw is then raised either by the fingers or in the lion-forceps, and forcibly depressed and drawn somewhat outwards, while the cheek flap is pulled upwards so as to bring the coronoid process into view with the attachment of the temporal

muscle, which must be divided. If, as sometimes happens, this cannot be easily reached, the coronoid process may be cut through with a saw and removed afterwards. As soon as the bone is freed from the temporal muscle it may be drawn more outwards and its inner side cleared from the internal pterygoid, care being taken to keep the edge of the knife turned towards the bone to avoid the submaxillary gland and the lingual nerve. Lastly by forcibly depressing the bone the condyle is dislocated; the external pterygoid is divided by a touch of the knife, and the bone then comes away. Fig. 686. During this stage of the operation care must be taken not to divide the internal maxillary artery, which lies close to the neck of the bone between it and the internal lateral ligament. If the bone be twisted too much outwards, the condyle will pass under the artery, which is then torn through or cut. Should the artery be divided, it must be ligatured, or, if it be cut very close to the main trunk, it may be necessary to tie that immediately below the point at which it divides into the temporal and internal maxillary. In depressing the bone to reach the temporal muscle and the joint, care must be taken not to use too much force, lest it happen that the ramus give way, having been weakened by the disease; this accident causes a good deal of difficulty in disarticulation, which can be accomplished only by seizing the fragment left behind in necrosis forceps, thus dragging it forwards, and then dividing the muscle and capsule. When the operation is completed, the raw surface should be touched with a solution of chloride of zinc and sprinkled with iodoform. The flap is then brought down and secured with sutures, a drainage-tube being inserted at the lower and posterior angle of the wound. If the symphysis have been removed, the root of the tongue must be attached forwards and the ligature through its tip must be retained for a few days till all danger of its falling backwards into the pharynx is passed, so that it may be drawn forward if necessity arises. When cicatrization is complete, a dense mass of fibrous tissue is formed in the place of the jaw, and comparatively little deformity results.

DISEASES OF THE TEMPORO-MAXILLARY ARTICULATION.—The articulation of the Jaw, though less frequently diseased than most other joints, is liable to the same affections as similar parts elsewhere. **Chronic Rheumatic Arthritis** of the temporo-maxillary articulation has been already described (p. 357). **Acute Arthritis**, terminating in destruction of the joint and fibrous or osseous ankylosis, most commonly occurs in consequence of disease of the middle ear in scarlet fever. According to A. E. Barker, who has specially called attention to this form of disease, it is met with almost exclusively in children, and is due to the persistence of a hiatus in that part of the tympanic plate forming the floor of the meatus and the roof of the articulation. This hiatus is always present in infancy, and may remain in adult life. The disease may result, also, from necrosis of the bone in chronic suppurative inflammation of the middle ear after fevers. The symptoms are those met with in other joints—acute pain, redness, swelling, and the formation of abscesses discharging either on the cheek or by the ear. The treatment consists in rest and opening the abscesses. **Ankylosis of the Jaw** may be fibrous or osseous. It necessarily, even if affecting one side only, prevents mastication. If fibrous, it may be treated by forcibly opening the mouth under chloroform by means of a screw-gag, or of an apparatus specially constructed for the purpose, after which a wedge may be placed between the teeth to keep them apart. This treatment is painful, and has to be repeated at intervals for some time, lest the articulation become again stiffened. It is not usually very satisfactory. Spanton has succeeded in producing a better result by dividing the fibrous bands in the articulation by means of a tenotome passed into it. In firm fibrous ankylosis in which other means

have failed, or in osseous ankylosis, the only treatment likely to be followed by good results is excision of the condyle of the jaw. This is best done by an incision carried along the lower border of the zygoma from immediately in front of the ear, avoiding the temporal artery, to the malar bone. From the middle of this, a short vertical incision may be carried downwards, for about three-quarters of an inch, dividing the skin and fat only. The masseter is then separated from the zygomatic arch as far as it is exposed by the scalpel and periosteal elevator. The neck of the bone is thus fully exposed, and must be carefully cleaned with a narrow elevator, keeping close to the bone so as to avoid injuring the facial nerve or internal maxillary artery. The neck of the bone is then divided with a narrow chisel. After this, if the ankylosis is fibrous, it may be possible to lever the condyle out with an elevator; if it is osseous, a second section of the bone must be made with the chisel immediately below the zygoma. This operation has been successfully performed by Davies-Colley, Heath, and others. The result is usually very satisfactory. Humphry, of Cambridge, also successfully removed the condyle, in 1856, for rheumatoid arthritis.

Enlargement of the Condyle of the Jaw is a rare condition occasionally met with. There is great and irregular increase in size of the condyle, apparently due to the formation of ossifying cartilaginous outgrowths similar to those of rheumatoid arthritis. In a case of this kind recorded by Adams, other joints were similarly affected. In two other cases recorded by McCarthy and Heath, there were no signs of general articular affection. In Heath's case the chin was thrown over to the opposite side, and great deformity resulted. The diseased condyle was successfully removed. It measured one inch and three-quarters from before back and one inch across. The improvement in the appearance of the patient and the utility of the jaw was very marked.

Closure of the Jaws.—*Spasmodic closure* of the jaws, lasting weeks or months, and often accompanied by considerable pain, is not an uncommon result of retention of the wisdom tooth, either from faulty position, or from the second molar not allowing room for it to reach the surface. It occurs between the ages of 20 and 35, at the period at which the wisdom tooth should be cut. Chloroform must be administered, and the mouth gagged open. The second molar must then be extracted to give room for the wisdom tooth, after which the symptoms at once subside.

Permanent closure of the Jaws may be due to ankylosis of the joint, as already described. It is perhaps, however, more commonly the result of contraction of cicatrices, resulting from cancer of the oris, or from gangrenous stomatitis following the excessive administration of mercury, or, more rarely, from extensive necrosis. When the mucous membrane has been destroyed by ulceration from the one alveolar border to the other, the resulting cicatrix binds the jaws so firmly together, that not only is movement impossible, but the inside of the cheek is in such close contact with the teeth that there is scarcely room to pass a director between them. Under these circumstances it is evident that little can be done to relieve the patient from within the mouth. Division of the cicatrix, followed by forcible extension, has been recommended and practised, but never with any good result. As the raw surface heals, the contraction necessarily recurs, and the last state of the patient is much the same as the first. If the band were very narrow, and healthy mucous membrane existed on each side, which could be drawn in by contraction of the sore in healing while the mouth was gagged open, some benefit might result, but practically such a condition is never met with. Various attempts at plastic operations, similar to those performed for faulty cicatrices in the skin, have been suggested and attempted, but no good result

has been obtained. In order to relieve this distressing deformity, Esmarch, of Kiel, in 1855, suggested division of the jaw and the formation of a false joint in front of the cicatricial bands. About the same time, Rizzoli, of Bologna, made a similar suggestion. In Rizzoli's method, the jaw is simply divided from within the mouth by a pair of strong cutting pliers; in Esmarch's operation, a wedge-shaped piece of bone, with the apex towards the alveolar border, is removed by a saw from an incision made from outside at the lower border of the jaw. The performance of the operation is sufficiently easy, but considerable difficulty is found in maintaining the movement between the fragments after cicatrization is complete. The tendency to reunion by bone, or by fibrous tissue, so dense as to prevent all movement, is certainly less when a considerable piece of the jaw is removed. C. Heath, who was one of the first to perform the operation in this country, expresses a strong preference for Esmarch's operation. In one case operated on by him by this method, in 1864, the patient was found to have good use of the sound side of the jaw in 1880. The wedge of bone removed measured seven-eighths of an inch at the lower border.

CHAPTER LVII.

PLASTIC SURGERY OF THE FACE AND MOUTH.

By **Plastic or Reparative Surgery** is meant the performance of operations for the repair of deficiencies in structure, whether resulting from injury, from disease, or from malformation.

It has been long known that portions of the body may retain sufficient vitality to become again adherent, when attached by but a very narrow tongue of tissue to the part from which they have been all but separated. This has often been observed in injuries of the face and fingers, portions of which have been almost completely severed, and yet have united again on being replaced. But there is a sufficient number of cases on record to show that certain parts, when completely separated, may, after being replaced, again become adherent. The most remarkable instances of this kind are those which are related by Hoffacher, and attested by Chelius and Velpeau. Hoffacher was officially appointed to attend as Surgeon at the duels which were then, as now, frequent amongst the students at Heidelberg; and, as at these encounters broad-swords were used, he had an opportunity of seeing a considerable number of incised wounds, and has related no fewer than sixteen cases in which portions of the nose, lips, or chin had been sliced off, and, being put on again, contracted adhesions. Amongst the most remarkable of these, is one in which the end of the nose was sliced off by a cut with the broad-sword, and fell under a chest of drawers; it was not found for some time, but, on being recovered and washed, was stitched on, and became firmly attached. In another instance, a dog that was in the room snapped up the detached portion of the organ as it fell to the ground, but the nose, being immediately taken out of the animal's mouth and put on again and stitched, became firmly fixed.

In order that union should take place between parts that have been sepa-

rated completely or nearly so, and the rest of the body, it is necessary that they be soft and vascular, and more especially that their structure be of a homogeneous character, such as is met with in the tissues of the face; where no very large bloodvessels, nerves, tendons, or bones are found. It is the case in plastic operations, which succeed best under similar conditions of tissue and which are conducted on the same principle as an attempt at union in a partially severed structure.

It is principally for deformities and loss of the nose and lip that plastic operations are of much service; they may, however, occasionally be had recourse to in other situations, as about the cheeks and eyelids, but seldom with an equal amount of success. Reference has already been made (p. 842, vol. i.) to the performance of plastic operations on the perineum. In the practice of this very interesting branch of surgery, there is much opportunity for the display of manual dexterity. On this, indeed, almost the whole success of the operation depends; and a vast deal may be done in apparently the most unpromising cases by skill and patience. In these operative procedures the names of Serres, Dieffenbach, Liston, Syme, Fergusson, Sédillot, B. Laugenberg, Alibert, and Wolfe, deservedly take the first rank.

In performing the various plastic operations five methods have been employed. In the first, the flap of skin that is intended to repair the lost structure is transplanted from a distant part, as the arm. This operation, introduced by the Italian Surgeon, Tagliacotius, in the sixteenth century, and hence commonly called by his name, has in a great measure fallen into disuse on account of the difficulty of its execution, and the great uncertainty of obtaining a successful result. The second plan, which has been recently introduced by Wolfe, of Glasgow, consists in the transplantation of a piece of skin of considerable size from one part of the body to another, the transplanted portion being completely separated at the time of the operation, and carefully freed from every trace of subcutaneous fat with a pair of sharp dissection scissors. The third plan consists in transplanting the reparative structure from some part in the neighborhood of the organ to be repaired; the skin from the forehead, for instance, being used for the formation of a new nose; that from the chin for the restoration of a lost lip. This procedure, which seems first to have been adopted by the natives of India in restoring the nose of the nose, is the method that is most commonly employed in this country in plastic operations on the face. The fourth method consists in moving the skin by a process of subcutaneous section to some distance around the part to be repaired, and then drawing it forwards with or without tension through its substance. This gliding operation is chiefly practised for the closure of fistulous openings. The fifth method is employed in cases where an abnormal fissure exists in a part. It consists in bringing together and uniting the edges of the fissure, after having pared them evenly, so as to expose their vascular surfaces.

Union in plastic operations should take place by the first intention. Should this, however, fail from any accidental circumstances, the Surgeon need not despair; as the parts may unite by granulation, in a very satisfactory and complete manner.

For proper union to be effected, it is necessary that the edges be clearly and evenly cut, so as to adjust themselves accurately to one another. This may often be most skillfully effected by making the incision in the part that is to receive the flap somewhat oblique or bevelled, thus securing a more exact adaptation of the edges.

After the flap has been formed and the part in which it is to be transplanted properly pared, the operation should be delayed a few minutes until

all bleeding has ceased. This is of much importance, as the interposition of a layer of coagulated blood will materially interfere with union.

In bringing the parts into apposition, great care must be taken that no undue traction or constriction be exercised, lest their circulation be interfered with, and their vitality be endangered.

The parts may be maintained in apposition by sutures, collodion, or the application of a strip of isinglass plaster. The sutures should be as fine as possible, introduced with a small needle, and knotted on the sound part. Horsehair, fine catgut, or silkworm-gut will be found the best materials where there is no strain on the sutures; should there unavoidably be some strain a deep metallic stitch should be passed to relieve the finer sutures. Occasionally harelip pins may advantageously be used. The use of collodion, where applicable, is of great advantage in plastic surgery, as it not only secures adhesion, but, by excluding the air, lessens the chance of exsiccation. If the wound is large, it must not be completely covered by collodion lest discharges accumulate beneath the flap. In some parts in which the wound is moistened by the secretion of some neighboring mucous membrane and cannot be kept dry, as in the eyelids, wet boracic acid lint or boracic acid ointment will be found the best application; in other parts absorbent iodoform or salicylic wool may be applied, a small piece of the "protective" oil-silk being placed next the wound to prevent it from sticking. The wool may be fixed in position by collodion.

For a plastic procedure to succeed, it is absolutely necessary that no morbid process be going on in the seat of operation; and not only that none be actually in progress, but that all have ceased for some considerable time. This is more particularly the case when the deformity, for the remedying of which it is practised, has resulted from syphilitic ulceration. In such cases, it is necessary to see that the constitution is sound, as well as that all local disease has been eradicated; otherwise the irritation of the operation might set it up again, and the new flap might be invaded and destroyed. From want of this precaution, I have more than once seen disappointment result. When an operation, as on the nose or lip, is performed for epithelioma or rodent ulcer, ablation of the morbid part may be done at the moment of operating—the affection being a local one; when for struma or syphilis, the disease is constitutional, and cure must be taken that all morbid action has thoroughly and completely ceased. As a general rule, plastic operations practised for the repair of mutilations from injury, or of congenital deficiencies, are more successful than those that are performed after disease.

No routine system of treatment should be adopted; but a few days of rest, good diet, and a dose or two of aperient medicine, may be prescribed before the operation is proceeded with. In the after-treatment of the case, a nourishing but unstimulating regimen should be observed.

Faulty Cicatrices about the face and neck often occasion much deformity and annoyance, and may require a plastic operation for their removal. Those resulting from lacerations have already been considered, as also their treatment (vol. i. p. 384, *et seq.*). When due to other causes, such as the unskilful opening of strumous abscesses, or the healing of wounds with dirt or grains of gunpowder embedded in them, being puckered, depressed, adherent, or discoloured, much may be done by proper surgical means to remove the disfigurement they occasion. This is best done by dissecting them out cleanly, then loosening the edges of the cut by running the point of the scalpel under the skin, so that they may be brought together without puckering, and then uniting them by means of horsehair or fine catgut sutures passed by a round sewing-needle.

Burow's Operation.—A plastic operation specially suited for the repair of deformity consequent on the removal of morbid growths from the cheeks and other parts of the face, has been introduced by Burow, a Polish Surgeon, and successfully performed and described by Stokes (Fig. 687). The steps are as follows. The growth to be removed is included in three incisions, 1, 2, 3; and the integuments from which it springs are then carefully dissected off, leaving a raw triangle, the apex of which is on one, the base on the other side of the tumor. The incision 1, 4, 3, is then carried outwards to 5, 8, 7, so that the whole distance from 1 to 7 is exactly three times that of the base of the raw surface; a second triangle, 5, 6, 7, is then made, having its base on the outer third of this horizontal incision. The two triangles must be of equal size, and the integuments are dissected off, 5, 6, 7. There are thus two raw surfaces to be covered in. This is done by dissecting up carefully the flaps 1, 5, 6, and 2, 3, 7. When this is done, the points 1 and 3, and 5 and 7, are respectively drawn together, each by one suture, and the two raw triangular surfaces are thus covered in.

Plastic operations of various kinds are frequently performed on the eyelids. **Blepharoplasty**, or the operation by which the eyelids are repaired, is occasionally required for loss of substance—the result of wounds, cicatrices, or operations. It is less satisfactory in its results than most of the other

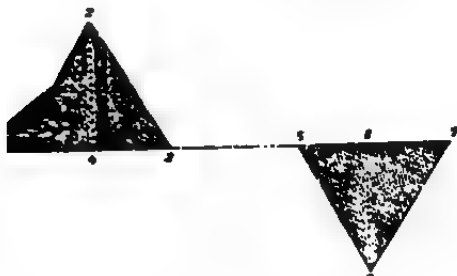

Fig. 687.—Lines of Incision in Burow's Operation.

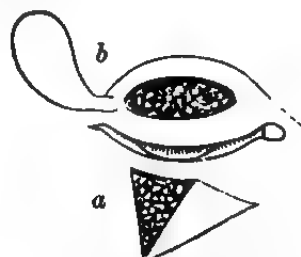

Fig. 688.—Operation for Repair of Eyelid; (a) Gliding Method; (b) Twisting Method.

plastic procedures about the face; yet it may, in some cases, improve materially the patient's appearance.

When the upper eyelid requires repair, the flap is taken from the forehead; when it is the lower lid, from the cheek or temple. This operation may be performed by the gliding method, by twisting a flap into its new situation, or by transplantation of a piece of skin. By the gliding method, a triangular flap is cut and partially detached (Fig. 688, a), and then drawn gently forwards until it corresponds to and fills up the gap that requires repair, when it is there fixed by a few points of suture. When the twisting method is employed, an oval flap is detached (Fig. 688, b), except its pedicle, and twisted down, to be planted on the raw surface.

Occasionally neither of these methods is applicable; and then the procedure that I successfully adopted in a case of which the annexed cut (Fig. 689) is a representation, may be followed. In this case, which was that of a lady who had received a severe mutilation of the face by the explosion of a ginger-beer bottle, there was a deep and hard cicatrix across the lower eyelid, causing depression and eversion of its outer portion, and adhesion of the inner part to the ball of the eye. After dividing the adhesions and removing the cicatrix, I made a semilunar incision *ss* as to dissect up

the eyelid, and then fixed it by points of suture in its new situation, when it became firmly adherent (Fig. 689), and scarce any apparent deformity was left. In another very similar case, in which a girl was bitten through the lower eyelid by a dog, a similar operation was practised with equally good results. In both these cases, the eyeball, having been injured, had become atrophied, with opacity of the cornea. But, when an artificial eye was adjusted to the shrunken globe, the appearance of the patient was most satisfactory.

Restoration of the lower eyelid in extreme ectropion by complete transplantation of a piece of skin was introduced by Wolfe, of Glasgow, in 1875, since which time it has been repeatedly performed with success. The operation is thus performed: the eyelid is first freed from the abnormal situation into which it has been drawn until its free border can be brought in contact with the upper lid, the two lids then being tied together by sutures passed through them. An accurate pattern of the raw surface to be covered is then taken, and a flap of skin is raised from the forearm corresponding in shape, but a little larger to allow for shrinking. The under surface of the flap is then freed from every vestige of subcutaneous tissue with a pair of flat sharp

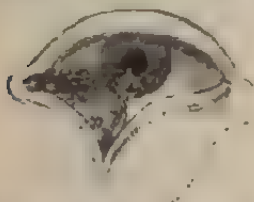

Fig. 689.—Lower Eyelid deformed by Cicatrix.

Fig. 690.—Lower Eyelid after Operation

scissors, so as to have a white appearance. It is then applied to the raw surface and united to the surrounding skin by fine silk sutures. A dressing of warm wet boracic acid lint may then be applied and covered by gutta-percha tissue and cotton-wool. About a fortnight after the operation, after the flap has become firmly adherent, the sutures uniting the lids may be removed and the eye allowed to open. In a case successfully operated on by Wolfe, the oval piece of skin transplanted measured two inches by one and a quarter. It united by first intention, without even desquamation of the cuticle taking place.

PLASTIC SURGERY OF THE NOSE.

RHINOPLASTIC OPERATIONS are occasionally required for the restoration of the form of the nose, which has been destroyed by injury or disease. This branch of plastic surgery has long received much attention, and has been reduced to distinct rules. Either the entire nose, or a portion of it, may demand operation.

Columna.—When the columna and a portion of the septum are destroyed, a large gap is left at the nasal aperture; and, the nose becoming flattened in consequence of its tip falling in, great deformity necessarily results. The upper lip also, losing that amount of support which it receives from the columna, becomes pendulous, projecting, and thickened at the end, thus adding to the disfigurement. The restoration of the columna is effected from this thickened and prominent upper lip, which, by being reduced in size, is rendered far more shapely. The operation consists in cutting through the whole length of the lip from above downwards on each side of the mesial

be, so as to leave a tongue about one-third of an inch in width. This is then turned up; and its ends being well pared, and the under surface of the tip of the nose properly freshened, it is fixed by means of a fine harelip pin and twisted suture, which should be left in for about four days. Union takes place in a few days; but until this is firm, the new column must be properly supported with narrow strips of plaster fixed to the cheek on each side. No testing of this small flap is required, as the mucous surface speedily becomes cutaneous, and vice versa. The division in the upper lip must be treated in the same way as an ordinary harelip, and unites without difficulty, lessening greatly the deformity in this part.

Ala.—When one ala only is deficient, the rest of the nose being sound, one of three processes may be adopted to remedy the deformity. 1. When a small portion only of the free border of the tip has been lost, an incision should be made (Fig. 691) across the nose, and the remains of the ala and a portion of the nasal integument thus marked out dissected down, and attached to the end of the organ. In this way a very excellent result may be obtained.

2. If the loss of substance be greater, a flap of skin, of the proper shape to restore the deformity, may be raised from the cheek, applied to the previously pared edges of the part requiring it, and fixed there by a few points of fine suture.

3. If the loss of the substance of the ala be very considerable, or if it extend to a part of the body of the nose, then it is more efficiently restored by bringing a long narrow flap from the forehead in a way that will immediately be described. In the majority of cases, the destruction of the ala and of the body of the nose is so considerable, that other plans, to be presently described, are required for the repair of the deformity.

Entire Nose.—For the restoration of the entire nose, two procedures have been employed: viz., 1, the Taglianacotian Operation; 2, the Indian Operation.

1. The **Taglianacotian Operation** consists in taking the integument and areolar tissue required for the repair of the lost organ from the inside of the arm. Here a flap of sufficient extent is to be marked out and dissected up with its subjacent areolar tissue, leaving it merely attached to the limb by a root at its distal end. No attempt at fixing this flap to the nose should be made for at least a fortnight, during which time it should be kept upon a piece of wet lint, and allowed to thicken, granulate, and become vascular, so as to fit itself for adhesion to the new surface to which it is to be applied. The remains of the reformed nose having then been properly pared and the flap shaped, they must, after all bleeding has ceased, be properly adjusted and fixed to one another by points of suture. The arm must then be closely attached to the head, so as to be as nearly as possible immovable. At the end of about one day, when adhesions have taken place, the connecting medium may be cut across, and the part left to be supported by the vitality which it may gain from the new surface to which it is now attached. This process is comparatively seldom had recourse to, for obvious reasons. The uncertainty of maintaining the vitality in the flap, the extreme tediousness of the prolonged constrained position in which it is necessary to keep the patient, and the great difficulty of guarding against movements of the arm, especially during sleep, and which, however slight and involuntary, would be sufficient to disturb union between the opposed surfaces, and occasion the failure of the operation, have caused this plan of procedure to fall into disuse; and it is

Fig. 691.—Deformity of Ala of Nose.

now, I believe, universally abandoned by Surgeons in this country, having been replaced by the more certain procedure, which will now be described, of borrowing the skin for the new nose from the forehead.

2. The **Indian Operation**, a knowledge of which was brought to this country by Carpué in 1814, is extremely successful in its results, though requiring a good deal of nicety for its proper execution. The operative procedures required by this method are somewhat complex, and may conveniently be divided into three distinct stages: 1, the Dissection of the Flap from the Forehead, and its Attachment to its new situation; 2, the Separation of the Root of the Flap where it is turned down from the Forehead, and the Formation of a proper Bridge to the Nose; 3, the Formation of the *Columa Nasi*.

1. **Formation and Attachment of the Flap**—In the shaping of the flap, care must be taken that it is of sufficient size; as during the after part of the treatment it often has a tendency to shrivel, and more inconvenience usually results from its not having originally been made large enough, than the reverse. The size adapted to the particular face may best be judged of by moulding a thin piece of gutta-percha to the nose, then flattening it out by dipping it in hot water, and using this as the guide for marking the outline of the flap upon the forehead. This should be traced with tincture of iodine, which will not be washed off so readily as ink by the flow of blood, which is often rather free. This flap should be of the shape shown in Fig. 692, taking care that it is rather square at the angles, and not too much rounded

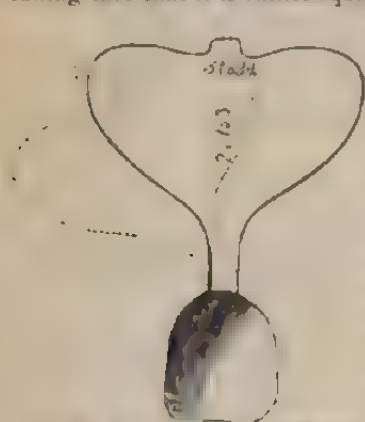

Fig. 692.—Diagram of Flap in Rhinoplasty Operation

off. The size will necessarily vary according to the character of the countenance, and the extent of loss that has to be repaired. When the whole of the nose requires restoration, it is usually necessary to make it about two and a half to three inches in length, by about the same in width at the broadest part. It may either be taken from the middle of the forehead, or obliquely from one side; if the latter, the right side is the most convenient. It must now be dissected off the forehead; in doing this, care must be taken to cut the flap as thick as possible, especially at its root between the eyebrows. It must also be but little handled, and, above all, not pinched, either with fingers or forceps.

The dissection should be commenced at the root, so that the outline may not be obscured by blood; and this part should be left long, in order to admit afterwards of a very gradual and easy twist. In order to facilitate this, it is desirable also to make the incision on the right side a little lower than that on the left. After the flap has been raised throughout the whole of its extent, pressure should be applied to the forehead by means of a sponge, with a view of arresting the bleeding, before the next step is taken. This consists in paring the surface and edges of the stump of the nose, and removing the integuments from it in such a way as to leave a triangular raw surface. In doing this, care must be taken—whilst a good base of attachment is left—not to remove the parts too widely, lest the cheeks should retract, and flatten out the nose. The integuments also should be dissected away in such a manner as to form a deep groove shelving inwards, so as to receive and hold the flap more securely and with less

overlapping of the edges. The operation must now be discontinued for a few minutes until all bleeding has ceased, and the cut surfaces have become glazed; this point is of great importance in securing direct adhesion, and must be carefully attended to. The bleeding having been arrested by exposure to the air, and by the torsion rather than the ligature of any spouting branch, the flap from the forehead should be brought down by a twist from left to right, and attached by a few points of fine suture on each side to the edge of the incision, around the nasal aperture. A pledget of soft lint or wool greased with carbolic oil, should now be gently insinuated under the flap, the lower part of the incision in the forehead drawn together by a point of suture, but not so as to constrict the root in any way, and the rest of the exposed surface covered with some simple dressing. The parts now then present the appearance of Fig. 694, taken from a patient of mine the day after the operation. Fig. 693 represents the deformity for which the operation was performed. The patient should be put to bed with a piece of soft lint laid over the whole of the face, so as to maintain its temperature; and if it be winter, he must be placed in a room that is well warmed day and night. The diet for the first few days should be simple, but abundant, consisting chiefly of nutritious stews.

The dressings must not be disturbed for three days; by this time, if all go well, the flap will be found somewhat tumid, warm, and sensitive, but free from odor. The plug in the nose will now require changing, lest it be rendered offensive by the discharge; its withdrawal and the substitution of another must be done with the greatest gentleness, the surgeon bearing in mind that any undue pressure or traction may destroy adhesions, and prove fatal to the vitality of the flap. If the sutures produce no irritation, they may be left in till the fifth or sixth day, by which time adhesion will be tolerably perfect, and they may with safety be cut and withdrawn. As adhesion strengthens and the vitality of the flap improves, it must be supported by putting underneath it a larger plug of lint; for which, after a time, may be substituted a small gutta-serena tube moulded to the figure of the inside of the nose. Oedema of a somewhat solid character is apt to set in on the flap, giving it a white appearance; but this is of little moment, and will gradually subside as the circulation through it becomes more actively established. The flap gradually becomes thicker and firmer, throwing out granulations from its under surface, which eventually becomes covered by epithelium. The wound on the forehead must be dressed like an ordinary ulcer, and be well touched with nitrate of silver from time to time, to insure its contraction. It usually cicatrizes with great readiness, and leaves remarkably little deformity.

2 Separation of the Root of the Flap.—This may be done about a month after the flap has been fashioned, when its vascularity, through its lateral adhesions, will be perfected. The division of the root is best done by passing a narrow-bladed bistoury under the twist, and cutting upwards towards the eyebrows, removing a wedge-shaped portion of the soft parts, so as to make a smooth and proper bridge.

Fig. 693. — Deformed Nose.

Fig. 694. — New Nose, day after Operation.

3. **Formation of the Columna Nasi.**—The addition of the columna is now all that is wanted to make the nose complete. This must be made from the upper lip, perhaps at the same time when the bridge is fashioned; and it may be cut and fixed in the way that has been already described in speaking of the restoration of this feature, the interior of the apex of the new nose having been well pared to receive it. The columna must be well supported by means of a narrow strip of plaster passing from one cheek to the other, and usually requires a good deal of fashioning before it is perfect; indeed, this is the part of the operation that I have found always most troublesome, and requiring most attention.

The new nose must continue to be supported from beneath, for some months after its formation, by plugs of lint or small gutta-percha tubes, as it will evince a great tendency to contract and to alter in its general outline and shape; becoming, if the Surgeon be not careful, either depressed or dumpy. The sensibility of the new nose is entirely destroyed for a time after the division of the bridge; but it slowly returns from all sides, appearing first in the neighborhood of the adhesions between it and the cheeks, then near the columna, next in the bridge, and thus the organ at last has its sensation restored; for this, however, several months will usually be required, and the part in which it returns last of all is its central portion.

The annexed cuts (Figs. 695, 696) give a very faithful representation of a

Fig. 695.—Patient before Rhinoplastic Operation.

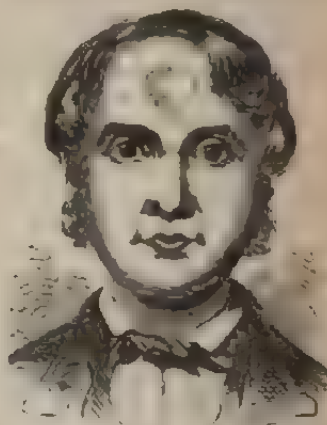

Fig. 696.—Same Patient some months after Operation

patient on whom I operated, before and after the restoration of the lost organ.

The success of the case will depend very greatly upon the minute attention which the Surgeon bestows on the details of the operation, and on the care which he takes in the after-treatment. During the operation, the chief points to be attended to are, that the flap be made of sufficient size, that all oozing has ceased before the cut edges are brought into contact, and that no tension or constriction be exercised. A principal source of failure in the operation, or in the result so far as concerns the after-appearance of the patient, is gangrene of the flap, in whole or in part, arising from the root being too narrow or too tightly twisted, or from the flap being too roughly handled in its dissection. So also, if it be cut too small and not properly supported afterwards, the result will not be very satisfactory. Other acci-

Some occasionally happen; thus, erysipelas may occur early, destroying the vitality of the flap, or come on at a later period, causing the new nose to slough under the attack of inflammation, which it has not sufficient vitality to resist, as happened in one of Liston's earlier cases; or the new nose may be destroyed by a return of the lupus which proved destructive to the old one. Hemorrhage also may occur from underneath the flap. In the last case operated on by Liston just before his death, and which was completed by Morton at University College Hospital, hemorrhage to the extent of more than a pint took place on the ninth day, without any evident cause, from under the flap, and could be arrested only by plugging. Further, the operation is not without its dangers. Dieffenbach lost two patients out of six on whom he operated in Paris; their constitutions having probably been in an unfavorable state.

The operation as just described will usually be attended by very satisfactory results. Of late years some modifications have been introduced into it. The Langenbeck recommends that the periosteum should be dissected up from the frontal bone together with the skin flap, in order that, by the after-development of osseous tissue, a firmer and better organ should be left. It has been feared by some Surgeons that exposure of the frontal bone, by stripping off its periosteum, would probably be followed by necrosis. Experience has, however, shown that this fear is groundless, as, indeed, might have been inferred from analogous conditions often observed in injuries of the head, in which large portions of the pericranium may be detached without the exposed bone losing its vitality. But it appears to me that there are more serious objections to "Osteo-rhinoplasty," and that it is an unnecessary complication of the operation to turn down the pericranium in the nasal flap, for two reasons. First, the pericranium is very firmly attached to the bone, and very loosely to the integumental structures, which glide over it. From the bone it is not detached without difficulty and a certain amount of tearing, by which its vitality is likely to be impaired to so great a degree that it would be of no service as a bone-producing organ in the new nose, and would not improbably, when twisted down, slough from insufficient vascular supply. Secondly, even if the pericranial lining of the new nose were to retain its bone-producing power, it seems to me that an osseous layer inside that organ would rather be a disadvantage than of service, and would certainly expose it to greater risk of fracture and other injury than if such brittle material as a thin shell of bone did not enter into its composition.

The operation practised by Ollier appears to me to be less happy than many of that excellent Surgeon's suggestions. It consists in cutting down the nasal process of the superior maxilla, and then bending it across so as to form a kind of bridge, on which to sustain the tegumento-pericranial flap deflected from the forehead. But by doing this the lateral supports to the bridge of the new nose are removed, and necrosis of the bent or rather broken fragment of bone, which has actually occurred, is not an unlikely accident.

Should the operation fail, or if from any reason it is not advisable to attempt it, the patient may be fitted with a painted vulcanite nose, attached to spectacles, by which the deformity is most efficiently concealed.

FISTULOUS OPENINGS THROUGH THE NASAL BONES leading into the interior of the nostrils are occasionally met with. Such apertures as these are, I have best closed by paring the edges, and then bringing forward a flap of neighboring skin by the gliding operation. In some cases of this kind, providence may be required, in which the Surgeon may display much ingenuity and benefit his patient greatly. The cuts represent a case many years since under my care, before and the day after operation, in which a

large aperture into the side of the nose, resulting from necrosis of the left nasal bone consequent on scarlatina (Fig. 697), was successfully closed by a flap of skin taken from the forehead by the twisting process (Fig. 698). The patient, who was a child at the time of the operation, has since grown into a comely woman, presenting scarcely a trace of the operation.

Fig. 697.—Opening into Anterior Nares.

Fig. 698.—Opening into Anterior Nares closed by Operation.

OPERATION FOR DEPRESSED NOSE.—Sometimes the nose is depressed and flattened in consequence of the loss of the cartilages, vomer, and septum, though the external parts remain entire. Dieffenbach has proposed a plan for raising it by slitting it longitudinally into three pieces; dissecting the lateral slips from the osseous attachments; paring the edges to such an extent that they overlap, and stitching them together; then bringing the whole organ forwards by pushing long harelip pins across its base, so as to elevate and narrow its attachments, which are brought more into the mesial line. Ferguson has improved this procedure by not slitting the nose down, but dissecting it away from the bones from within the nostril, and then pushing long steel-pointed silver needles across from cheek to cheek, and twisting their ends over perforated pieces of sole-leather, through which they had previously been passed, thus bringing the whole organ bodily forwards. The column is next fashioned in the way which has already been described; and the nose is completed.

PLASTIC SURGERY OF THE LIPS.

HARELIP.—By harelip is meant a congenital perpendicular fissure or fissures through the upper lip, the result of an arrest of development. Without going into the details of the development of the face, the mode of origin of harelip, cleft palate, and congenital transverse fissure of the cheeks, or macrostomia, may be made clear by recalling the main features of the process. The face is developed partly from a central process, the fronto-nasal plate, descending from the front of the cranium between the ocular vesicles. From this are developed the prominent part of the nose, the septum nasi, the columna, the central part of the upper lip, and the intermaxillary bone with the incisor teeth. The remainder of the face above the line of the lower jaw

is developed from a lateral process on each side, the superior maxillary plate, which gradually grows forwards till it coalesces with the vertical process just mentioned. From these processes are developed the cheeks and the whole of the superior maxillary bone, except the part of the palate corresponding to the incisor teeth, which, as already stated, is formed from the fronto-nasal plate. The lower jaw, and the soft parts covering it, are formed from similar processes, the inferior maxillary plates advancing from each side and coalescing in the middle line. The superior and inferior maxillary plates coalesce at each side, leaving the open space of the mouth in the middle line. The lines in which these various processes unite are roughly indicated in the diagram on p. 938, vol. i. The mode of origin of the various deformities of the face is, therefore, evident. If one maxillary plate fails to unite with the naso-frontal in front, a cleft will be left through the upper lip on one side of the middle line, forming a single harelip. If both plates fail to unite a double harelip results, and the intermaxillary bone may be left adherent to the tip of the nose and septum nasi. If at the same time the development of the naso-frontal process is arrested, we get the rare condition of a wide gap in the middle line with absence of the incisor portion of the superior maxilla. If the anterior parts unite, but development is arrested posteriorly, cleft

Fig. 699.—Single Harelip.

Fig. 700.—Ordinary Double Harelip.

Fig. 701.—Ordinary Double Harelip. Side View.

palate results, the fissure being single, and in the middle line as far as the posterior part of the premaxillary bone. If the arrest of development is more complete, the fissure may extend to the lip, deviating in front from the middle line as it passes between the main part of the superior maxillary and the premaxillary bone. If both sides fail to unite completely, the fissure is single behind and double in front, passing on each side of the intermaxillary bone. In exceedingly rare cases the fissure of the harelip has been seen extending upwards on one side of the nose towards the eye. Macrostomia or congenital transverse fissure of the cheeks results from arrested union of the superior and inferior maxillary plates.

Single Harelip is by far the most common deformity (Fig. 699). In it the mesial side of the gap is usually rounded; the outer edge is flattened;

and the frenum at the angle is long and subcutaneous. It most frequently, so far as I have observed, occurs upon the left side. When double (Figs 700, 701), the fissure is often deeper on one side than on the other, and usually extends into the nostril, and is associated with cleft palate; though sometimes it stops short of this. In these cases the nose is usually flattened and expanded, and between the fissures there is always a central or median lobule, consisting of the intermaxillary bones in a rudimentary condition; to this a triangular labial nodule is commonly attached. In many cases this is pushed forwards, and tilted on its base, so that the alveolar border projects forwards. Sometimes the projection is so considerable that it is attached to the tip of the nose.

Median fissure is so rare that there are scarcely any authentic cases of it in the records of surgery. Delahaye, however, mentions one instance of mesial fissure of the upper lip with two lateral fissures, and Nicati has described one in the lower lip, the only case of the kind that I have met with on record.

The fissure, when single, may be confined to the lip; but in the majority of cases it extends to the alveolus of the upper jaw, giving rise to a deep notch between the outer incisor and the canine tooth. When it is double, the four incisors, usually imperfectly and irregularly developed, are included in the central intermaxillary tubercle. Meckel and Nicati have described a rare form of harelip, in which the fissure corresponds to the line of junction between the central and lateral incisors. In many cases the fissure extends back into the palate; this more frequently happens when the harelip is double, and in these cases every variety of palatal deformity is met with (Fig. 702).

Fig. 702.—Skeleton of Jaw in Double Harelip, and Cleft Palate.

Age for Operation.—The cure of harelip can be effected only by a properly conducted operation. In the performance of this, the first point that has to be determined is the age at which it should be done. On this there has been, and is still, a good deal of difference of opinion. Surgeons generally are, however, I think, agreed that it is better not to perform the operation during dentition; at all events not during the cutting of the incisor teeth, when there is much local excitement and general irritability of the nervous system; but they are not agreed as to whether it should be done before

or after dentition. In support of the opinion that it is more prudent to wait until after this period, it is alleged that very young infants are especially liable to convulsions; that the performance of operations on them is troublesome; and that it interferes with suckling. These statements, however, are not supported by what we meet with in practice. There is no evidence to show that there is any danger in operating during early infancy; on the contrary, very young children, those but a few weeks or months old, bear operations remarkably well. I have repeatedly operated at these tender ages, not only for harelip, but for hernia, the removal of tumors and nevi, the division of tendons, etc., and have never seen any bad result follow. Besides this, the performance of the operation is easier at a very early age than when the child has reached its first or second year; when, its intelligence being more developed, it knows what it has to suffer, and screams and struggles more than a very young infant does, whenever it sees the Surgeon, or when he makes an attempt to examine the wound or dressings. After the operation, also, the child will, when young, take to the breast without difficulty and with the greatest avidity. The act of suction is advantageous,

as in it the sides of the incision are more closely compressed and brought together. At very early ages, union of the wound takes place with great readiness and solidity; and, as no time has been given for the rest of the features to become distorted, there will not be that permanent flattening and deformity of the face which is apt to continue after the harelip is cured, if the operation be deferred to a more advanced age. For these various reasons I agree with Dubois, Fergusson, and Butcher, that the operation had best be performed early; if possible, at about the sixth week after birth, or from that to the third month, which may, I think, be considered the time of decision for this procedure. At this time the vitality of the child is good, and the tissues are not so lacerable as at an earlier age. The operation may well be performed at a much earlier period in single than in double harelip; and the greater the deformity, the more marked the intermaxillary projection, the wiser will it be to defer operation, which not only becomes increasingly severe with the extent of the deformity, but after the performance of which the traction on the pins becomes too great for the tender tissues to sustain. Should circumstances require it, however, the operation might be done at a much earlier period than that advised above. Thus, at the urgent solicitations of the parents, I have performed it within the first twenty-four hours after birth, and several times during the first week. But in these very early days of life the operation is not without danger; the vitality of the child is often feeble, it suffers greatly from the loss of even a very small quantity of blood, and the tissues are so lacerable that there is great danger of the pins or stitches cutting out. I would, therefore, not advise its performance then.

It is scarcely necessary to observe that, as union by the first intention is aimed at, the operation should not be undertaken unless the health be good; and certainly not if the child, at whatever age, have but recently recovered from measles, scarlet fever, or other infantile disease.

Operation for Harelip.—In the treatment of harelip, there are three main objects to be kept in view: 1. The procuring of Union by First Intention of the cut edges of the Fissure; 2. The Prevention, as far as possible, of Deformity during the process of Union; and, 3. The Avoidance of all Traction on the line of incision that may interfere with these results.

These principles of treatment are carried out by paring the edges of the fissure freely, bringing them together by means of the twisted or interrupted suture, and taking off all tension by means of strips of plaster and the cheek-compressor. The American "rubber-plaster" will be found invaluable. But the details of the treatment vary so much, according as the fissure is single or double, or complicated by more or less projection of the intermaxillary portion, that the steps of each operation require to be separately described.

Single Harelip.—The operation for single harelip is performed in the following way. The child having been well pinned in a jack-towel that smothered it tightly, the Surgeon, sitting down, places his feet on a stool so as to raise them; and, covering his knees with a piece of mackintosh cloth, holds the child's head firmly between them. Bleeding from the coronary artery of the lip may be prevented (Fig. 703), either by an assistant or the Surgeon grasping the lip between his forefinger and thumb, or by compressing the lip with the little contrivance here figured, which consists of ordinary ring forceps converted into a compressor by having a vulcanized India-rubber ring slipped over the handles. This will be found to be invaluable in many operations about the face and jaws. The lower this ring is drawn down, the tighter will the forceps grip. The Surgeon first freely divides the *frænum* and all membranous connections between the angle of the cleft and

the gum of the upper jaw, and then, putting the lip on the stretch by seizing the extreme edge of the cleft with a pair of artery-forceps or a tenaculum, he pares the edges of the cleft by transfixion with a narrow-bladed bistoury, or

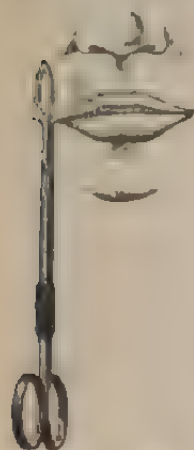

Fig. 703. — Elastic Compressor applied over Coronary Artery.

fine scalpel, from above downwards, first on one side, then on the other; taking care that the incisions unite neatly and cleanly above the upper angle of the fissure, which must be well cut out; and that they extend sufficiently far outwards to cut away the rounded portion of the prolabium which forms the side of the base of the fissure. The incision on each side must be curved with the concavity towards the fissure (Fig. 703), so that by bringing the two curves into a straight line a slight projection of the prolabium at the point of union shall be produced. If this be not done, a notch will be left when the lip is healed. Care should be taken that enough is cut away; there is more danger usually of taking too little than too much.

Fine harelip pins, made of soft iron wire, with hardened points, should then be deeply introduced through the lip from one side of the fissure to the other. The pins should be entered at about a quarter of an inch from the pared edge on one side, and brought out at a corresponding point on the other; care being taken that, though they are passed deeply, the mucous membrane is not transfixed; if it be, it will be doubled into the wound, and thus interfere with union. Two pins are usually required; if the child be some years old, and the fissure very long, three may be used. The lower pin should be introduced first underneath or through the cut coronary artery, in such a way that its pressure may stop the bleeding from this vessel, which is often rather free. In passing this pin, great care should be taken to bring the opposite sides of the fissure well into contact, so as to be on a level below, that no irregularity may be left in the prolabium. The twisted suture is then applied in the usual way (Fig. 704), first round the lower pin, and then round the upper one (separate threads, however, being used for each); and, lastly,

Fig. 704. — Application of Twisted Suture.

Fig. 705. — Application of Pins and Sutures in Harelip.

the two are united by a few cross-turns, so as to press down and support the whole length of the fissure (Fig. 705). In applying the twisted suture, the Surgeon must be careful, whilst drawing the edges closely into apposition, not to apply the threads too tightly, lest sloughing result; and in crossing them from one pin to the other, great caution must be used not to draw the two pins together horizontally, lest puckering of the line of union take place. The pins are then cut short, the whole is coated with a layer of collodion, and a piece of plaster is put under the ends of the pins to prevent excoriation of the skin. In addition to the pins and twisted suture, I invariably introduce one point of interrupted suture through the mucous membrane of the lower part of the fissure, just inside the mouth; and I look upon this as

of great importance in preventing the notching, which is otherwise very apt to occur in consequence of that portion of the incision between the lower part and the edge of the lip being kept open by the child in sucking, or protruding its tongue against it. At the end of from 72 to 96 hours, according to the age of the child, the pin should be withdrawn, or it may be removed by a gentle rotatory movement, in such a way that the cut end does not tear or lacerate the aperture in the lip. The threads, matted together with coagulation and a little blood, form a good crust, which may be left on for about three days longer, and then allowed to separate of itself; the less any crust that forms over the line of incision are interfered with, the better will the result usually be. The lip may, if thought desirable, be supported by a strip of American rubber or other adhesive plaster, which should, indeed, be continued for about a fortnight after the operation, so as to prevent stretching of the cicatrix and notching of its lower part. The point of interrupted suture may be left in for about four days. It sometimes, though rarely happens in single harelip that the intermaxillary portion is so large and projecting, that there is difficulty in bringing the lateral segments together over it. Should this be the case, the better plan is to notch it at its anterior border on the side that is not fissured, and then to break it back so as to remove all projection. If the fissure be wide, and the child restless, so that there is danger of the parts being dragged upon during its screaming or crying, it is a very good plan to apply the spring check-compressor, invented by Hainsby, here represented slack (Fig. 706). It must fit the child accurately, and commonly requires to be made specially for the case. If it is not obtainable, the cheeks may be drawn together by a piece of muslin cut out to form a large rounded piece in each cheek connected by a narrow strip over the lip. This must be applied while the cheeks are pressed together with the fingers and sealed down with collodion. American rubber-plaster may be applied in the same way.

When the fissure does not extend through the lip the operation recommended by Nélaton will be found to give most excellent results. The mode of performing it is fully explained by the accompanying figures.

Double Harelip.—The operation for double harelip is performed on the same principle as that for the single form of the disease, viz., of procuring union by adhesion between the opposite surfaces. The difference in the operations consists chiefly in dealing with the intermediate portion of the lip and alveolus (Fig. 708). The management of the intermaxillary process must vary according to its size and degree of projection. If it be small and rudimentary, or fixed to the tip of the nose, as in Fig. 709, it should be cut off with bone-nippers, as it would prevent the lateral segments from coming into

Fig. 706.—Hare lip. Spring Check compressor.

Fig. 707.—Nélaton's Operation for partial Harelip.

union, or fixed to the tip of the nose, as in Fig. 709, it should be cut off with bone-nippers, as it would prevent the lateral segments from coming into

proper apposition. Most commonly, when this is done, there is first an even dangerous bleeding from a dental artery deep in the bone, which may

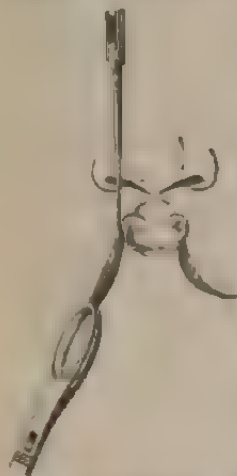

Fig. 708. Operation for Double Harelip. Right side of lip drawn down by Spring hook Forceps; long arrow Knife entered at angle. Dotted line shows direction of the incisions.

require to be touched with a red-hot needle or wire before the hemorrhage from it will cease. If the central intermaxillary portion be large and projecting it may be bent or broken back by strong forceps covered with vulcanized India-rubber. Ferguson, however, pointed out that if this be done the loose teeth contained in the intermaxillary portion will if they develop at all, project backwards into the roof of the mouth, as the bone is not pushed in its normal situation, but rather rotated on its transverse axis, the slender neck attaching it to the center being bent upon itself. He was of opinion therefore that in all cases it is better to remove the bone, than to attempt to force or bend it into a new position. If it be large and not projecting, the soft parts should be well pared on each side, and transected by the hare-lip pins, and thus be interposed between and united to the pared lateral surfaces; in fact it is always advisable not to remove this, unless it is awkwardly situated, as in Fig. 709. When the left, though the union may not appear quite so perfect and uniform as it would if the lateral halves had been directly united, yet eventually the row will turn out better; the central portion being, if developed, and forming the natural mesial process of the lip, which is lost when the lateral halves are directly united. In some of these cases great care is required in planning the incisions, and in the introduction of the sutures. The central portion

most advantageously pared in a somewhat convex manner, so that the free cut edges of the lateral halves are more accurately fitted upon it. Should, as often happens in single as well as in double harelip, one of the nasal segments be tied down to the gum and alveolus by a doubling of mucous membrane, this must be freely divided, and the portion of lip, with perhaps the corresponding ala of the nose, freely dissected up from the osseous structures, so as to admit of its being moved forwards without too much traction being put upon it.

In those cases in which the intermaxillary portion is projecting, and attached to and fused with the column of the nose, as in Figs. 709 and 710, I have performed the following operation with great success.

1. The triangular flap of skin covering the intermaxillary portion is dissected up as thick as possible.
2. The intermaxillary process is then cut away at its root, which is small and pedunculated, with a pair of scissors.
3. The edges of the lateral fissures are then pared in the usual way.
4. The free lower margins of the pared edges are brought together by one hare-lip pin and twisted suture.
5. The leaf-shaped flap is then laid down in the triangular hollow left above the pin, and retained there by one or two pairs of silver suture on each side, the gap being thus completely filled up by it.

Treatment by Simple Suture.—During several years I have been in the habit of treating harelip of all kinds, double as well as single, with the simple interrupted suture alone, without using any pins. I have in this way treated most successfully many cases in children, whose ages have varied from a few days to four years, with most satisfactory results, and with no

marking of the lip than I have ever seen attend union by means of the twisted suture. I prefer the simple to the twisted suture as being equally safe, more simple, and followed by less scarring of the lip, provided the case be not too complicated, nor associated with very wide fissure in the palate, or with great projection of the intermaxillary bones. In these circumstances, the pins should be preferred.

When the fissure is single, the edges, having been pared in the usual way, should be brought together by two points of suture; the first passed deeply near the free edge, and in such a way as to compress the cut coronary artery; the other nearer the nasal angle. These sutures should be of thick well-

Fig. 709.—Double Harelip; Intermaxillary Portion fixed to Nose.

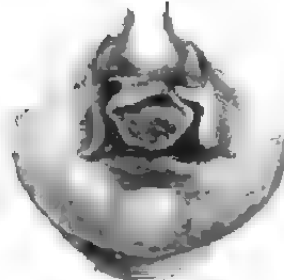

Fig. 710.—Double Harelip; Projecting Intermaxillary Portion.

waxed dentist's twist that will not cut out too readily, or, what is better, of silver wire. A point of fine interrupted suture should then be inserted through the mucous membrane inside the lip. The lip may then be supported by two narrow strips of plaster, one placed between the sutures, the other between the upper suture and the nose. On the third day the upper suture should be taken out, but the lower one may be left in for a day or two longer, when it and the one through the mucous membrane may be removed together, unless the latter have already cut its way out. If silver wire sutures be used, they may be left in for six or seven days without producing irritation. The lip must then be supported for a few days with a strip of plaster.

In the case of double harelip the same plan is to be adopted, first on one side, then on the other; but here, as the gaps are wider, and the tension, more particularly when the intermaxillary prominence is very projecting, is apt to be considerable, it is necessary to support the cheeks, and thus to prevent undue traction on the stitches, by means of the check-compressor (Fig. 710) or properly applied plaster. In this way all risk of the stitches cutting out before union is completed is avoided; an excellent and solid union will speedily be obtained even in cases of double harelip, with some intermaxillary projection and fissured palate.

The operation occasionally fails. The probability of the occurrence of such an untoward event is, however, greatly diminished by the use of the check-compressor. It may, however, happen either in consequence of the child's health being in an unsatisfactory state, so as to prevent union by the first intention; or in consequence of the pins having been withdrawn too early, before secure cohesion has been effected. In such circumstances as these, an attempt might be made to unite the granulating edges by the re-introduction of the pins or sutures, and by firmly fixing the lip by means of the check-compressor or plaster applied as above described. Such at-

tempts, however, rarely succeed; should they not do so, it will usually be found most prudent to wait at least a month before taking any further steps, and then to pare the edges afresh and repeat the original operation.

CONGENITAL TRANSVERSE FISSURES OF THE CHEEKS, extending from the angle of the mouth to the anterior border of the masseter or up towards the malar bone, are occasionally met with, and have been specially described by Klein and Nicati. Their mode of origin has been already referred to (p. 614). In these malformations, which are of extremely rare occurrence, the ear on the affected side is imperfectly developed. As has been observed by Fergusson, the tragus is detached from the auricle, and is fixed to the cheek, where it forms a small lobulated appendage. The external ear generally is malformed, the helix being twisted and curled inwards. These malformations require to be treated on exactly the same principles, and with the same attention to details, as harelip; union between the pared edges being effected by means of harelip pins and the twisted suture.

CHEILOPLASTY.—Simple plastic operations are commonly practised on the lower lip for the removal of epithelioma, by cutting out a V shaped piece of the lip, including the whole diseased structure, and then bringing together the opposite sides of the incision by harelip pins. These operations have already been described and figured at p. 554, vol. ii. We shall consider here those cases in which it becomes necessary to repair more or less extensive loss of substance in the labial structures. The restoration of a portion of the lip that has been destroyed by accident or disease, is not so readily effected as that of the nose; yet a good deal may be done to remove the deformity. The plan originally introduced by Chopart consists, when it is the lower lip that is deformed, in carrying an incision each side of the diseased portion of the lip vertically downwards below the jaw, for a greater or less distance according to the amount to be removed, even if necessary as far as the hyoid bone. The diseased part of the lip is then removed by a transverse incision below it. The square flap marked out by the two vertical incisions is then detached from above downwards. It is then brought up, and fixed to the pared edges of the remaining portion of the lip by points of suture; the head being kept properly inclined, in order to prevent undue tension. After sufficient union has taken place to preserve the vitality of

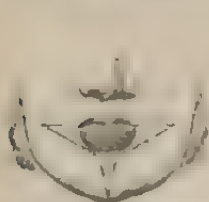

Fig. 711.—Lines of Incision in Cheiloplasty.

Fig. 712.—Incisions and Sutures in Cheiloplasty.

the flap, its lower attachment may be divided. This operation is not usually very satisfactory in its results, as the new flap is apt to become oedematous and inverted at the edge, or the flow of saliva may interfere with proper union. In those cases in which the greater portion of the lower lip has been excised for cancerous disease affecting its upper margin, another procedure for the restoration of the deformity consists in a modification of the plan recommended by Serres; and from this I have derived excellent results, as in the case which is here represented (Fig. 711). The object of the operation is to raise the lower lip to a level with the incisor teeth. An incision

about three-quarters of an inch in length, is made directly outwards from the angle of the mouth, on each side, into the cheek; from the extremity of this, a cut is carried obliquely downwards on to the upper margin of the lower lip, so as to excise the included triangular piece; the lower lip is then directed away from the jaw, from the inside of the mouth, and a V-shaped piece is taken out of its centre. By means of a harelip pin on each side, and a point of suture, the incisions in the angle of the mouth are brought accurately together; and in the same way the vertical one, in the centre, is united (Fig. 712). In this way the whole of the lower lip is raised, and brought more forwards. If care have been taken in removing the cancer from the edge of the lip, to leave the mucous membrane rather long (which may always be done, when the skin is affected to a greater extent than it), a good prolabium may be formed, and the restoration effected with but little deformity.

Buchanan, of Glasgow, as far back as 1841, published an account of a method for restoring the lower lip when affected by extensive cancerous disease, which leaves most satisfactory results. The accompanying figures illustrate the kind of case in which Buchanan's operation is applicable, the lines of incision required, and the appearance presented by the chin and lip after the disease has been removed, and the flaps brought into proper apposition.

The steps of the operation are simple, and the result is excellent. The diseased part of the lower lip is first removed by an elliptical incision (Fig. 713, *A B A*). An incision, *B C*, is then carried downwards and outwards on each side of the chin; and another incision, *C D*, upwards and outwards parallel to, and corresponding in length to, *A B*. The flaps formed by these

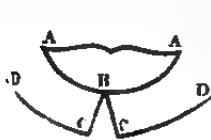

Fig. 711.

Fig. 714.

Fig. 715.

Buchanan's Operation for the Restoration of the Lower Lip.

incisions are represented in Fig. 714. They are detached from their sub-jacent connections; and the whole is raised upwards, so that the curved incision, *A B*, comes into a horizontal line, and is made to constitute the margin of the new lip; the secondary incisions, *B C*, coming together in a vertical direction, in which they are retained by twisted and interrupted sutures (Fig. 715).

Syme recommended a somewhat different mode of operating. Instead of the incisions *C D* being made, those marked *B C* are carried onwards for some distance in a direction curving downwards and outwards, so that they terminated below the angles of the jaw. The flaps so formed are raised and united in the middle line, as in Buchanan's operation, the Λ -shaped portion of skin above the chin serving to maintain them in position and prevent their sliding downwards. The long curved incisions enable this to be done by merely stretching the convex edges of the flaps, without sufficiently displacing them to prevent their readily meeting the concave edges of intervening skin, and being united to them by sutures. No surface is, therefore, left to granulate, and the whole wound heals by the first intention.

In performing this operation, it is essential to success that the incisions should be sufficiently free, so that the flaps may be brought into position without tension. If the chin be removed as well as the lower lip, it becomes

Fig. 716.—Syme's method of restoring the Lower Lip. Lines of Incision.

Fig. 717.—Syme's method of restoring the Lower Lip. Operation completed.

very difficult to restore the loss, as there is no fixed point below to support the new lip, which consequently tends to sink downwards.

PLASTIC SURGERY OF THE PALATE.

Various degrees of congenital deformity may occur in the palate and uvula; thus the uvula alone may be bifid; or the cleft may extend through the greater part or the whole of the soft palate; or the hard palate may be divided as well (Fig. 718); and, lastly, the separation may extend forwards to the integuments of the face, producing single or double harelip (Fig. 702). The soft palate and uvula are not unfrequently cleft without the hard palate being divided; and, in some very rare cases, the lip and the hard palate are cleft without the soft being cleft. The mode of origin of these deformities has already been described (p. 604).

These malformations necessarily give rise to great inconvenience, by interfering with deglutition, and rendering speech nasal and imperfect. During the swallowing of fluid, there is a tendency to regurgitation through the nose, though this is occasionally prevented by the approximation of the edges of the fissure in the soft palate.

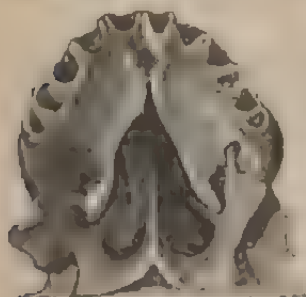

Fig. 718.—Fissure of Hard and Soft Palate.

An infant born with a cleft palate is necessarily unable to suck, and unless carefully fed by hand will soon perish. It must be fed with milk, the mother's milk being the best, which may be drawn periodically and administered to the child. The feeding may be done by a properly constructed bottle, in which the milk will flow slowly without the necessity of sucking on the part of the child; this must be fitted with an India rubber tube, which must be pushed well to the back of the

pharynx as the milk is given. In the absence of a bottle the child may be very efficiently fed by means of a teaspoon.

Until a few years ago, the operation was always deferred until the patient had attained the age to understand the necessity of remaining quiet during

the proceeding, and was able to control his movements, as success depended in a great measure upon his remaining perfectly tranquil and steady during the necessary manipulations, which are of a tedious and protracted character; and upon his assisting the Surgeon by opening his mouth, and not struggling during the introduction of instruments. Chloroform was never administered, from the fear that suffocation might be caused by the blood from the operation, which is always abundant, entering the air passages. In 1869, however, Thomas Smith, of St. Bartholomew's Hospital, demonstrated that with proper care anaesthetics may be safely administered, and at the same time he invented a most ingenious gag, by means of which the patient's mouth can be kept widely open without the Surgeon being interfered with either by the hands of assistants or the instrument itself. By the help of this gag and the administration of chloroform, the operation can now be performed at any age; but as the bleeding is always very free, it is advisable not to attempt it in too young children. At the age of three it may be safely undertaken, and the advantage of having it done before the child has learned to speak is very great.

STAPHYLOGRAPHY.—The operation for the cure of a cleft in the soft palate may be said to have been introduced by Roux; for although several attempts at the cure of this deformity had been made by Surgeons before his time, yet he was the first to establish **Staphyloraphy** as a distinct operation. Many modifications of Roux's plan have been practised by Von Graefe, Warren, Dieffenbach, Liston, and others, in order to render it more easy of execution, and certain in its results, and especially by making incisions through the palate so as to take off the traction on the sutures; but to Fergusson was due the merit of introducing a new principle of treatment in the operation, viz., the application of myotomy to it, thus paralyzing the movements of the muscles of the palate. Fergusson was of opinion that the great cause of failure in these operations was the mobility of the parts, and the traction exercised by the muscles, principally the levator palati and the palato-pharyngeus, in the line of union; in order to obviate this, he conceived the idea of dividing these muscles. Before Fergusson laid down the principles of this operation, it is true that various cuts had been made in the palate by different Surgeons, with the view of taking off the tension after the sutures were tied. Thus Dieffenbach, Pancoast, Liston, and Sedillot, all recommend that the traction on the stitches should be lessened by longitudinal incisions in the levator palati. Mettamer practised several small incisions for this purpose, and Mason Warren divided the anterior pillar of the fauces and the anterior laminae of the palate to the posterior pillar, coming nearer than any previous operation to Fergusson's method. These operations, however, were done almost at hazard, and in an empirical way, without the recognition of any distinct principle being involved in them.

Operation. The patient is placed in the recumbent position, the Surgeon standing on his right side. The gag is then inserted, and chloroform administered, or if the patient be nervous the gag may be inserted when anaesthesia is induced. The gag represented in the accompanying drawing (Fig. 719) is a modification of T. Smith's, invented by Wood. It can be adjusted to fit any patient by more or less widely separating the two halves.

Fig. 719.—Wood's Modification of Smith's Gag.

proper apposition. Most commonly, when this is done, there is even dangerous bleeding from a dental artery deep in the bone, which

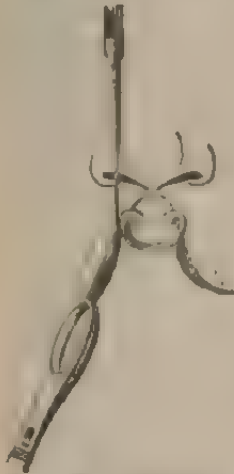

Fig. 708. — Operation for Double Harelip. Right side of lip drawn down by Spring-hook Forceps, long narrow Knife entered at angle. Dotted line shows direction of the incisions.

require to be touched with a red-hot needle, before the hemorrhage from it will cease. The central intermaxillary portion being large and projecting, it may be bent or broken back by strong force, and covered with vulcanized India-rubber. For this, however, it is pointed out that if this be done the teeth contained in the intermaxillary portion, if they develop at all, project backwards from the roof of the mouth, as the bone is not pushed into its normal situation, but rather rotated on its transverse axis, the slender neck attaching it to the body being bent upon itself. He was of opinion that in all cases it is better to remove the bone, rather than to attempt to force or bend it into a new position. If it be large and not projecting, the bone should be well pared on each side, and then united by the harelip pins, and thus be interposed between the lateral surfaces, and united to the pared lateral surfaces; it is always advisable not to remove this, unless it is awkwardly situated, as in Fig. 709. When the lip is left, though the union may not appear quite so perfect and uniform as it would if the lateral portions had been directly united, yet eventually it will turn out better; the central portion being developed, and forming the natural mesial part of the lip, which is lost when the lateral portions are directly united. In some of these cases great care is required in planning the incisions, and in the introduction of the sutures. The central por-

tion is most advantageously pared in a somewhat convex manner, so that the cut edges of the lateral halves are more accurately fitted upon it, as often happens in single as well as in double harelip, one of the segments be tied down to the gum and alveolus by a doubling of the membrane, this must be freely divided, and the portion of lip, which has the corresponding ala of the nose, freely dissected up from the underlying structures, so as to admit of its being moved forwards without traction being put upon it.

In those cases in which the intermaxillary portion is projected and fused with the columna of the nose, as in Figs. 709 and 710, I have performed the following operation with great success.

1. The triangular flap of skin covering the intermaxillary portion is dissected up as thick as possible.
2. The intermaxillary process is cut away at its root, which is small and pedunculated, with a pair of scissors.
3. The edges of the lateral fissures are then pared in the usual way, leaving free lower margins of the pared edges are brought together by one or two silver sutures.
4. The leaf-shaped flap is then laid down in a triangular hollow left above the pin, and retained there by one or two of silver suture on each side, the gap being thus completely filled up.

Treatment by Simple Suture.—During several years I have been in the habit of treating harelip of all kinds, double as well as single, by a simple interrupted suture alone, without using any pins. I have in this way treated most successfully many cases in children, whose ages have varied from a few days to four years, with most satisfactory results, and

marking of the lip than I have ever seen attend union by means of the twisted suture. I prefer the simple to the twisted suture as being equally safe, more simple, and followed by less scarring of the lip, provided the case is not too complicated, nor associated with very wide fissure in the palate, nor with great projection of the intermaxillary bones. In these circumstances, the pins should be preferred.

When the fissure is single, the edges, having been pared in the usual way, could be brought together by two points of suture; the first passed deeply at the free edge, and in such a way as to compress the cut coronary artery; the other nearer the nasal angle. These sutures should be of thick well-

Fig. 709.—Double Harelip; Intermaxillary Portion fixed to Nose.

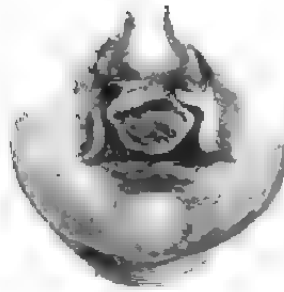

Fig. 710.—Double Harelip; Projecting Intermaxillary Portion.

fixed dentist's twist that will not cut out too readily, or, what is better, of silver wire. A point of fine interrupted suture should then be inserted through the mucous membrane inside the lip. The lip may then be supported by two narrow strips of plaster, one placed between the sutures, the other between the upper suture and the nose. On the third day the upper suture should be taken out, but the lower one may be left in for a day or two longer, when it and the one through the mucous membrane may be removed together, unless the latter have already cut its way out. If silver wire sutures be used, they may be left in for six or seven days without producing irritation. The lip must then be supported for a few days with a strip of plaster.

In the case of double harelip the same plan is to be adopted, first on one side, then on the other; but here, as the gaps are wider, and the tension, more particularly when the intermaxillary prominence is very projecting, apt to be considerable, it is necessary to support the cheeks, and thus to prevent undue traction on the stitches, by means of the check-compressor (fig. 706) or properly applied plaster. In this way all risk of the stitches cutting out before union is completed is avoided; an excellent and solid union will speedily be obtained even in cases of double harelip, with some intermaxillary projection and fissured palate.

The operation occasionally fails. The probability of the occurrence of such an untoward event is, however, greatly diminished by the use of the check-compressor. It may, however, happen either in consequence of the child's health being in an unsatisfactory state, so as to prevent union by the intention; or in consequence of the pins having been withdrawn too early, before secure cohesion has been effected. In such circumstances as these, an attempt might be made to unite the granulating edges by the re-rodution of the pins or sutures, and by firmly fixing the lip by means of the check-compressor or plaster applied as above described. Such at-

tempts, however, rarely succeed; should they not do so, it will usually be found most prudent to wait at least a month before taking any further steps, and then to pare the edges afresh and repeat the original operation.

CONGENITAL TRANSVERSE FISSURES OF THE CHEEKS.—Extending from the angle of the mouth to the anterior border of the masseter or up toward the malar bone, are occasionally met with, and have been specially described by Klein and Nicati. Their mode of origin has been already referred to (p. 614). In these malformations, which are of extremely rare occurrence, the ear on the affected side is imperfectly developed. As has been observed by Fergusson, the tragus is detached from the auricle, and is fixed to the cheek, where it forms a small lobulated appendage. The external ear generally is malformed, the helix being twisted and curled inwards. These malformations require to be treated on exactly the same principles, and with the same attention to details, as harelip; union between the pared edges being effected by means of harelip pins and the twisted suture.

CHILLOPLASTY.—Simple plastic operations are commonly practised on the lower lip for the removal of epithelioma, by cutting out a V-shaped piece of the lip, including the whole diseased structure, and then bringing together the opposite sides of the incision by harelip pins. These operations have already been described and figured at p. 554, vol. ii. We shall now consider here those cases in which it becomes necessary to repair more or less extensive loss of substance in the labial structures. The restoration of a part of the lip that has been destroyed by accident or disease, is not so readily effected as that of the nose; yet a good deal may be done to remove the deformity. The plan originally introduced by Chopart consists, when it is the lower lip that is deformed, in carrying an incision each side of the diseased portion of the lip vertically downwards below the jaw, for a greater or less distance according to the amount to be removed, even if necessary as far as the hyoid bone. The diseased part of the lip is then removed by a transverse incision below it. The square flap marked out by the two vertical incisions is then detached from above downwards. It is then brought up, and fixed to the pared edges of the remaining portion of the lip by point-suture; the head being kept properly inclined, in order to prevent undue tension. After sufficient union has taken place to preserve the vitality

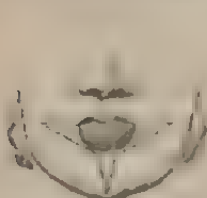

Fig. 711.—Lines of Incision in Cheloplasty.

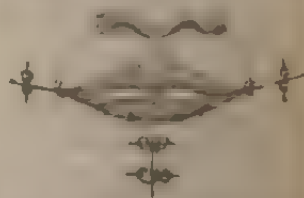

Fig. 712.—Incisions and Sutures in Cheloplasty.

the flap, its lower attachment may be divided. This operation is not usually very satisfactory in its results, as the new flap is apt to become everted and inverted at the edge, or the flow of saliva may interfere with proper union. In those cases in which the greater portion of the lower lip has been excised for cancerous disease affecting its upper margin, another process for the restoration of the deformity consists in a modification of the one recommended by Serres; and from this I have derived excellent results in the case which is here represented (Fig. 711). The object of the operation is to raise the lower lip to a level with the incisor teeth. An incision

about three-quarters of an inch in length, is made directly outwards from the angle of the mouth, on each side, into the cheek; from the extremity of this, a cut is carried obliquely downwards on to the upper margin of the lower lip, so as to excise the included triangular piece; the lower lip is then dissected away from the jaw, from the inside of the mouth, and a V-shaped piece is taken out of its centre. By means of a harelip pin on each side, and a point of suture, the incisions in the angle of the mouth are brought accurately together; and in the same way the vertical one, in the centre, is united (Fig. 712). In this way the whole of the lower lip is raised, and brought more forwards. If care have been taken in removing the cancer from the edge of the lip, to leave the mucous membrane rather long (which may always be done, when the skin is affected to a greater extent than it), a good prolabium may be formed, and the restoration effected with but little deformity.

Buchanan, of Glasgow, as far back as 1841, published an account of a method for restoring the lower lip when affected by extensive cancerous disease, which leaves most satisfactory results. The accompanying figures illustrate the kind of case in which Buchanan's operation is applicable, the lines of incision required, and the appearance presented by the chin and lip after the disease has been removed, and the flaps brought into proper apposition.

The steps of the operation are simple, and the result is excellent. The diseased part of the lower lip is first removed by an elliptical incision (Fig. 713, A B A). An incision, B C, is then carried downwards and outwards on each side of the chin; and another incision, C D, upwards and outwards parallel to, and corresponding in length to, A B. The flaps formed by these

Fig. 713.

Fig. 714.

Fig. 715.

Buchanan's Operation for the Restoration of the Lower Lip.

incisions are represented in Fig. 714. They are detached from their subjacent connections; and the whole is raised upwards, so that the curved incision, A B, comes into a horizontal line, and is made to constitute the margin of the new lip: the secondary incisions, B C, coming together in a vertical direction, in which they are retained by twisted and interrupted sutures (Fig. 715).

Syme recommended a somewhat different mode of operating. Instead of the incisions C D being made, those marked B C are carried onwards for some distance in a direction curving downwards and outwards, so that they terminated below the angles of the jaw. The flaps so formed are raised and united in the middle line, as in Buchanan's operation, the Λ -shaped portion of skin above the chin serving to maintain them in position and prevent their sliding downwards. The long curved incisions enable this to be done by merely stretching the convex edges of the flaps, without sufficiently displacing them to prevent their readily meeting the concave edges of intervening skin, and being united to them by sutures. No surface is, therefore, left to granulate, and the whole wound heals by the first intention.

In performing this operation, it is essential to success that the mesoderm should be sufficiently free, so that the flaps may be brought into position without tension. If the chin be removed as well as the lower lip, it becomes

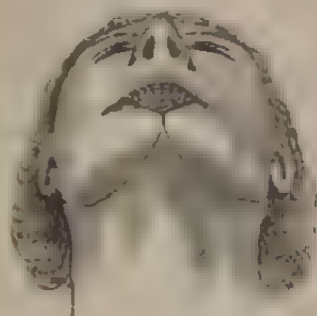

Fig. 716.—Syne's method of restoring the Lower Lip. Lines of incision.

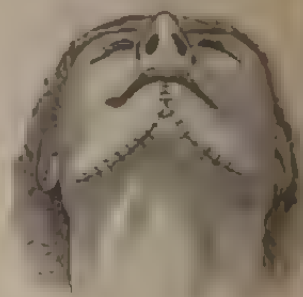

Fig. 717.—Syne's method of restoring the Lower Lip. Operation not completed.

very difficult to restore the loss, as there is no fixed point below to support the new lip, which consequently tends to sink downwards.

PLASTIC SURGERY OF THE PALATE.

Various degrees of congenital deformity may occur in the palate and uvula; thus the uvula alone may be bifid; or the cleft may extend through the greater part or the whole of the soft palate, or the hard palate may be divided well (Fig. 718); and, lastly, the separation may extend forwards to the teguments of the face, producing single or double harelip (Fig. 702). The soft palate and uvula are not unfrequently cleft without the hard palate being divided; and, in some very rare cases, the lip and the hard palate are cleft without the soft being cleft. The mode of origin of these deformities has already been described (p. 604).

These malformations necessarily give rise to great inconvenience, by interfering with deglutition, and rendering speech nasal and imperfect. In the swallowing of fluids, there is a tendency to regurgitation through the nose, though this is occasionally prevented by the approximation of the edges of the fissure in the soft palate.

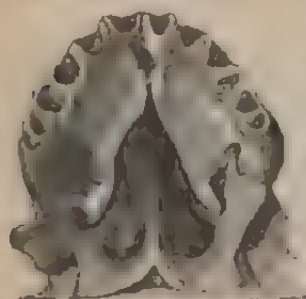

Fig. 718.—Fissure of Hard and Soft Palate.

An infant born with a cleft palate is necessarily unable to suck, and unless carefully nursed by hand will soon perish. It must be fed on milk, the mother's milk being the best, which may be drawn periodically and administered to the child. The feeding may be done by a properly constructed bottle, from which the milk will flow slowly without the necessity of sucking on the part of the child. The bottle must be fitted with an India-rubber tube which must be pushed well to the back of the

pharynx as the milk is given. In the absence of a bottle the child may very efficiently be fed by means of a teaspoon.

Until a few years ago, the operation was always deferred until the patient had attained the age to understand the necessity of remaining quiet during

the proceeding, and was able to control his movements, as success depended in a great measure upon his remaining perfectly tranquil and steady during the necessary manipulations, which are of a tedious and protracted character; and upon his assisting the Surgeon by opening his mouth, and not struggling during the introduction of instruments. Chloroform was never administered from the fear that suffocation might be caused by the blood from the operation, which is always abundant, entering the air-passages. In 1869, however, Thomas Smith, of St. Bartholomew's Hospital, demonstrated that with proper care anesthetics may be safely administered, and at the same time he invented a most ingenious gag, by means of which the patient's mouth can be kept widely open without the Surgeon being interfered with either by the hands of assistants or the instrument itself. By the help of this gag and the administration of chloroform, the operation can now be performed at any age; but as the bleeding is always very free, it is advisable not to attempt it in too young children. At the age of three it may be safely undertaken, and the advantage of having it done before the child has learned to speak is very great.

STAPHYLOGRAPHY.—The operation for the cure of a cleft in the soft palate was said to have been introduced by Roux; for although several attempts at the cure of this deformity had been made by Surgeons before his time, yet he was the first to establish **Staphyloraphy** as a distinct operation. Many modifications of Roux's plan have been practised by Von Gräfe, Warren, Dieffenbach, Liston, and others, in order to render it more easy of execution, and certain in its results, and especially by making incisions through the palate so as to take off the traction on the sutures; but to Fergusson was due the merit of introducing a new principle of treatment in the operation, viz. the application of myotomy to it, thus paralyzing the movements of the muscles of the palate. Fergusson was of opinion that the great cause of failure in these operations was the mobility of the parts, and the traction exercised by the muscles, principally the levator palati and the palato-pharyngeus on the line of union; in order to obviate this, he conceived the idea of dividing these muscles. Before Fergusson laid down the principles of this operation, it is true that various cuts had been made in the palate by different Surgeons, with the view of taking off the tension after the sutures were tied. Thus Dieffenbach, Pancoast, Liston, and Sedillot, all recommend that the tension on the stitches should be lessened by longitudinal incisions in the *pendulum palati*. Mettauer practised several small incisions for this purpose, and Mason Warren divided the anterior pillar of the fauces and the attachments of the palate to the posterior pillar, coming nearer than any previous operator to Fergusson's method. These operations, however, were done almost at hazard, and in an empirical way, without the recognition of any distinct principle being involved in them.

Operation.—The patient is placed in the recumbent position, the Surgeon standing on his right side. The gag is then inserted, and chloroform administered, or if the patient be nervous the gag may be inserted when anaesthesia is induced. The gag represented in the accompanying drawing (Fig. 719) is a modification of T. Smith's invented by Wood. It can be adjusted to fit any patient by more or less widely separating the two halves.

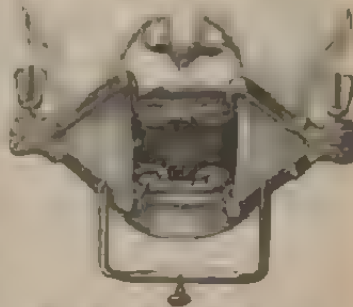

Fig. 719.—Wood's Modification of T. Smith's Gag.

In the operation as performed by Fergusson, there are four distinct steps.

1. The *muscles of the palate are divided*, by passing a curved lancet and knife through the fissure behind the velum, midway between its attachment to the hard palate and the free margin, and about half way between the velum and the end of the Eustachian tube. By cutting deeply with the point of the knife in this situation, the levator palati is divided. The arch is then seized and drawn forwards, so as to put the posterior pillar of the fauces on the stretch, which is to be snipped across, so as to divide the palato-pharyngeus. The anterior pillar, the palato-glossus, may then be notched in a similar way.
2. The next step in the operation consists in *paring the edge of the fissure from above downwards*, by means of a sharp-pointed bistoury. This is best done by seizing the lower end of the uvula, putting it on the stretch, and cutting first on one side and then on the other, leaving the size of union to be afterwards removed. A piece of ice fixed in a holder may then be applied to the wound to check the hemorrhage, while the fauces are frequently cleared of blood and mucus by means of sponges on speculum-holders.
3. When the bleeding is arrested, the Surgeon proceeds to the next step, that of *introducing the sutures*. The best material for these is in most cases, fine silver wire or silkworm gut. Catgut is absorbed too readily and is apt to yield before union is complete. Silk, which was formerly used, cannot be retained beyond a few days, as it excites too much irritation when soaked in decomposing fluids. Horse-hair will be found useful in opening the uvula, but is not strong enough for the other parts of the palate. Wire sutures are usually introduced by a tubular needle specially constructed for the purpose, from which the wire is protruded by a small wheel at the lower end. In the absence of this apparatus they may be very readily passed as follows: a common mayus needle is threaded with a loop of fine silk; this is passed through the right side of the cleft and drawn out at the mouth. A similar loop is then passed on the left side. The right loop is then passed through the left, which is withdrawn, carrying the first loop with it through the right side of the palate. There is thus a double ligature passed across the cleft having two free ends on the right side and a loop on the left. A fine hook is then made with a pair of dissecting forceps on a piece of wire; this is hooked into the loop, which is then withdrawn, carrying the wire with it across the cleft. This proceeding, though it seems rather complicated in its written description, can be carried out with great ease and rapidity, and the needle being passed on both sides from before backwards, the sutures can be inserted more accurately and evenly than when on one side it is passed from behind. In tying the knots, great care should be taken that no undue traction be exercised upon the parts; in fact, the use of the suture is not to draw, but simply to *hold* the parts together; the division of the muscles has caused these to be relaxed, so that they hang down loosely, and merely require to be held in apposition by the sutures. The patient may next be put to bed, and every care taken to avoid any movement of the palate. He should be restricted to fluid but nourishing food for a few days, and should be directed to swallow this with as little effort as possible, and indeed should not be allowed anything solid until complete union has taken place. Spitting must be strictly forbidden until union is complete. The stitches should be left in for several days; and, indeed, not be disturbed long as they produce no irritation. They usually require removal by the eighth or tenth day, but occasionally may be left with advantage for a time longer; they should then be cut across with scissors and drawn out, the upper one first, the middle next, and the lower one last. Should there be any aperture left in the palate, where union has not taken place, this is

be closed by touching it with a point of nitrate of silver, or the thermocautery.

The voice in these cases does not usually recover its natural tone after the operation, although in some cases it may. The nasal or "Punch-like" voice that is often left after operations, appears to arise from two causes. The first is the mere habit of faulty articulation, and this can be corrected by careful instruction in elocution. The second, which is much more difficult to deal with, arises from a mechanical condition, and is dependent on the contraction upwards of the palate along the line of the cicatrix, so that the velum becomes unable to shut off the posterior nares from the pharynx. Mason has proposed to remedy this condition by dividing the soft palate perpendicularly on each side, so as to leave a square and mobile central flap.

In dividing the levator palati, Pollock adopts a different practice from that of Fergusson. Instead of cutting from behind, he passes a ligature through the curtain of the soft palate so as to control it and draw it forwards; then, pushing a narrow-bladed knife through the soft palate to the inner side of the hamular process, he readily divides the muscular fibres by raising the handle and depressing the point. This method of dividing the levator palati, which is analogous to the plan employed and depicted by Sédillot (Figs. 720, 721, 722), appears to be more simple and easy of execu-

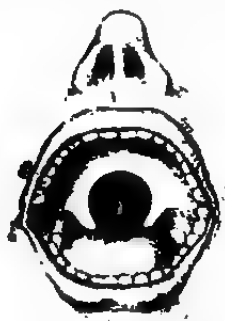

Fig. 720.

Fig. 721.

Fig. 722.

Sédillot's Operation for Staphyloraphy.

tion than the division of the muscles of the velum from behind. The gap that is left closes without difficulty by granulation, and seems still more to take off tension from the parts.

In some cases in which the cleft is limited to the soft palate, which is however otherwise well developed, so that during attempted deglutition with the mouth open the two sides of the fissure meet to a considerable extent, division of the muscles may be dispensed with, and two deep sutures of thicker wire introduced to relieve the strain on the finer stitches. The deep stitches may be removed on the fourth or fifth day.

URANOPLASTY.—Fissures of the Hard Palate are usually closed by means of "obturators" made of gold, vulcanite, or ivory. To Warren, of Boston, is undoubtedly due the merit of having been the first to close these fissures by a surgical operation. The operation was first brought before the Profession in this country by Avery and subsequently by Pollock, who have invented some very ingenious instruments for its proper performance. Warren operated by dissecting the soft tissues from the palatal arch between the

margin of the cleft and the edge of the gum, and then uniting them in the middle line by means of stitches in the same way as in fissured soft palate.

If the arch of the palate be very high, there may be sufficient tissue to meet in the middle line when separated from the bone and allowed to hang down, but it is better not to trust to this, but to make a free incision on each side. The operation is performed in the following way in a case of complete cleft of the hard palate. An incision is made from near the canine tooth parallel to the alveolar margin and about a third of an inch, or less, internal to it, reaching backwards to a little beyond the last molar. A second incision is then made along the edge of the cleft at the junction of the nasal and palatal mucous membranes. This incision must be carried backwards into the soft palate, from which a strip of mucous membrane must be removed, as in the operation for closure of clefts, implicating that part only. The soft structures covering the hard palate are then raised from the bones with a curved periosteal elevator, shaped somewhat like an aneurism needle. In fact, if the proper instrument be not at hand, a strong aneurism needle will answer the purpose admirably. The periosteum should be raised with the flap as completely as possible. Langenbeek pointed out, that if this be done, not only are the flaps thicker and stronger, but they may eventually throw out bone, and thus more efficiently close the gap in the hard palate. In raising the flaps, care must be taken to avoid those points anteriorly and, if possible, posteriorly, where the bloodvessels and nerves enter. Another point of equal importance, as pointed out by Thomas Smith, is to separate the attachment of the soft palate to the hard with a sharp instrument—either a pair of scissors or a knife, bent at a convenient angle. If an attempt be made to tear this through with the elevator, the parts will be so bruised that union by first intention will not take place even if sloughing be avoided. When these structures have been well loosened on each side, the covering of the palate will be found to hang down as a curtain from the vault of the mouth—the two parts coming into apposition along the mesial line, or possibly overlapping. The edges are then brought into apposition by means of wire sutures introduced as before described and without any dragging. On this point great care is necessary. In cases in which the flaps do not meet readily, one or more deep sutures of thicker wire may be inserted further from the edges, so as to relieve the strain on the finer stitches; or, if necessary, the lateral incisions may be continued back some way into the soft palate. The hemorrhage during the operation is usually rather free, but may be arrested by a few minutes' pressure on the bleeding point with a piece of dry sponge. The patient is confined to bed for several days, and allowed an abundant, but fluid or pulpy diet. Union, if it take place, will usually be found to be perfect at the end of a week. The wire sutures need not be removed for a month or six weeks. In fact, it is much safer to retain them until healing is complete, not only in the middle line but in the two lateral wounds as well, otherwise the contractions of the granulations as healing takes place may tear open the young cicatrix in the middle line.

Secondary hemorrhage of a somewhat serious character has been known to occur after this operation. In one case of this kind, Howard Marsh successfully arrested the bleeding by plugging the posterior palatine canal with a piece of wood.

Sir William Fergusson suggested a modification of the operation, in which an incision was made on each side of the fissure, and the bone divided longitudinally with a chisel, the two edges being then forced into contact. Although in his own hands some satisfactory results were obtained by this method, further experience has led to the abandonment of this operation as

being in no way superior to that already described, and being somewhat liable to be followed by necrosis of the divided bone.

It was formerly advised by some Surgeons, not to undertake the closure of the hard and soft palate at the same time, but it is now generally recognized that nothing is gained by dividing the operation into two parts.

Success will very much depend on the proper selection of cases. Fergusson considered that about one-half of the fissures of the hard palate admit of successful operation. If the cleft be very wide, a well-constructed obturator will probably give more relief to the patient than any operative procedure. In fact, at the present time, Dental Surgeons have brought the obturators for cleft palate to such perfection that it is a question whether any adult who is in a position to pay the necessarily heavy cost of such an instrument, should be advised to submit to operative interference.

PERFORATION OF THE HARD PALATE.—Perforations of the hard palate, consequent on necrosis of the bones, the result of syphilis or injury, are not amenable to surgical treatment. In such cases, a well-fitting obturator will most effectually remedy the inconvenience.

CHAPTER LVIII.

DISEASES OF THE MOUTH AND THROAT.

DISEASES OF THE TONGUE.

TONGUE-TIE.—Infants and even adults are said to be *tongue-tied*, when the frenum linguae is shorter than usual, causing the end of the tongue to be slightly bifid, depressed, and fixed, so that it cannot be protruded beyond the incisors. If this malformation be considerable, suckling and distinct articulation may be interfered with; and then division of the fold becomes necessary, which may readily be done by snipping it across with a pair of round-ended scissors. In this operation, the risk of wounding the ranine arteries, that is sometimes spoken of, may be avoided by keeping the point of the scissors downwards towards the floor of the mouth.

HYPERTROPHY AND PROLAPUS OF THE TONGUE OR MACRO-GLOSSIA is occasionally met with, either as a congenital or acquired condition. Of 113 cases collected by A. E. Barker, in only 39 was it apparently acquired, and in most of these it appeared at a very early age. In this condition, the tongue lolls out of the mouth with constant dribbling of saliva, is greatly swollen, of a purplish color, but somewhat dry. If the swelling have existed for a long time, it may give rise to deformity of the teeth, and of the alveolus of the lower jaw, which is pushed forwards. The protruded tongue is liable to attacks of subacute inflammation, which lead to its still further increasing in size. The *Pathology* of this condition was first clearly pointed out by Virchow. There is a great overgrowth of the interstitial connective tissue of the tongue, and in this tissue are found dilated lymphatic vessels of considerable size, and spaces filled with lymphoid cells. It presents, therefore, a close analogy to elephantiasis. In many cases the dilated lymphatics form so important an element in the new tissue, that the disease has been termed

by some writers "lymphangioma of the tongue." In the *Treatment* of this disease pressure has been attempted by strapping the protruding part but without benefit. Excision of a portion of the tongue by the *scalp* scissors, or *ectraseur* is the only efficient remedy for the disease. In some

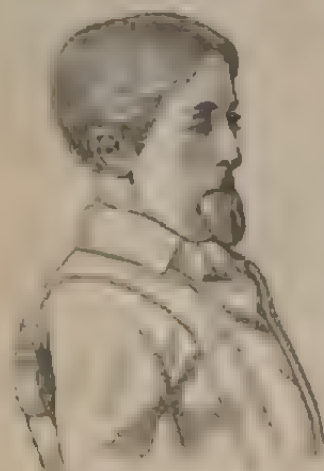

Fig. 723.—Hypertrophy and Protrusion of Tongue in a boy.

cases the removal of a V-shaped piece will give the best result. This operation was successfully performed by C. Heath in the case from which the accompanying illustration was taken (Fig. 723).

INFLAMMATION OF THE TONGUE. GLOSSITIS, is not a common affection. Its most common form is that which arises from immoderate and injudicious administration of mercury. In this the tongue becomes greatly swollen; it may hang from the mouth, and profuse discharge of saliva and inability on the part of the patient to swallow or speak, and perhaps a threatening of suffocation. The sides are marked by deep impressions of the teeth, in which after a time foul ulcers may form. Acute glossitis with great swelling of the organ occasionally occurs after fever, and more rarely without any apparent exciting cause. In this form there is great pain with considerable fibrillar disturbance. The tongue swells rapidly, so that in a few hours it may reach such a size as to threaten

suffocation. The dyspnoea may be due to the obstruction caused by the swollen tongue, or to extension of the oedema to the arytenoid and folds of mucous membrane. The inflammation may end in resolution or it may rapidly to the formation of pus. The *Treatment* of glossitis varies with the cause and the degree of swelling. If of mercurial origin, the removal of the cause, and the administration of saline purgatives and a chlorate of potash gargle, will usually arrest the progress of the inflammation. If the swelling be very great, more especially in the idiopathic form of the disease the only efficient treatment consists in making a long and free incision on the dorsum of the tongue on each side of the raphe, which gives forth an immediate relief by the escape of blood and infiltrated fluids. I have seen a patient, who was nearly suffocated by the immense size of his tongue, relieved at once by such incisions, and nearly well in the course of a few hours afterwards.

ABSCESS OF THE TONGUE, though rare, occasionally occurs. I have seen several instances of it. The abscess forms a small, deeply seated, elastic, but firm tumor, which sometimes feels slightly movable, and presents no superficial discoloration. There is no discoloration or other change in the mucous membrane or epithelium of the tongue. The walls of these abscesses are very thick and dense; hence the disease may unless care be taken be easily mistaken for solid tumors. The abscess is always very chronic, and the liability to error in diagnosis is increased. It is commonly seated at the edge and towards the anterior part of the tongue, but it may occur in the middle of the tongue. A boy was once brought to me with an elastic tumor of slow growth, and of about the size of a small plum, situated deeply in the centre of the tongue; on puncturing it, about half an ounce of thick pus was let out, after which the cyst speedily closed. The *Treatment* consists in making a longitudinal incision into the abscess. In all cases of doubt in diagnosis, this should be done before any other operation is undertaken.

CHRONIC SUPERFICIAL GLOSSITIS—PSORIASIS OR ICHTHYOSIS OF THE TONGUE—LEUCOPLAKIA.—Under these names a diseased condition of the tongue has been described which is far from uncommon in this country and in France, but it is said to be much less frequent in Germany. The disease consists essentially of a chronic inflammation of the mucous membrane of the tongue. In the earliest stages there is hyperemia of the papillae, with some swelling. If seen at this period the mucous membrane presents red patches, usually limited to the dorsum of the tongue, but occasionally appearing simultaneously on the cheeks, and passing through the same stages there as on the tongue. It can be recognized clearly only after the mucous membrane has been thoroughly dried with a towel. This must never be omitted, for unless the surface is well dried it is impossible to observe accurately the condition of the papillae and epithelium. As the disease advances, an excessive growth of epithelium takes place over the swollen papillae. The superficial layers of cells become horny and opaque, the neighboring spots coalesce, and thus white patches of considerable size form on the mucous membrane, from which appearance the name of *leucoplakia* was suggested by Schwimmer for the disease. As the disease advances, microscopic examination shows that the papillae and the superficial parts of the corium present the ordinary signs of chronic inflammation, the vessels are dilated and the surrounding tissues infiltrated with small round cells. The next stage in the process is characterized by atrophy of the papillae. The opaque patches then become perfectly smooth. In this stage the surface of the tongue is somewhat indurated, having upon its surface smooth patches of a dead-white color, irregular in shape, and varying in size from that of a split pea to an inch in diameter. This condition closely resembles the appearance of psoriasis of the palms of the hands, and from this resemblance has been termed *psoriasis of the tongue*. When the disease has reached this stage, cracks, fissures, or superficial ulcers may form in the opaque patches. The ulceration takes place mostly by an exaggeration of the process already described. At some point, possibly as the result of injury, the small round cells become increased in number by migration from the vessels, the epithelium becomes loosened and is rubbed off by the movements of the tongue, and a raw surface is thus left, from which ulceration may gradually extend. A more serious result is the supervention of epithelioma, which is a common termination of the disease. Microscopic examination of a tongue in which this is taking place may show all the stages of the disease in one section: at the margin of the patch will be enlarged papillae covered with a thick layer of epithelium; nearer the centre the papillae have disappeared, the corium being covered by a thick layer of epithelium, the greater part of which is composed of flattened horny scales; near the centre the cells of the rete mucosum are seen to be growing actively and forming columns which force their way into the spaces of the submucous tissue, and further on, amongst the muscular fibres. These columns are surrounded by the zone of small cell-infiltration always seen at the edge of a growing cancer.

Various modifications of the process above described may be met with; thus, in some cases the growth of epithelium is less abundant, so that instead of the formation of white patches, the surface of the tongue becomes smooth, red, and shining, giving rise to the condition known as the "*glazed red tongue*." In other cases the growth of epithelium may be very excessive, forming thick scaly masses on the surface, from which this variety has been termed *ichthyosis of the tongue*. These forms, though differing in detail, are essentially the same pathologically.

All forms of the disease are accompanied by some discomfort, though usually no actual pain. The tongue is tender, so that the patient cannot

take mustard, or spices or drink hot fluids. The speech may become slightly lisping or indistinct. The duration is very indefinite. In some cases it progresses slowly for many years, at last becoming stationary and causing little patient but little inconvenience. In others ulceration may take place after a few years. The invasion of epithelioma may occur after ten or even twenty years, and in many cases the patient escapes altogether. The causes of this disease are not always to be clearly ascertained. The earlier writers believed it to be invariably an effect of syphilis, but there seems no doubt that the view cannot be maintained. A. E. Barker has paid great attention to the subject, and to his valuable article on the "Diseases of the Tongue" in *Holmes's System of Surgery* I would refer the reader for more detailed information than can be given here. He has collected from various sources 110 cases of chronic superficial glossitis. Of these, 101 occurred in males and 9 in females. Of the 101 cases in males, 56 affected the tongue only, 33 the tongue and cheeks; 12 the lips and cheeks; 1 the hard palate, and in 4 the seat was not mentioned. Of the 110 patients, 33 had certainly had syphilis, and 19 certainly had not; in the remaining cases it was doubtful. The fact that nearly one-third of the patients had suffered from syphilis would suggest that, though not the sole cause, it may form an important element in the production of the disease. The disease was associated with psoriasis and eczema in 6 of Barker's cases, and with syphilitic psoriasis in 2. It has also been seen associated with ichthyosis of the skin. In 75 cases evidence was given as to smoking. Only 4 patients did not smoke, while 46 are said to have indulged in the habit to excess. Smoking may, therefore, be fairly considered to exert some influence on the occurrence of the disease. Chronic dyspepsia and habitual spirit-drinking are also supposed to act as predisposing causes. That dyspepsia should take a part in its causation is not surprising, as it is well known to every smoker that the tongue becomes sore more readily when "the stomach is out of order."

The *Prognosis* is always bad as to cure. Of the 110 cases recorded by Barker the disease ended in epithelioma in 43. The average duration of the disease before this took place was 14 years. Such cases must be carefully watched for the earlier signs of the invasion of epithelioma, as by early removal only can the patient be saved.

The *Treatment* is not usually very satisfactory. If there is any evidence of syphilis the patient must be treated for that disease. Smoking, the use of spirits, and hot condiments must be prohibited. Locally, before ulceration has taken place, Barker recommends frequent washing of the mouth with a solution of bicarbonate of soda (gr. xx to ʒj). The application of strong caustics to the diseased surface does nothing but harm. If simple ulceration has taken place, a solution of bichloride of mercury (gr. ij to ʒj) applied to the diseased tongue with a camel's hair pencil twice a day will often be found extremely useful. Its chief value is as an antiseptic, as the surface of the ulcer is apt to become very foul.

OTHER SUPERFICIAL AFFECTIONS OF THE TONGUE.—Various other superficial affections of the tongue are commonly met with. The small tender whitish patches or *aphthæ* met with so commonly as the result of dyspepsia and thrush belong rather to medicine than to surgery, and need not be described here. A peculiar wandering rash which has been described under the name of "*lichenoid of the tongue*" by Gubler, has been called attention to by Barker in this country, who suggested for it the name of "*annular migrans*." It is characterized by the appearance on the tongue of annular, circlets or crescentic bands of light-colored rash, which rapidly spread centrifugally over the tongue. It causes some salivation and itching. It is not

apparently due to the presence of a parasite. The disease runs a chronic course, and no treatment seems to have any effect upon it.

Simple Ulceration is not uncommonly met with upon the side of the tongue usually opposite to the molar teeth, most commonly dependent on irritation of sharp projecting stumps. These ulcers cause considerable pain in eating and speaking; they are red on the surface, with slightly raised but not everted edges, and the base is free from induration. They are thus easily distinguished from epithelioma. They readily heal if the offending tooth is filled, stopped, or removed.

Tubercular Ulcer of the Tongue.—Tubercular ulceration of the tongue was first noticed by Portal, and has been since accurately described by Raynaud and Nedopil and others. It is not common, but occurs with sufficient frequency to justify a description here. It commences as a minute white spot, over which the mucous membrane gives way and a small quantity of puriform matter escapes, leaving an excavation which gradually extends. Similar spots appear round about, and the sores thus formed may coalesce, forming a larger irregular ulcer with a yellowish, uneven surface, and slightly indurated base. They occur usually at the anterior part of the tongue at the edges or on the under surface, very rarely on the dorsum. It is extremely painful. These ulcers commonly appear in advanced pulmonary phthisis, but may occur before the lung symptoms become marked. Nedopil has microscopically demonstrated the presence of tubercle in these sores. In a case under the care of Godlee, the tubercle bacillus was detected in the base of the ulcer. In another, recorded by Boyd, it was not found. The treatment consists in the application of morphia and glycerine to relieve the pain. If the patient is in a state to stand an operation, the sore may be scraped with a sharp spoon and dressed with iodoform, or the whole sore may be dissected out. Some efficient treatment may become necessary to relieve the pain, which may be so great as almost to prevent the patient feeding.

SYPHILITIC AFFECTIONS OF THE TONGUE.—The following are the chief syphilitic affections met with in the tongue: *primary sores* (vol. i. p. 1045), these are very rare and present nothing peculiar; in the early secondary stage *popules* are not uncommon; later on *small superficial ulcers* may occur; and later still *fissures* with thickened epithelium around them may be met with; *mucous tubercles* are more rare. In the tertiary stage the patient may suffer from *fissures* and superficial ulcers similar to those already mentioned, from *chronic superficial glossitis* with leucoplakia, from *diffuse induration* of the organ, and from *gummata*. These have already been described in the chapter on Syphilis (vol. i. p. 1066), and the gummata alone need be further referred to here.

Syphilitic Gummata are not uncommon in the tongue. A gumma forms an irregular indurated mass imperfectly circumscribed, and of rounded shape situated deeply in the substance of the organ. It may occur at any part of the tongue, but it is perhaps most frequently situated near the dorsum, sometimes in the middle line, a situation in which epithelioma is very rarely found. It commences distinctly beneath the surface, the mucous membrane covering it being at first unaltered. As it approaches the surface the mucous membrane becomes adherent to it, and dusky red in color. Under proper treatment the growth may disappear, but frequently it softens; the mucous membrane over it then gives way and a ragged cavity is exposed, in which the remains of the gumma are seen as an adherent slough, resembling wet wash-leather in appearance. If the gumma is watched from the beginning, and presents the typical course and appearances above described, there can be little difficulty in its diagnosis. If, however, it be seen for the first time after the

characteristic slough has separated, the foul cavity that is left may always resemble an epithelioma. If there is great doubt, a piece of the floor of the ulcer may be removed and examined microscopically, when the true nature of the disease can usually be determined.

The *Treatment* consists in the administration of large doses of iodized potassium, and if that produces no effect mercury may be given. If the gumma softens and ulcerates, the same constitutional treatment must be continued and the sore dressed with iodoform.

TUMORS OF THE TONGUE. Papillomata.—Small warts are sometimes formed on the tongue and are easily removed with scissors. Warty growths of larger size are occasionally met with composed of large papillae covering the end or side of the tongue. These must always be regarded with suspicion, for epithelioma may assume this form, or if the growth is at first simple it tends soon to become malignant.

Nævus and Aneurism by Anastomosis are but rarely seen in the tongue and when met with would require to be treated on the same principles that guide us in the management of the disease elsewhere. A very remarkable instance of an erectile tumor of nevus character affecting the tongue came under my care, in which the whole of the free extremity of the organ was implicated in the morbid growth, presenting a club-shaped end, which protruded between the teeth and lips of the patient, a girl about three years of age.

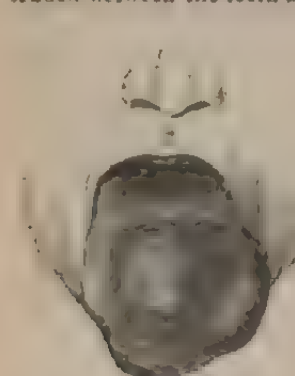

Fig. 724. Vascular Hypertrophy of Tongue.

In these cases Image, of Bury St. Edmunds had very judiciously arrested the activity of the disease, and had produced consolidation of the mass, by the introduction of oceras, which were worn for some months, and when the child subsequently came under my care, the chief inconvenience that existed resulted from interference with speech, and the deformity occasioned by the hypertrophied and elongated organ (Fig. 434). By means of the ceraseur I removed all the redundant tissues, and so reduced the tongue to its normal length and breadth.

A form of very vascular local hypertrophy may occur in the tongue at a later period of life, which may perhaps be best classed with these growths. The case of which Fig. 724 is a good representation was of this kind. It

occurred in a lady about 50 years of age, and persisted strongly. The disease was confined to the anterior half of the tongue, which I successfully removed with the ceraseur.

Cystic Tumors of the Tongue.—Two forms of cyst have been met with in the tongue, *hydatids*, which are extremely rare, and *mucous cysts*.

Mucous cysts seldom reach any large size. They lie immediately beneath the mucous membrane, usually on the dorsum or at one side. They may be so tense as to resemble solid growths. Chronic abscesses which are occasionally found in the tongue cannot with certainty be distinguished from mucous cysts till the fluid has been let out by a puncture. The *treatment* of a mucous cyst consists in dissecting it out if possible. If this cannot be done it will usually suffice to puncture the cyst and apply a strong solution of chloride of zinc to the interior.

Fibrous Tumors have been met with in the tongue, but are extremely rare. Should such a growth be met with, it may readily be removed by drawing the tongue forwards by means of a hook or piece of whipcord.

passed through its tip, and then dissecting it out. Any bleeding that occurs may be arrested by ligature, or by passing a suture by means of a curved or corkscrew needle across the gap in the course of the divided vessels, and thus closing the aperture at the same time that the vessels are compressed.

CANCER OF THE TONGUE.—**Epithelioma** is the form of cancer met with in the tongue. **Scirrhus** was formerly described as being common, and we are not now in a position to deny that it may occur, especially if the growth commences in the floor of the mouth, and arises possibly from the sublingual gland. It is however so rare, that it need not be further considered in describing cancer of the tongue.

Epithelioma almost always commences on the edge, usually at the middle third, extending back to the anterior pillar of the fauces, but it may occur at the tip of the tongue, in the floor of the mouth, or, in rare cases, on the dorsum. It most usually occurs in individuals between the ages of 40 and 60. It is more frequent in men than in women; according to Barker, in the proportion of 247 to 46. It may develop without any evident cause in persons who are otherwise perfectly healthy, whose teeth are sound, and in whom there has been no preëxisting disease of the tongue; but most commonly it occurs in consequence of local irritation, as from the abrasion produced by a broken tooth. In other cases, as before pointed out, it is preceded for some years by psoriasis or other chronic disease of the mucous membrane (p. 621). It may arise in an old syphilitic crack or unhealed fissure. If it appear in an otherwise healthy tongue, as a tubercle or warty growth, this is usually flat, indurated, and of a purplish-red color, gradually running into ulceration; if as a fissure, this from the commencement has an indurated base, a foul surface, and a callous edge. As the ulceration extends, a chasm with everted edges and ragged sides, and a sloughy surface that cannot be cleansed, gradually forms over a widely indurated base; there are great fetor of the breath, and profuse salivation; and, as the disease progresses, implication of the mucous membrane and of the structures of the floor of the mouth, and of the glands under the jaw and in the neck, takes place. Sometimes the whole mass of the organ is infiltrated by the cancerous growth, becoming generally hard, nodulated, ulcerated, and in some parts covered by thin red cicatrices, and in others by foul putty-like accumulations of epithelium. The pain is very severe in most cases; every movement of the organ in articulation, mastication, or deglutition causes great suffering. The friction or compression by neighboring teeth, the profuse salivation, all aggravate the patient's distress in this most agonizing disease. The pain is not confined to the tongue, but runs through all the branches of the fifth nerve over the side and crown of the head, to the face and the ear. The lymphatic glands under the jaw usually become involved at an early period; though the disease may exist for a year or two without their becoming implicated. Cachexy at last supervenes, and the patient dies from the conjoined effects of exhaustion, irritation, starvation, and poisoning of the system.

There are three conditions in cancer of the tongue that are of serious import, and that may, singly or in conjunction, lead to a fatal termination. 1. The pain not only wears out the patient by depriving him of rest and comfort in life, but, being greatly aggravated by mastication and deglutition, causes him to avoid these acts, and hence leads to a process of gradual starvation, either by his abstaining from food altogether, or taking a liquid and innutritious diet, because it is more easily swallowed than solid and more substantial meat. 2. The profuse salivation tends still further to exhaust the patient; and 3. The occurrence of hemorrhage, when the disease has crept so deeply as to open up one of the larger branches or trunk of the lingual artery, may, by repeated recurrence or by sudden gush, destroy life.

If cancer of the tongue be allowed to run its natural course unimpeded by operation, nothing can exceed the misery of the patient's death brought about as it is by pain, starvation, and hemorrhage. When the patient dies by recurrence of the disease after removal, he has probably obtained some months of immunity from suffering. The fatal termination usually takes place from recurrence in the glands of the neck, secondary growths in the viscera being rare, as in epithelioma of other parts. The enlarged cervical glands gradually reach the skin, soften, and break down, leaving fistulous tracts, and the patient gradually dies exhausted from pain, and poisoned by the absorption of the decomposing discharges. Sometimes the enlarged glands push into the pharynx, obstructing both deglutition and respiration. Such, as a rule, if recurrence in the mouth can be avoided, the mode of death is far easier than when directly due to the primary disease in the tongue.

Diagnosis.—The diagnosis of epithelioma of the tongue in its advanced stages is usually easy enough; the deep foul ulcer on one side of the tongue, the pain, the fixity of the organ and the enlargement of the lymphatic glands make the nature of the disease unmistakable. At this period, however, little can be done to cure the patient or even to relieve him. To be of any service to the patient, the diagnosis must be made early, while the disease is still localized, and an operation can be undertaken with some prospect of giving lasting or permanent relief. *Syphilitic ulceration*, with an indurated base, commonly closely resembles cancer of the tongue; so closely indeed, that it is only with great difficulty that the diagnosis can be effected. This, however, may generally be accomplished by observing that the syphilitic ulcer is elongated, irregular, does not rapidly extend, and is associated with other evidences of constitutional syphilis, while the cancerous ulcer is of a more circular shape, has hard and everted edges, is more painful, and spreads with greater rapidity. The influence also of treatment will at a time throw light upon the nature of the disease.

The diagnosis between the *syphilitic gumma* and *cancer* is most important; here the duration of the disease and the coexistence of constitutional syphilis must be taken into account. It is also of much moment to attend to the situation of the tumor; the syphilitic gumma being almost invariably met with deeply in the substance of the organ, whilst the cancerous growth is commonly seated at its edges or tip. It must, however, be remembered that a tongue which has long been the seat of those morbid changes in the way of thickening of its epithelium and ulceration of its mucous membrane which are common sequelae of syphilis, may at length become affected by true epithelioma, the tongue being simultaneously affected by both diseases.

In all cases of grave doubt, it is better not to wait till the advance of the disease renders the nature of the growth evident. The removal of a small and superficial portion of the tongue is an operation so simple and so free from danger that it may be undertaken without hesitation for a distant cure upon the tongue, while if the disease be left till the glands are affected not only are the necessary operative procedures for its removal far more serious, but the hopes of giving even prolonged relief are very small.

Treatment.—In the treatment of cancer of the tongue, medicine is utterly useless, except as palliatives of pain. No measures hold out any chance of cure, or even of prolongation of life, except the complete removal of the diseased structures, and this it is by no means easy to accomplish as the cancerous infiltration often extends much further than at first appears, passing deeply between the muscular fasciculi and planes, into the root of the tongue. In those deep cancerous affections there is usually considerable enlargement of the glands under the jaw with infiltration of the floor of the

mouth and neighboring soft parts to such an extent as to render it impossible to excise or in any other way remove the whole of the disease.

There are two operations occasionally practised, having for their object to palliate the suffering or to retard the progress of the disease, viz., Division of the Gustatory Nerve, and Ligature of the Lingual Artery.

Division of the Sensory Nerve of the Tongue. Section of the gustatory branch of the fifth nerve was first proposed and practised by Hilton, with the view of relieving the pain of the cancerous ulcer, retarding the progress of the disease, lessening the profuse salivation, and enabling the Surgeon to apply ligatures for the removal of the cancer to a part that has been deprived of all sensibility. This operation, which Moore repeated several times, and to which he specially drew the attention of the Profession, undoubtedly accomplishes the objects for which Hilton originally proposed and practised it; more especially so far as relief of pain and diminution of salivation are concerned. And it deserves to be considered as one of the most efficient modes of relief to the suffering produced by cancer of the tongue, in all cases in which an operation for the removal of the disease is not desirable or practicable.

Division of the gustatory nerve may be done in two ways; one originally employed by Hilton, the other adopted by Moore. Both operations consist in dividing the gustatory nerve in that part of its course which extends from its emergence between the internal pterygoid muscle and the jaw to the point where it enters the tongue. Opposite to the second molar tooth, the nerve lies under the mucous membrane of the floor of the mouth. There it can be easily reached by the division of the mucous membrane covering it, when it will be found close behind the sublingual gland. It may be raised by a blunt hook, seen, and divided. It was in this situation that Hilton practised its section. The advantage of this choice of place is, that the nerve can be seen and its division thus rendered certain. The disadvantages are, that the guides to the spot are not quite certain; that the cut is apt to be obscured by hemorrhage; and that, when the disease has extended to the floor of the mouth, the operation is inapplicable. Moore consequently recommended, and in five cases practised, section of the nerve further back. The guide to it in this situation is the last molar tooth; and a line drawn from the middle of the crown of the tooth to the angle of the jaw will cross the nerve in the exact place where it should be cut. The nerve lies about half an inch from the tooth, between it and the anterior pillar of the fauces, parallel to but behind and below the bulging alveolar ridge, which can be felt in the lower jaw ascending towards the thin coronoid process. By entering the point of a knife, therefore, into the mucous membrane of the mouth, three-quarters of an inch behind and below the last molar tooth, and cutting down to the bone, the nerve must be divided. Moore advises that for this purpose a curved bistoury be used, as the projection of the alveolar ridge would protect the nerve from a straight blade. The good effect of the operation is instantaneous; pain ceases in the tongue, ear, face, and head, and the flow of saliva is greatly diminished; and the relief is continuous, for it does not appear that the nerve reunites.

Ligature of the Lingual Artery may be required to restrain profuse hemorrhage from an ulcerated cancer of the tongue. This operation has been practised also with the view of starving the morbid growth and thus retarding its development. That it does so for a short period is undoubtedly the case, but that it does so permanently is a fallacy. This operation has been recommended for these purposes by Demarquay, and has been performed in this country by Moore and C. Heath.

The lingual artery may be exposed and tied in the following manner:

The artery is reached with most certainty in the digastric triangle of the neck, where it lies beneath the hyo-glossus muscle. A curved incision carried from about one finger's breadth external to the symphysis menti downwards to the great cornu of the hyoid bone, and prolonged upwards to nearly the angle of the jaw, will expose the lower border of the submaxillary gland. In fat subjects, or when the parts are swollen, the incision must be of the full length above mentioned, but under ordinary circumstances it may be curtailed by about half an inch at each end. The first incision divides the skin, superficial fascia, and platysma, exposing the strong fascia covering the submaxillary gland. If the incision be carried too far backwards, the facial vein will be divided. The deep fascia must now be opened, and the submaxillary gland raised and drawn upwards towards the jaw. The tendon of the digastric then comes into view, and a space is exposed bounded below and externally by the curved tendon of the digastric, internally by the free edge of the mylo-hyoid, and above by the ninth nerve accompanied by a small vein. The floor of the space is formed by the part of the hyo-glossus arising from the great cornu of the hyoid bone. The fibres of the hyo-glossus must now be picked up carefully in this space, and divided horizontally, when the lingual artery will come at once into view (Fig. 725). Care must

Fig. 725.—Ligature of Lingual Artery.

be taken while exposing the artery not to cut too deeply, as it is separated from the mucous membrane of the pharynx merely by a few fibres of the middle constrictor. Sometimes the stylo-hyoid ligament comes into view; it may be recognized at once by its passing upwards and outwards, while the artery is directed upwards and inwards. Should it be seen, it may be used as a guide to the artery which passes between it and the hyo-glossus. Rare cases the artery lies with the ninth nerve superficial to the hyo-glossus, in which situation it must be sought if not found in its proper place.

OPERATIONS ON THE TONGUE.—The operations that are practised on the tongue when it is affected by cancer consist in removal of a portion of the organ only, or its complete extirpation from the hyoid bone according to the situation of the disease and the extent to which the tongue is implicated. Unless the disease can be very fully and freely extirpated, it is better not to attempt any operation, for in no organ is there a greater tendency to rec-

rence of cancer than in the tongue. When the disease extends to the floor of the mouth, implicates the arches of the palate, or has largely infiltrated the submaxillary lymphatic glands, the propriety of operating becomes very doubtful. Even under these circumstances, however, extensive operations have been performed with at least temporary benefit in some cases. In determining the question of operating, much will depend upon the condition of

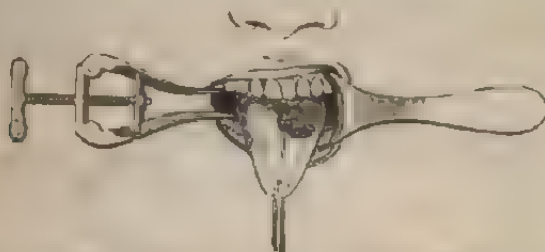

Fig. 726.--Application of Screw-gag, Check-retractor, and Whipcord, in Operations of the Tongue.

the patient. If he be otherwise in good health, though suffering greatly from the pain of the cancer, and if the secondary affection be limited to the glands below the jaw, which can be removed without difficulty, an operation may be undertaken. If he be greatly exhausted by pain and want of food, and more especially if the glands under the sterno-mastoid are enlarged, an operation would at the best give very temporary relief, and would be very likely to be directly fatal.

In all operations upon the tongue, three precautions must be taken; 1, to prevent the patient from biting it; 2, to expose it thoroughly; and, 3, to keep it under control. The first object is attained by placing an efficient gag between the teeth on the side opposite to the seat of operation. The screw-gag (Fig. 726) may be used in some cases, but it is rather apt to slip. Fergusson's (Fig. 727) or Whitehead's gag (Fig. 728) will be found more efficient. Fergusson's is very difficult to keep in position when the back teeth are wanting, as it tends to slip forwards. Whitehead's gag may then be of service, but it also is uncertain if the front teeth are wanting. Efficient gagging is

Fig. 727.--Fergusson's Gag.

one of the most essential parts of all operations on the tongue, and in all cases it is better to entrust the gag to an assistant, whose sole duty shall be to see that it does not slip. The slipping of the gag and the sudden closure of the mouth at a critical point in the operation may necessitate a sudden performance of laryngotomy, or may even cost the patient his life. If the patient be efficiently gagged, the jet of blood from a divided lingual will usually be thrown out of the mouth, and cause but little trouble. If a gag be used which acts on one side only, the tongue must be fully exposed by a check-retractor (Fig. 726) applied on the opposite side. During the operation the tongue must be controlled by a strong whipcord ligature passed through it about an inch from its tip. If only a small portion of the anterior part is to be removed, a single thread will suffice. In removing half the tongue two ligatures must be passed, one on each side of the middle line,

so as to control not only the part to be removed, but the remaining parts, so that the stump may be drawn forwards at the end of the operation to arrest hemorrhage. When a portion only of the tongue is to be removed it may be done by the ligature, the cæraseur, the knife or the sensors. When extirpation of the whole organ is decided upon, the ligature is not applicable.

For the purpose of operation the tongue may be divided into three regions, viz., the anterior third, the central lateral portion, and the posterior part.

Excision of a small part of the Tongue may readily and safely be done when the free anterior portion only is diseased, or when it is only superficially affected at its side or back part. The patient having been gagged the tongue is secured by passing a thread through it. It is then drawn well

Fig. 728.—Whitehead's Gag.

forward while the lingual artery is compressed in the way recommended by C. Heath. To do this the forefinger is passed over the dorsum of the tongue till it touches the epiglottis; it is then turned towards the side on which the artery is to be compressed, and hooked forcibly upwards against the jaw. The diseased portion of the tongue is then dissected out with a scalpel or sensors, and forceps. If the artery be well compressed, the operation will be practically bloodless. On removing the pressure the hemorrhage is free, but profuse, but the larger vessels are easily ligatured, and the oozing will soon cease on the application of ice.

Strangulation of the diseased mass by means of the **Ligature** was formerly much more employed than at the present day, and is indeed now seldom adopted, on account of the pain that attends and the fear that it may be used. If, however, the surgeon be single handed or unprovided with trustworthy assistants, or if hemorrhage is much to be feared, this means may still be employed.

For the purpose of this operation strong thick saddler's whipcord is the best, as it does not readily cut through the soft and brittle tissue of the

Fig. 729.—Corkscrew needle.

organ, which will be the case if the small compressed cord usually sold by the instrument makers be used. There is little danger of hemorrhage after this operation; and the pain and subsequent discomfort are consequently much less than might be expected. The pain may be prevented by section of the gustatory nerve prior to the application of the ligature (p. 627).

The ligature is passed by means of an ordinary navvies-needle, or, what is often more convenient, a corkscrew-needle curved on the side as well as

the point (Fig. 729). In many cases, the plan described for tying flat naevi will be found the most convenient mode of passing the whipcord round the cancer of the tongue (Fig. 730). In whatever way the ligatures are applied, care should be taken to pass them through the healthy tissue of the organ wide of the disease, and they should then be tied very tightly, so as to strangle the mass effectually. This may then be cut away by scissors, so as to diminish the quantity of slough that would otherwise be left in the mouth. Swelling of the tongue, followed by rather profuse salivation and fetor of the breath attends this operation; but the mass, if properly constricted, will

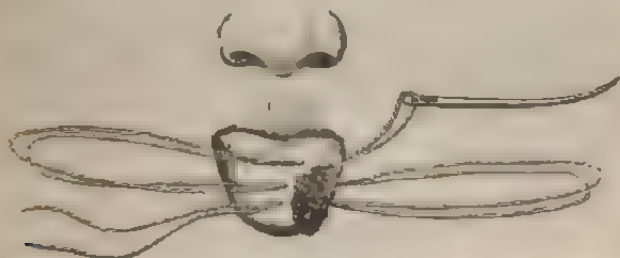

Fig. 730. - Application of Ligature to Cancer of Anterior Part of Tongue.

slough away in a few days, leaving a large gap that readily fills by granulation. When the disease extended so far back that it could not readily be reached from the mouth, Cloquet, Arnott, and others succeeded in strangling it by making an incision in the hyoid region, between the genio-hyoid muscles, carrying the ligatures by means of long needles through the base of the tongue, and then drawing them tight through the aperture in the neck, so as to constrict the diseased mass. This method of operating was rarely successful and has long been abandoned.

Excision of the Whole or of a Large Portion of the Tongue.—This operation may be performed in four ways. 1. From the inside of the mouth, without any external incisions. 2. By the submental method, through the mylo-hyoid space. 3. By the buccal method, a free incision being made through the cheek; and 4. By division of the lower lip and jaw.

The excision of the whole tongue *from the interior of the mouth* is most easily performed by means of the *ceraseur*, and it is to the introduction of this instrument into surgical practice by Chassaignac that we owe to a great extent the advances made in this operation during the last thirty years. There are many methods by which this operation may be performed, the difference in the minor details being dependent on the extent and situation of the cancer, and the amount of tongue that consequently requires extirpation. The following plan is that most usually adopted, and will be found effectual and safe in the vast majority of cases.

The gag having been applied, the end of the tongue should be secured with a piece of whipcord and well drawn forwards and upwards. The Surgeon then cuts across the *frenum* by means of strong curved scissors, and divides successively the insertions of the genio-hyoid and genio-hyo-glossal muscles into the lower jaw, cutting freely backwards so as to liberate the base of the tongue. He now snips across the reflection of the mucous membrane of the floor of the mouth from the lower jaw, and then, laying aside the scissors, separates widely with his fingers the base of the tongue from these parts. As he does this the assistant, who has charge of the whipcord ligature, draws the tongue well forwards, and it comes bodily out between the lips. If the anterior pillar of the fauces offer any obstacle it

may be snipped across, and the wire of the *céraseur* may then be applied well round the back of the organ, the shaft being pressed up under the base of the tongue. If the wire have a tendency to slip forwards, a large tooth hook should be passed in front of it into the base of the tongue so as to steady it and prevent its slipping. By now working it slowly, the whole organ can be removed without hemorrhage.

Nunneley, of Leeds, devised an ingenious mode of applying the *céraseur* so as to remove portions of the tongue, or, indeed, the whole organ as far back as the hyoid bone. This operation consists in passing the chain of the *céraseur* through the centre of the mylo-hyoid space by means of a needle-shaped needle, about 4½ inches long and as broad as a bistoury blade. In this needle the chain is brought into the mouth close to the trismus. Two or three curved and strong barelip pins are now passed deeply into the tongue obliquely, behind the seat of the disease, their points being made to project forwards below the organ, so as to prevent the chain from slipping. The loop is now gradually tightened, and the tongue is cut or shaved off obliquely from behind forwards.

Two *céraseurs* were successfully used by Chassaignac in removing portions of the tongue. When the disease occupies only one side, and it is not thought

necessary to cut away the whole breadth of the organ, two instruments are required, which, as Chassaignac represents (Fig. 731), must be passed through the substance of the tongue in opposite directions, so as to reach and detach the diseased portion. The operation may, however, be performed much more rapidly and easily by splitting the tongue in the middle line by means of a knife or a pair of scissors. As Marrant Baker has especially pointed out, an incision, if made accurately in the middle line, is almost bloodless. The incision can be safely carried backwards as far as the root of the tongue, and the separation of the diseased half of the organ and the application of the *céraseur* are much facilitated by so doing.

Fig. 731. - Two *Céraseurs* applied to Cancer of Tongue.

The following points must be attended to in removing large portions of the tongue by means of the *céraseur*. The wire should be thick. If too thin, it cuts almost as readily as a knife, and the lingual arteries will certainly spout and require the ligature. The instrument should be worked very slowly, in order that time may be given for the vessels to contract. As an additional security against hemorrhage, a strong ligature should be applied behind the *céraseur* just before it finally cuts through the lingual artery.

The wire *céraseur* (Fig. 732) will be found better than the chain-instrument. The form of wire best suited to the instrument is strong piano-wire. It will be found better to attach one end only to the movable part of the instrument, the other being twisted round the handle, as in the figure. It cuts by a slow sawing movement and divides the vessels more surely. Middelorp's galvanic cautery was much used a few years ago in operation on the tongue (Fig. 733). By working this slowly, and not heating the platinum wire beyond a red heat the tongue may be removed without the loss of a drop of blood. This I have done in several cases in which the whole tongue required removal, from the inside of the mouth, without an external wound. The galvanic cautery cuts more rapidly than the ordinary

instrument, and it was at first hoped that its use would considerably simplify the operation. Experience has, however, shown that the charred surface left by the passage of the hot wire heals more slowly, with more discharge and sloughing, than that left by the *écraseur*. Secondary hemorrhage has occurred, moreover, in a considerable number of cases after its use. It was urged as another advantage attending its employment, that a charred surface offers a barrier to the absorption of septic matter, but the fallacy of this idea has been demonstrated by experimental investigations on animals.

Fig. 732.—Wire Écraseur for Removal of Tongue.

The instrument has, therefore, been abandoned almost universally, most surgeons preferring the wire *écraseur* in those cases in which the scissors or knife cannot be safely employed.

In 1877, W. Whitehead, of Manchester, successfully removed the whole tongue through the mouth with scissors, and since then the operation has been repeated in a large number of cases with excellent results. This operation is conducted as follows: The mouth is efficiently gagged, and a double

Fig. 733. Galvanic Écraseur.

ligature passed through the tip of the tongue. The assistant in charge of this is directed to maintain throughout the operation a steady traction upwards and forwards. The operator commences by dividing all the attachments of the tongue to the jaw and to the pillars of the fauces with an ordinary pair of straight scissors. The muscles attached to the base of the tongue are then cut across by a series of successive short snips of the scissors, until the entire tongue is separated in the plane of the inferior border of the lower jaw as far back as the safety of the epiglottis will permit. Any vessels requiring torsion are twisted as divided, but a moment's pressure with a small piece of sponge, held in sponge-forceps, suffices temporarily, if not permanently, to arrest any bleeding. A single loop of silk is then passed by a long needle through the remains of the glosso-epiglottidean fold of mucous membrane, as a means of drawing forwards the floor of the mouth should secondary hemorrhage take place. This may be withdrawn on the second day. The hemorrhage in this method of operating is much less than would be expected. Whitehead states that in two cases he removed the whole tongue without twisting a single vessel. Treves and others have,

however, met with very troublesome hemorrhage during the operation. In a paper read before the International Medical Congress of 1881, Whittaker recorded twenty-eight cases in which the operation had been performed, and only three deaths, two of which occurred at a remote period after the operation.

If only half the tongue is affected, it may be removed by scissors in the same way, after having been split in the middle line.

When the floor of the mouth is implicated in the disease, no operation through the mouth should be attempted, as it is impossible by this means to extirpate the whole of the disease in this situation, and partial removals will be followed only by rapid recurrence and increased activity of development. Slight enlargement of the glands under the jaw should not be a bar to the operation, provided the disease be limited, and the constitution good. If not too much enlarged, the glands may be excised at the same time with the disease of the tongue; or if they be so slightly enlarged as to be scarcely recognizable, they may be left, when they will perhaps subside without the necessity of operation, as their enlargement may perhaps be dependent upon simple irritation; should they continue indurated, they may readily be removed at a subsequent period.

Submental Operation for Excision of Tongue.—Regnault, of Paris, published, in 1838, a description of a method by which the whole tongue could be successfully removed. The plan that he proposed was as follows: An incision of a semilunar shape was made along the line of the lower jaw beginning near one angle and terminating close to the other. A perpendicular incision was carried from the centre of this line immediately under the skin to the hyoid bone (Fig. 734). In making this semilunar incision, care must

Fig. 734.—Lines of Incision in Regnault's Operation.

Fig. 735.—Tongue drawn out between Jaw and Hyoid Bone.

be taken not to wound the facial artery on either side. The track of the vessel should be protected by the finger of an assistant as it curves round the lower jaw, and the incision should be confined within the space between the two facials. The triangular flaps of skin formed in the manner above are dissected back, and the muscles and mylo-hyoid space are now exposed. These must be successively divided, the anterior bellies of the digastrics cut across, the mylo-hyoid muscle divided transversely at its anterior end, and the attachments of the genio-hyoid and genio-hyoglossi are detached.

detached from the lower jaw by a few touches of the scalpel, and by separating with the fingers the mucous membrane of the floor of the mouth. An aperture is then made into this by pushing the scalpel through it, and its reflection from the inside of the lower jaw is divided as far back as the outer angles of the external incision. The submaxillary glands are pushed aside, and the tip of the tongue being seized with a strong hook or vulsellum forceps, the organ is drawn out to its full extent on to the anterior part of the neck, between the jaw and the hyoid bone (Fig. 735), when the whole of it may be removed close to its attachments to the latter bone by means of the knife or the *écraseur*. The latter instrument is to be preferred, as its use is attended by less hemorrhage than follows that of the knife. It will occasionally be found that the anterior pillar of the fauces is somewhat in the way of the application of the instrument. Should this be inconveniently so, it may be snipped across before the wire of the *écraseur* is applied. By means of this operation, which I have several times performed, the whole of the tongue may be shaved off clean from the base of the epiglottis and hyoid bone. After the removal of the tongue the hemorrhage will usually be found to be trifling; but should one or other of the lingual arteries bleed, it may readily be seized and ligatured. The line of incision in the skin must then be stitched up, a good sized drainage-tube being inserted at the lower end of the vertical incision.

Koehler, of Berne, believing that the best hope of giving prolonged relief or possibly permanently curing the patient, lies in a complete removal in every case of the lymphatic glands below the jaw simultaneously with the diseased part of the tongue, has introduced a method of operating which in his hands has been attended by a considerable degree of success. He makes a free external incision, commencing a little below the lobule of the ear and running downwards along the anterior border of the sterno-mastoid to the level of the great cornu of the hyoid bone; from this an incision is carried forwards nearly to the body of the hyoid bone, and then upwards along the line of the anterior belly of the digastric to the jaw. The flap thus marked out is turned upwards over the face. The lingual artery is then tied before it passes beneath the hyoglossus. By a process of careful dissection, all the lymphatic glands are removed from the region exposed by the wound. In so doing the carotid sheath will be exposed, as one gland always lies upon it close to the sterno-mastoid. The facial artery and vein will be divided, and must be secured by ligature. It is usually necessary to remove the submaxillary and sublingual glands, which otherwise are somewhat in the way. Some lymphatic glands, touching the inner surface of the jaw, between it and the sublingual gland, must be sought for and removed. The mylo-hyoid muscle and the mucous membrane of the mouth are now fully exposed, and must be carefully divided, when the side of the tongue to its very root comes into view. If only one side is affected, the tongue may now be split down the middle line from the mouth, and the base cut through from the external wound. Koehler recommends a preliminary tracheotomy and plugging the pharynx during the operation. In fourteen cases operated on by himself by this method only one patient died, from secondary hemorrhage from the tracheotomy wound. In 8 recurrence of the disease took place, 1 died a year after of pneumonia, and 4 remained well at 14 months, 5, 5, and 6½ years after the operation. The operation is a bold one, and requires skill and patience in its performance, but the danger does not seem to be great, and the results are such as to encourage further attempts in the same direction.

The Buccal Operation.—Furneaux Jordan has introduced an operation which consists in dividing the cheek on the affected side backwards as far as

the ramus of the jaw, care being taken to go below the parotid duct. The tongue is then seized in the usual way, and cut off by two *cerasurs* worked simultaneously, the chain of one dividing the organ transversely close to the pillars of the fauces, that of the other severing the tissues along the floor of the mouth. I have performed this operation in one case of unilateral cancer of the tongue, and found that the organ could readily be reached, commanded, and a portion removed through a gap in the cheek. After the operation is concluded, this is closed by sutures.

Excision of Tongue after Division of the Lower Jaw.—Sedillot, of Strasburg, described, in 1855, a method of removing the whole of the tongue, which he stated that he had practised for some years with success. The operation consists in making a vertical section through the lower lip, sawing through the inferior maxilla at its symphysis, separating the bone on each side, drawing the tongue forward and removing it. In performing this operation, its inventor recommends that the section of the lower lip should

Fig. 736.—Removal of Tongue by Division of Lower Jaw and *Cerasur*.

be made carefully through the median line, and carried across the chin as far down as the hyoid bone. The lower jaw is then sawn through at its symphysis. In order to fix the bone more accurately after the operation, he recommends that, instead of making one vertical incision, two oblique cuts should be practised with the saw in this shape \triangleright , so as to form a triangle, the point of which corresponds to the middle of the body of the bone, so that the two opposite sides may be locked together after the removal of the tongue. Before sawing the bone it may be drilled on each side half an inch from the edge of the intended incision through it. After having divided the lower jaw, the muscles connecting it to the tongue should be cut across and the mucous membrane forming the floor of the mouth detached from the bone, the two sides of which are drawn asunder; and the tongue then removed from the hyoid bone by a stroke of the knife, or gradually snipped through with *scissors*. The lingual arteries bleed freely, and must be at once secured. Fildes,

of Jamaica, recommends that the artery be divided and tied, first on one side and then on the other, so as to avoid dangerous hemorrhage. The opposite sides of the jaw bone are then brought together, and held in position by wire twisted round the teeth, or passed through a hole drilled on each side before the division of the bone. If Sedillot's angular cut be adopted, the bone may be kept *in situ* much more easily than if the vertical incision to which he first of all had recourse, and which is commonly adopted in this country, be practised. The incision in the lower lip must be united in the usual way by harelip pins or sutures. This operation was first done in this country by Syme and Nunneley, and has of late years been very extensively practised by many Surgeons. By it the whole tongue can be freely exposed and cut out

from its deepest attachments. If it be preferred, the écarreur may be applied when the tongue has been fully exposed (Fig. 736).

Hemorrhage during Excision of the Tongue is the only serious danger of the operation, and so long as the mouth is thoroughly gagged even this need cause no anxiety. If only a part of the tongue is being removed, hemorrhage may be immediately arrested by drawing the tip well out of the mouth by the ligature through it and compressing the lingual against the jaw by the method already described. The pharynx must then be thoroughly cleaned with sponges on sponge-holders. When this is done the assistant relaxes his finger, and the bleeding point can usually be seized without difficulty in a pair of forceps. If the whole tongue have been removed, the stump must be hooked forward with the forefinger and seized in a pair of vulsellum forceps while the artery is compressed as before described. In tying the lingual artery, as the tissues are brittle, it is better to include some of the surrounding structure. The ligature may then be cut short. The most serious accident is when the gag slips while free hemorrhage is going on. In a case of this kind I had to perform laryngotomy, as a conglutium formed in the pharynx before the vessel could be secured. The patient made a good recovery, dying two years after the operation from the recurrence of the disease in the lung and in one of the toes.

Oozing of blood may usually be arrested by ice, or if it be more than usually free the bleeding point may be touched with Paquelin's cautery or perchloride of iron, but this should be avoided if possible, as it interferes with the healing of the wound.

If very free hemorrhage is expected, it may be advisable in some cases to perform a preliminary tracheotomy and to introduce Trendelenburg's obturator or to plug the pharynx with a sponge.

After-treatment.—The chief trouble in the after-treatment is to keep the mouth free from decomposing discharges. Various means have been tried for this, chlorinated gargles, sanitas, terebene, Condy's fluid, etc., but nothing approaches iodotannin in efficiency. It should be applied in the form of crystals not precipitated immediately after the operation. Subsequently a small quantity may be sprinkled over the raw surface daily by means of a camel's-hair pencil. The mouth may be washed at intervals after the first thirty-six hours with a weak solution of permanganate of potash. Ice may be sucked at intervals for the first few days, if it be found grateful to the patient. A tendency to dyspnoea is sometimes manifested after the operation, owing to the stump of the tongue falling backwards. This is remedied by opening the mouth and drawing the stump forwards. If it occurs frequently, a thread must be passed through the stump and retained, for a few days. If only a part of the tongue have been removed, the patient will be able to swallow fairly well after the first few hours, but if the whole organ have been taken away he must be fed by enemata, or through an India-rubber tube passed down the œsophagus, for the first three or four days. There is often trouble from profuse salivation for two or three weeks, owing to the patient being unable to swallow the viscid saliva excreted from the wounded and irritated glands. This is best controlled by alum and pyrethrum gargles.

Accidents after the Operation.—Secondary hemorrhages may occur about the fifth or sixth day, especially after the galvanic cautery. The free use of ice or a spray douche of ice-cold water may arrest it if it be slight. If free and arterial, perchloride of iron or the actual cautery may be required. If this fail, the lingual may be ligatured above the hyoid bone unless that has been already done as a preliminary step to the operation. *Septic fecer, septic*

poisoning, and septic infection are prevented by avoiding whenever possible those methods of operating which leave a sloughing surface, and by the free use of iodoform in the after-treatment. *Septic pneumonia* due to the inhalation of decomposing matter from the floor of the mouth is a common cause of death in excision of the tongue, as in cut-throat and similar injuries. It is characterized by scattered patches of broncho-pneumonia, rapidly ending in breaking down of the lung-tissue. Sometimes, apparently by extension from these centres, large areas of lung-tissue may become gangrenous. This very fatal complication is best avoided by the use of iodoform and by drainage from the floor of the mouth in cases of removal of the entire tongue. A. E. Barker suggested and successfully practised in several cases a preliminary tracheotomy. After the operation the patient was made to breathe by the tracheal opening until the mouth had become clean. The introduction of iodoform has, however, so efficiently prevented septic processes in these cases that tracheotomy is now rarely required.

Comparison of the Methods of Operating.—In instituting a comparison between the different methods of dealing with cancer of the tongue it should be understood that the same plan of treatment is not equally applicable to all cases, but that one or other should be adopted according to the size, situation, and extent of the cancerous mass. If this be small and situated at the tip, this portion of the organ may be easily and safely excised. If situated towards the side so as to require the removal of perhaps the anterior third of one side of the organ, it may be best done by splitting the tongue and excising the diseased part by the *céraseur* or scissors, and the same methods are equally applicable when half the organ has to be removed. If the posterior part be superficially affected, the disease may be cut out and the buccal operation will then, in some cases, be found to expose the part most fully. If the organ be so deeply affected that the whole requires extirpation, it can be done from the mouth by the *céraseur* or by Whitehead's method. In some cases it will be found most convenient to split the tongue and remove the halves separately. If the floor of the mouth is implicated recourse must be had to Sedillot's operation of division of the lower lip and jaw in the middle line. If it is intended to remove the glands below the jaw, Kocker's method will be found the best. Whichever method be adopted, the sublingual gland should always be removed either with the tongue or by scissors after the main part of the disease has been taken away, as there are some small lymphatic glands buried in its substance which are often an early seat of secondary infection.

Results.—The prognosis in cancer of the tongue is always bad. The unfortunate victim of this most terrible disease is almost inevitably destined sooner or later to fall a sacrifice to it. Removal of the diseased organ in part or in whole may relieve for a time, but very rarely does more than this. The more acute the cancer, the more rapid will be its recurrence, either locally or in the glands. A. E. Barker, who has most carefully investigated this point, states that out of 170 cases collected from various sources he could only find 17 in which recurrence did not take place under one year; and in the whole of medical literature he could meet with the record of only 42 cases in which the patient had remained free from recurrence for a sufficient length of time to justify the hope that he was permanently relieved of the disease. One of the most successful cases on record was operated on by C. Heath. The cancer was situated near the *frænum* adhering to the jaw, and extending upwards into the substance of the tongue. The whole anterior portion of the lower jaw and the anterior half of the tongue with the corresponding part of the floor of the mouth were removed in one piece. The

operation was performed more than ten years ago, and the patient is still alive and in good health.

The mortality directly due to the operation is considerable, but not very high.

Barker has collected 218 cases from various sources, and finds that the death-rate is 16.9 per cent. It is satisfactory, however, to note that of late years it has considerably diminished. Thus, at University College Hospital 38 cases were operated on between 1871 and 1881, of these 10 died; 20 of these operations were performed before 1877, and of these 8 died, while of the 18 since that date only 2 died. The diminished death-rate seems to be due in part at least to the more successful prevention of decomposition by the use of iodoform. The records of excision of the tongue are so far from satisfactory, that some Surgeons have doubted the propriety of performing the operation; but when we remember the terrible fate of the patient if the disease be allowed to run its course, and that cases of apparent cure, although exceptional, are not unknown, it cannot be denied that the operation is not only justifiable but advisable. The hope of improvement in the results seems to lie first in early recognition of the disease, so that it may be removed before the glands are affected; and, secondly, if this period be passed, in free removal of the diseased organ with the whole of the lymphatic glands, which receive lymph from it, if this be possible. The fact that epithelioma seldom recurs in the viscera, encourages us to attempt the removal of the affected glands whenever their situation is such that the operation can be safely undertaken.

Effect of the Removal of the Tongue on Speech.—Although distinctness of articulation is necessarily affected for a time by these operations on the tongue, yet it is usually restored when only the anterior third or half is removed; the tissue of the organ recovering its normal mobility with remarkable facility, and, indeed, appearing to possess a very considerable reparative power, and to be capable of reproduction to some extent. Even after removal of the whole of the tongue, the power of deglutition is preserved, and that of articulation, although at first somewhat imperfect, eventually returns, so that the patient is able to speak so distinctly that strangers would not be aware of the loss he had sustained. Amongst the tortures to which Christian martyrs were subjected in the early ages, and the punishments which have been inflicted on heretics, "cutting out the tongue" was one of the most barbarous. Martyrologists, in describing this horrible mutilation, have remarked with wonder, that, although it was practised with the view of depriving the sufferers of the power of speech, yet it often failed in its effect, and those who had been subjected to it were enabled to speak afterwards as plainly as before. This they have attributed to direct miraculous intervention. But, as modern Surgery has shown that the power of speech returns equally, whether a cancerous tongue have been extirpated by the knife of the Surgeon, or a heretical tongue by that of the executioner, we must look upon the return of speech rather as a physiological fact, than as a miracle specially wrought for the benefit of those mutilated in and for the propagation of the true faith.

DISEASES OF THE FLOOR OF THE MOUTH.—**Solid Tumors** are occasionally met with in this region, *Epithelioma* being the most common. *Adenoma* also in connection with the salivary glands may occur. *Naevi* also have been observed in this situation. These tumors require removal by irregular operations, varying according to the size and situation of the growth. For these proceedings no special directions can be given. In removing such tumors as these, when situated under or by the side of the tongue, the knife must necessarily be used with much caution. It must, however, be borne in

mind that, if these growths cannot be reached from the inside of the mouth, they may be got at by incision through the mylo-hyoid region, where there is but a slight thickness of soft parts between the surface and the floor of the mouth.

Cystic Tumors in the Floor of the Mouth may occur under three forms: 1, Ranula; 2, Congenital Dermoid Cyst; and, 3, Burial Cyst.

1. **Ranula.**—A globular swelling, semi-transparent, evidently containing fluid, and often attaining the size of a walnut or a pigeon's egg, may be situated under the tongue, pushing this organ upwards and backwards, and consequently interfering with deglutition and speech. Fig. 737. Treatment

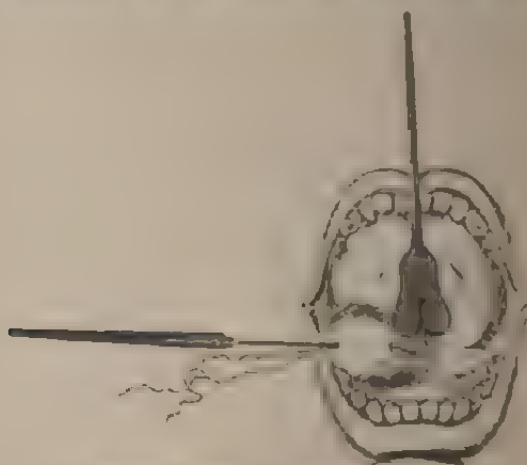

Fig. 737.—Ranula. Introduction of Seton.

of the cyst are usually thin, with small vessels ramifying on them; its contents are glairy and unlike saliva. This form of ranula is usually said to be a dilatation of Wharton's duct; but there is no proof of the disease being of this nature, nor is it very easy to understand how so small a duct can be dilated to so large a size as is occasionally attained by these tumors, which seem, in some cases at least, rather to consist of independent cystic formations, not as commonly occur in connection with other secreting glands, and in other parts of the mouth. And this view of the case is strengthened by the fact that these globular cystic tumors containing glairy fluid may occur under the substance of the tongue itself, far away from any salivary duct.

Morrant Baker, who has investigated the connection between ranula and the Whartonian duct, finds that, in cases of ranula, Wharton's duct is quite free, without any alteration in size, and that saliva may be seen issuing from it. A probe passed into the duct is separated from the ranula by a thin membranous wall, showing clearly that the duct and the ranula do not communicate. I have, however, lately seen a case in which a ranula resulted from a wound of the floor of the mouth, in the situation of the Whartonian duct. The wound was caused by the accidental slipping of a pair of extraction forceps during extraction of the first molar tooth. As the wound healed a ranula formed, the contents of which were thick andropy, like the natural secretion of the submaxillary gland. It ultimately reached the size of a pigeon's egg. That this tumor was formed by an accumulation of the secretion of the submaxillary gland, there can be no doubt; but it is quite possible

ble that the collection formed in the submucous tissue, and that it was not enclosed in an actual dilatation of the Whartonian duct.

The *Treatment* of this form of ranula consists either in passing a seton through its walls, so that contraction may take place on this (Fig. 737.; or else in the excision of a large portion of the anterior wall of the cyst, the remainder contracting, until it at last becomes obliterated.

2. The Congenital Dermoid Cyst.—This rare form of cyst is met with in the middle line. It most commonly forms a swelling, projecting into the mouth beneath the tongue, and also appearing on the neck. In a case of this kind under my care, the contents closely resembled cream-cheese in appearance, and were composed of epithelial scales and fatty matter (see also vol. i. p. 938). These cysts may be dissected out from the mouth or by an external incision in the middle line between the chin and the hyoid bone. The operation is troublesome and may be accompanied by free bleeding.

3. Bursal Cyst.—This is believed to arise from enlargement of the bursa above the hyoid bone between the genio-hyoidei and genio-hyo-glossi. It projects usually more distinctly in the neck than into the mouth, and thus forms a large tumor, soft or elastic, and semi-fluctuating, occupying, perhaps, all the space between the symphysis and the hyoid bone. It may attain the size of an orange. The tumor is best treated by making a free incision into it, from the mouth if possible, and wiping out the cavity with chloride of zinc (gr. 40 to 5j of water), after which a drainage-tube may be inserted. If the tumor is more superficial externally, the same treatment may be carried out from the outside. It is not possible in most cases to dissect the cyst out, as its wall is thin and its connections deep and important.

SALIVARY CALCULI are occasionally met with in connection with the sublingual, submaxillary, and parotid glands. They are most common in the sublingual gland, and will then be found to be situated in the Whartonian duct. From this situation I have two or three times removed them. Gross mentions a case of calculus in the duct of the submaxillary gland. Wherever occurring, they obstruct the duct and produce retention of saliva in it. Hence, when the salivary glands become actively secreting, as at meal-times, the calculus, by preventing the escape of the salivary fluid, causes distention of the gland, with pain and tenderness, rendering mastication difficult.

The *Treatment* is simple. It consists in dividing the mucous membrane over the calculus and then extracting it with forceps. The largest which I have removed was of the size of a small damson-stone; it was loose in Wharton's duct.

DISEASES OF THE PALATE, UVULA, AND TONSILS.

HARD PALATE. The hard palate is liable to *necrosis*, usually the result of syphilis or scrofula, but occasionally arising from a subperiosteal abscess, starting from a diseased tooth. These conditions have already been sufficiently described in the chapter on Diseases of the Jaws. *Epithelioma* is occasionally met with affecting the hard palate, but it is far from common. *Enchondroma*, *Fibroma*, and various forms of *Sarcoma* have also been met with in this region.

SOFT PALATE.—The most common disease of the soft palate is *syphilitic ulceration* (vol. i. p. 1067). *Epithelioma* is occasionally met with in this part, but more commonly the palate is affected by extension from the pillar of the fauces or the root of the tongue. *Adenoma* is, perhaps, the most common tumor in this region. It is hard, smooth, painless, and, being encapsuled, is readily shelled out from a single incision. A few years ago, C. Heath

successfully removed a tumor of this kind measuring about one inch and a half in diameter.

UVULA. **Elongation of the Uvula.**—The uvula occasionally becoming elongated and hanging down into the pharynx, so as to touch the epiglottis and sensitive mucous membrane in its neighborhood, gives rise to great irritation of the fauces, and to a tickling or spasmodic cough, which can be cured only by removing the pendulous body. This little operation may be readily done by seizing the end of the uvula with a pair of polypus forceps, and snipping it across near the root with a long pair of scissors. It is better not to remove the whole of the uvula. If this be done, throat-irritation is apt to continue. I have been most satisfied with the result of those cases in which a stump from a quarter to the third of an inch in length has been

Fig. 738. Vulsellum-scissors.

left. For some years I have been in the habit of using a pair of "vulsellum-scissors" (Fig. 738), by which the uvula is cut off at the same moment that it is seized, thus rendering the operation easier and less irritating to the patient. A very ingenious American instrument, consisting of a pair of forceps and scissors combined, may be employed with the same view; by closing the handles of this instrument the uvula is first seized, and is then immediately cut across (Fig. 739).

TONSILS. **Tonsillitis or Quinsy.**—The tonsils are not unfrequently the seat of disease, becoming inflamed or permanently enlarged. When inflamed, they become swollen and red, with much pain in the side of the neck and ear, increased by any attempt at swallowing; there is usually rather a profuse secretion of saliva, and a good deal of swelling under the angles of the jaws; the tongue is much coated with thick pasty mucus, and the voice is thick and nasal. The disease comes on suddenly, often accompanied by high fever, chills, and occasionally even delirium. The thermometer frequently rises to 105°, or even higher. In some cases, a trace of albumen may be found in the urine. Tonsillitis is often caused by exposure to impure air, such as results from the escape of sewer gas into a house, and it is not uncommon amongst the residents in hospitals. It may be mistaken for diphtheria, scarlet fever, or

Fig. 739.—Forceps-scissors.

erysipelas of the fauces. From diphtheria it is distinguished by the absence of exudation. The mucous secretion from the tonsil may somewhat resemble diphtheritic exudation, but it is readily distinguished by its want of adherence, as it is easily removed with a camel's-hair pencil. From scarlet fever, tonsillitis is distinguished by the absence of the red tongue, and by the redness of the throat being purple in tint, and limited to the tonsils and their immediate neighborhood, and later on by the absence of rash. From ery-

area of the fauces it is more difficult to distinguish, but it will usually be found that the redness is darker in tint and less diffused than in erysipelas, and there is less oedematous swelling, and no tendency to the supervention of tetanus from oedema glottidis. There is also less glandular enlargement at the angle of the jaw.

The *Treatment* should always be commenced by a good purge; a calomel and elæreth pill will be found most efficacious if it can be taken. This is followed by the application of fomentations, the inhalation of the steam of hot water, and low diet, which need scarcely be enforced, on account of the difficulty and pain in swallowing. If the mouth can be opened, much relief may be given by scarifying the tonsils with a probe-pointed bistoury; and, if abscess form, it should be opened early with a gum-lancet. The inhalation of the steam from a pint of boiling water, to which has been added a tea-spoonful of creosote or carbolic acid, will often give much comfort by allaying the odor of the breath.

Enlargement of the Tonsils.—There are two distinct forms of chronic enlargement of the tonsils. In one, these organs become increased in size in otherwise healthy children in consequence of repeated attacks of inflammation, and more especially of diphtheria, scarlet fever, and measles. In the second form the enlargement is due to a *true hypertrophy* of the normal structures of the tonsil. The lymphatic follicles are enlarged and increased in number, and the connective tissue between them is more abundant and denser than normal. The crypts are deepened and are filled with an abundant mucous secretion. In rare cases, calcareous concretions may be found in the dilated crypts. This form of enlargement may be complicated by the effects of repeated attacks of inflammation.

When the tonsils are chronically enlarged, one usually suffers to a somewhat greater extent than the other. The condition is obvious on opening the mouth and depressing the tongue so as to expose the fauces fairly, and must not be mistaken for any other morbid state.

In *chronic inflammatory enlargement* the tonsils are red, congested, and very liable under the influence of slight causes, to violent attacks of acute inflammation with ulceration or abscess.

In *chronic hypertrophy* the tonsil presents different characters; it is large, rather pale, hard, smooth, and semi-elastic. This disease is one which occurs in children and young persons who have a general tendency to strumous affections of the mucous membranes. Most commonly it develops without any assignable or external cause, usually commencing at five or six years of age and gradually increasing up to puberty, a period when the functional activity of these glands is greatest, and when they are most exposed to irritation from zymotic diseases, especially scarlatina and measles. When once the tonsils have enlarged, they become a source of great inconvenience and often serious derangement of health. The child is liable to attacks of inflammation of the throat, the tonsils then becoming congested, greatly enlarged, and readily running into ulceration or suppuration. In consequence of these repeated attacks of inflammation, the enlargement of the tonsils increases, they become indurated, rugged-looking, and nodulated, projecting far forwards into the fauces, and sometimes even touching each other beneath the uvula. Respiration, articulation, and deglutition are now seriously distressed with. The mucous membranes of the nose and eyes are often chronically congested, and there is an increased secretion, from the back of the throat and nose, of thick, tenacious, unhealthy, or fetid mucus, the exhalation of which is deleterious. The child cannot sleep without snoring, and is apt to start up with a feeling of suffocation; the voice becomes thick and husky; the sense of hearing is blunted; and, partly from the incipient

deafness, partly from the difficulty of breathing, causing the child to keep its mouth half-open, the countenance assumes a peculiar, vacant, semi-idiotic expression, which is very characteristic of the advanced stages of the disease. The most serious effect is the impediment to inspiration, which in the more chronic and severe forms of enlarged tonsils will go to such an extent as to prevent the full inflation of the lungs, and thus occasion a permanent flattening and contraction of the chest, imperfect aëration of the blood, and an interference with general nutrition.

Fig. 740.—Tonsil-guillotine applied.

Fig. 741.—Tonsil-guillotine shut.

Fig. 742.—Tonsil-guillotine with hooks to seize Tonsil.

The Treatment of chronic enlargement of the tonsils will vary according to the age of the child, and the degree and kind of hypertrophy and induration of these organs. In the earlier and slighter forms of the disease, the enlargement of the tonsils may gradually subside as the child grows older and stronger; and it is well not to be in too great a hurry to excise the tonsils in young children, but rather to adopt a course of constitutional treatment with the view to the improvement of the general health, by means that are ordinarily had recourse to in the management of struma. The internal use of iron, and the local application of the tincture of iodine, of nitrate of silver, or of burnt alum, are occasionally serviceable. In the majority of instances, however, the disease will not be materially influenced by any therapeutic means that may be adopted: and as the enlargement, continuing or increasing, gives rise to difficulty in respiration, and thus interferes with the due

arterialization of the blood in the lungs, and impairs the child's speech, it becomes necessary to remove that portion of the growth which projects beyond the arches of the palate. This may best be done by the ordinary tonsil-gnathome. The ring of the instrument being passed over the tumor, the ending blade is pushed forwards, and thus a slice of the projecting part of the growth is removed. In some cases difficulty is experienced in bringing the tonsil fairly into the ring of the instrument; this may be obviated by drawing it through with a vulsellum or double hook, and indeed, in some of the machines sold for the purpose, a double hook is attached, which, being fixed into the tonsil, draws it forwards before it is sliced off (Figs. 740-742). In performing this operation it is best for the Surgeon to stand behind the patient, more particularly in excising the right tonsil, as he can thus look better into the mouth and have more command over the head; or he may stand in front, and use the left hand for the right tonsil, and *vice versa*. Fig. 743. Should a guillotine not be at hand, the tonsil may be removed by

Fig. 743.--Removal of Right Tonsil with left hand.

strengthen with a vulsellum, drawing it forwards, and then taking off a slice with a probe-pointed bistoury, the base of the blade of which should be wrapped round with a piece of plaster, to prevent its wounding the tongue. In excising the tonsil in this way, care must be taken to cut from below upwards and inwards towards the mesial line, and on no account to turn the edge of the knife outwards, lest the internal carotid artery be endangered. The hemorrhage that follows this operation is usually very trifling; but it may be sufficiently abundant to endanger the patient's life. In such cases, ice and galic acid will usually arrest the bleeding. In one case, I found a gargle of tincture of turpentine suspended in mucilage effectual after all other means had failed.

It has been stated by some that excision of the tonsil is liable to be followed by want of development of the testes. This I have never observed. But it is possible that enlargement of the tonsils to such an extent as to impede respiration, and consequently to interfere with nutrition, may lessen the development of the generative or any other organs of the body.

Malignant Tumors of the Tonsil are occasionally met with, but are not common. The tonsil readily becomes implicated in epithelioma springing from the pillars of the fauces or the root of the tongue, but is very rarely the primary seat of the disease. Most of the primary tumors of the tonsil have been described as scirrhus or encephaloid, but it is doubtful whether true scirrhus ever commences in this situation. The soft "encephaloid" tumors appear to have been in most cases lymphomata or lympho-sarcomata. In malignant growths in this region the disease speedily extends to the

pillars of the fauces, the pharynx, and onwards to the floor of the mouth the glands under the angle become implicated, extensive infiltration of brawny character takes place in and around them, the swallowing becomes extremely painful and difficult, respiration is impeded, the pharynx and palate become congested and loaded with viscid mucus, and the patient eventually dies in a distressing manner, partly from starvation, partly from constitutional contamination.

Surgery, as a rule, offers the means only of relief in these sad cases. In one case of a soft malignant tumor of the tonsil, which was under my care, I obtained some temporary advantage by removing portions of the soft projecting and very vascular growth by means of the *écraseur*. Should the tumor be so situated that there seems a possibility of removing it, it may be brought more fully within reach by dividing the cheek, as in the lower operation for removal of the tongue. Foulia recommends an incision from the angle of the mouth to the angle of the jaw, division of the bone with a saw, and wide separation of the two parts, by which the tonsil is very completely exposed. Operations in this region are best carried out with Paquelin's hot knife. The results of attempts of this kind, although not very encouraging, have been sufficient to show that it is possible to remove the tonsil with the pillars of the fauces and the neighboring parts of the tongue and soft palate without fatal consequences ensuing. It is probable, therefore, that if performed sufficiently early much benefit might follow operations in well selected cases.

DISEASES OF THE PHARYNX.

Syphilitic Affections of the Pharynx have been already described (vol. i. p. 1067). The consequences of extensive syphilitic ulceration may have not been alluded to here, as they occasionally call for surgical interference. As the ulcers heal, the pharynx may contract so that deglutition becomes difficult, fluids only being able to pass. In such cases some relief may occasionally be given by careful division of some of the tight cicatricial bands which narrow the fauces, followed by the passage of bougies. Sometimes the soft palate becomes adherent to the posterior wall of the pharynx, completely shutting off the nasal cavity. For this condition nothing can be done, as it is impossible to set the soft palate free, and an opening through it would only add to the patient's discomfort.

Erysipelatous Pharyngitis is occasionally met with, accompanied by grave constitutional disturbance; it is best treated by the application of a strong solution of nitrate of silver, the use of emollient gargles, and the internal administration of ammonia, with bark, stimulants, and support. If it have a tendency to run to sloughing, the internal administration of the nitrate of silver, with bark and stimulants, the nitrate of silver lotion, and chlorinated gargles are useful. Sometimes abscess forms in the substance of the uvula, and then requires to be opened with a narrow-bladed bistoury.

Abscess occasionally forms in the areolar tissue behind the pharynx, pushed forward as to occlude the posterior nares, giving rise to a peculiar nasal intonation of voice, if the abscess be situated high; if low down, the consequences are more serious, as it may interfere with respiration by pressing upon the upper part of the larynx. This kind of abscess is often connected with disease of the bones at the base of the skull, or of the upper cervical vertebrae. In many cases, if left to itself, it would burst through the mucous membrane into the mouth; but in others it comes forwards under the sterno-mastoid muscles into the forepart of the neck. By exploring the

pharynx with the finger, which may readily be done, tension and fluctuation through its posterior wall may easily be made out.

In these cases the *Treatment* consists simply in letting out the matter by puncturing the tense membrane covering it. This may be done by means of a sharp-pointed bistoury properly protected, the ordinary abscess-knife, or a pharyngotome (Fig. 744). The pus let out is usually offensive, even though

Fig 744.—Pharyngotome.

the bones be not affected. If there is reason to believe the abscess is connected with disease of the cervical spine, an attempt should be made to open it externally, as described in the Chapter on Diseases of the Spine.

Tumors are occasionally met with in the post-pharyngeal areolar tissue, giving rise to the same swelling, difficulty in respiration and deglutition, and lateral projection, as occur in abscess of this region. These growths are mostly malignant, and speedily prove fatal. *Polypi* in the pharynx usually come down from the nasal cavities, but sometimes spring from the inside of this canal on one or other of its margins. They are usually, when truly pharyngeal, of a malignant character, and grow with great rapidity. The uses of the part are necessarily interfered with, and death may eventually result from obstruction to deglutition and respiration. The so-called *fibrous polypus* projecting from the base of the skull into the pharynx has been already described, p. 546. *Epithelioma* of the pharynx has occasionally been met with (Fig. 745). This form of the disease, which is of rare occurrence, does not differ from similar growths elsewhere.

STRICTURE OF THE ŒSOPHAGUS.

All diseases of the œsophagus have a tendency to constrict and eventually to occlude its passage, and hence are commonly described as **Strictures** of it. In some instances, the constriction of the œsophagus may be of a purely *nervous* or *spasmodic* character; but in the majority of instances it is the result either of fibrous or of cancerous infiltration of the walls of the canal, and is then termed *organic* stricture. The simple non-malignant or fibrous stricture is in most instances eventually the seat of an epithelioma, and hence appears to be more rare than in reality it is, as it is seldom met with after death in its simple form. Scirrhus cancer may implicate the œsophagus as it enters the stomach, and sarcomatous growths of various kinds may arise in its neighborhood and involve its coats.

The great feature of œsophageal stricture is difficulty of deglutition; but dysphagia may arise from many causes besides œsophageal stricture. Hence its diagnosis is in the highest degree important.

CONDITIONS PRODUCING DYSPHAGIA INDEPENDENTLY OF STRICTURE.—There are at least eight different conditions met with in the neck and chest capable of giving rise to dysphagia by compressing the œsophagus, independently of any stricture of that canal.

1. **Tumors connected with the Pharynx.** Putting out of consideration tumors of the tonsils, which would always be readily discovered, *polypus* of the pharynx may hang down and offer obstructions to the passage of food. In all polypoid growths connected with the pharynx (which are exceedingly rare) the nature, connections, etc., of the growth may be made out by draw-

ing the tongue well forward, keeping it fixed with the tongue-spatula, and passing the finger well down behind the root of the organ; the pharynx can thus be explored, even below the root of the epiglottis, without much difficulty. Abscess may exist between the posterior wall of the pharynx and the spine, possibly arising from caries of the cervical vertebrae; or a *post pharyngeal tumor*, as, for instance, a sarcomatous growth, may be developed from the bodies of the vertebrae, and push the pharynx forwards. The eye is often deceived in these cases, failing to detect the existence of an enlargement at the back of the pharynx; but the finger readily recognizes it. In the case of abscess there is fluctuation, and the dysphagia will be removed by opening the abscess and letting out the contents; and the solid, or semi-solid and soft, or other feel of a tumor in this situation will lead to a very probable guess as to its nature.

2. Morbid Conditions of the Larynx. (Edema about the back of the epiglottis, or chronic oedema, ulceration, and thickening of the mucous membrane there, dependent upon syphilis or tubercle or oedema about the rima glottidis, may give rise to a tendency for liquids to pass into the air-passages, and thus occasion a serious impediment in swallowing, the difficulty being attended with a feeling of spasm and suffocation. By passing the finger down behind the root of the tongue, the state of the parts can sometimes be felt, and the actual condition can be readily ascertained by the use of the laryngoscope; but the combination of dysphagia with a suffocative fit, and these probably associated with laryngeal cough, are the chief points to be attended to in the diagnosis.

3. Tumors in the Neck outside the Oesophagus.—Enlarged glands or a carotid aneurism, developing posteriorly, as has been known to occur with the internal carotid artery; or a tumor connected with the thyroid body, tightly bound down by the sterno-mastoid muscles and cervical fascia, may, by pressing on the oesophagus, give rise to dysphagia. In all cases where that symptom is complained of, the neck should be examined carefully for tumors, which will generally be very readily detected, especially where the difficulty has existed for some time, and the person has become much emaciated from deficient nourishment.

4. Aneurism of the Innominate Artery.—When this disease has risen into the root of the neck it is easily recognizable; but in certain cases it develops first in a direction backwards, and then one of the earlier symptoms is dysphagia. Indeed, the patient may suffer but little from any other symptom, and may apply to the Surgeon for relief from it alone, quite unconscious of the existence of any serious disease. The diagnosis will be effected by careful attention to the symptoms described at pp. 180-183, vol. ii. In such a case, much danger might be incurred by at once putting an instrument into the oesophagus, under the impression that stricture existed; for the point of the bougie, or whatever instrument might be used, might perforate the sac of the aneurism, and so give rise to instant death.

5. Aneurism of the Aorta, whether of the fusiform or the sacculated variety, may give rise to difficulty of deglutition by pressure on the gullet. In this case, also, there is great danger of the aneurismal sac being pierced by an instrument passed down for the purpose of ascertaining the existence of stricture. The presence of the symptoms of intrathoracic aneurism, described at pp. 173-177, vol. ii., will determine the diagnosis.

6. Intrathoracic Tumors, such as enlarged bronchial glands, sarcomatous and other growths, developed from the thoracic spine into the posterior mediastinum, may compress the oesophagus. In such cases the diagnosis is very difficult. It is difficult enough to determine the existence of a tumor, but still more so to distinguish it from an aneurism undergoing consolidation; but

dulness on percussion, and dyspnoea with dysphagia, together with fixed pain in or to one side of the spine, with neuralgia down the arms or up the side of the head, and a varicose condition of the superficial veins of the chest, are the signs on which we place our chief reliance in diagnosing the existence of a tumor. Indeed, in the diagnosis of aneurism of the aorta and of mediastinal tumor, I look upon the combination of dyspnoea with dysphagia, and fixed wearing pain between the shoulders, as of the greatest importance.

7. **Dislocation of the Sternal End of the Clavicle Backwards**, whether merely a simple dislocation, or produced in consequence of excessive curvature of the spine, may give rise to difficulty of deglutition. Of the latter kind there is at least one case on record, which is narrated by Sir Astley Cooper, in which the sternal end of the clavicle by its pressure so obstructed the passage of food, that the patient was brought into a condition of extreme danger. The Surgeon, under whose care the patient was, very skillfully and creditably sawed through and detached the sternal end of the clavicle, and thus relieved his patient from the imminent danger in which she was placed.

8. **Impaction of a Foreign Body in the Gullet**.—If a man swallow such a thing as a piece of mutton-bone, or the settings of artificial teeth, it generally lies across the gullet in such a manner as to be easily felt by the Surgeon on passing a probang; but there are other cases in which a foreign body becomes so lodged in the canal as to escape detection and removal. Some years ago I was requested to see a patient who was said to have swallowed a piece of gutta-percha. He had, it appeared, in consequence of having lost several teeth, endeavored to construct an artificial masticatory apparatus for himself, which had become loose, and he had accidentally swallowed it. A few days afterwards, finding that deglutition continued difficult, he consulted a very able Surgeon, who carefully examined him; but, not detecting any foreign body, he considered that the piece of gutta-percha had passed into the stomach, and that the œsophagus had been scraped by it in its passage down. Inability to swallow solids came on. I saw him six months afterwards. The question then was, whether the foreign body was still impacted in the œsophagus, or whether the symptoms arose from damage inflicted on that tube. I examined the œsophagus most carefully, but failed, as other Surgeons had previously done, to discover the existence of any foreign body. I thought that the œsophagus had been injured in some way, and that probably epithelioma was developing, and would, sooner or later, prove fatal. One day, while at dinner, the patient suddenly vomited a large quantity of blood, and fell down dead. On examination after death, we found that the piece of gutta-percha had formed for itself a bed in the wall of the œsophagus, lying parallel with the inside of the tube, and that the ulceration of the mucous membrane caused by its presence had opened some œsophageal vessel—which, we could not ascertain (it was not, however, either the carotid artery or the jugular vein)—thus giving rise to the copious and sudden hemorrhage which had caused the patient's death. The surface of the gutta-percha which looked into the œsophagus, being constantly covered and smoothed over by mucus, and being protected, as it were, by a rim of swollen mucous membrane all around it, had allowed the probang to pass easily without its presence being detected.

These, so far as my experience goes, are the eight conditions which are likely to simulate stricture of the œsophagus; and such are the points to be attended to in the diagnosis of these affections from each other. With regard to the diagnosis of stricture from these conditions, the process is rather a negative than an affirmative one, proving the absence of tumor, aneurism, etc. The conclusion that the difficulty of deglutition can arise from no

other cause than stricture is arrived at by a process of exclusion: and the situation and extent of the stricture are ascertained by exploration with a gum-elastic catheter or bougie.

FORMS OF STRICTURE.—There are three forms of this affection which it is necessary to distinguish from each other, inasmuch as they differ greatly in the mode of treatment, and in the ultimate result. These are—1. Hysterical or Spasmodic Stricture; 2. Fibrous Stricture; 3. Cancerous Stricture.

1. **Hysterical or Spasmodic Stricture** is met with chiefly in young females under twenty-five, though it may occur in much older persons of the hysterical temperament. It is possible for it to occur without evident organic disease or change of any kind. But I believe that the simple and uncomplicated hysterical stricture is of very rare occurrence. In the majority of instances it will undoubtedly be found to be dependent upon some local change of structure, most commonly of a simple kind, such as chronic inflammation of the pharyngeal mucous membrane, ulcerative abrasion of it, or follicular inflammation about the epiglottis and posterior part of the larynx. The disease in many cases is supposed to be dependent on it to have been occasioned by the swallowing of some foreign body as a fishbone, bead, bristle, etc., which after many months is still thought to be impacted. This is almost always erroneous. The foreign body may have been swallowed, and may have been the starting-point of the slight inflammation or ulceration that occasions the dysphagia, but it has long since disappeared, leaving merely a series of troublesome consequences in its train. The obstruction is generally high up in the pharynx, rather than in the oesophagus, being produced by the contraction of the constrictor muscles. The dysphagia is intermittent; when the patient's mind is allowed to dwell long on the affection, and she becomes anxious about it, then the difficulty is greatly increased; whilst at other times, when her thoughts are diverted from it, food passes easily. It will be found also, in these cases, that on attempting to pass a probang or large bougie, its progress will at first be resisted, but by patiently and gently pressing down upon the stricture, the instrument will soon pass easily.

2. **Fibrous Stricture.**—There are two kinds of organic stricture of the oesophagus—namely, the fibrous and the cancerous. Between these the diagnosis is often very difficult; strictures originally fibrous sometimes becoming the seat of a malignant growth; while others continue fibrous to the end. The fibrous stricture is scarcely ever idiopathic. It may possibly arise from contraction of the scar left by a syphilitic ulcer; but it almost invariably originates from the cauterization of the interior of the oesophagus by the accidental or suicidal swallowing of some corrosive fluid acid or alkaline, as the strong mineral acids or soap-leys, by which the mucous membrane is destroyed, charred as it were, and a cicatrix as of a burn forms. This gradually contracts till at last almost total occlusion of the gullet may ensue. The etiology, in fact, is an important element in the diagnosis, the fibrous stricture being almost invariably the direct result of escharotic action, the cancerous occurring without assignable cause, or being referred to some slight form of local irritation. Generally, on passing an instrument, we find that in the simple or fibrous stricture it goes smoothly, and gives no sensation of roughness, no feeling of lacerating its way, or as if it were passing over an ulcerated surface, no blood follows its withdrawal and the patient does not bring up pus, or blood, though there may be copious mucous discharge. There is no material enlargement of the neck, no swelling of the cervical glands, no sign of the cancerous cachexia. The fibrous constrictive stricture may occur at any part of the oesophagus. It is usually situated towards the middle.

3. **Cancerous Stricture.**—Cancer in the oesophagus always assumes the form of epithelioma. It is situated usually high up, most commonly rather in the pharynx than the gullet, immediately behind the larynx. Between that point and the cardiac orifice cancer is much more rare. At the cardiac orifice the oesophagus may become implicated in cancer, usually scirrhus, commencing in the stomach. In the malignant stricture, if an instrument be passed, it seems to pass over a rough and ulcerated surface, causes bleeding, and the patient coughs up blood, or blood and pus, mixed often with shreds of tissue—conditions all indicating a loss of substance.

Fig. 745. There is also, sometimes, an ovoid or elongated swelling at the root of the neck; the neighboring glands may be affected; there may be cancerous tumors elsewhere; and the symptoms of the cancerous cachexia may be present. The special causes of cancer of the oesophagus are not known.

TREATMENT.—The treatment of stricture of the oesophagus will depend upon its nature. In the *hysterical variety*, the occasional introduction of a full-sized oesophagus-bougie, the application of belladonna to the neck, and anti-hysterical treatment generally, iron, astringes, douches, and diverting the patient's mind from her malady, are the means to be employed. In such cases, Garrod has very advantageously employed large doses of assafetida.

The treatment of **organic stricture** is more difficult. In it, care should be taken that the patient lives chiefly upon nutritious slops, or upon meat that has been well chopped up, as larger fragments are apt to become impacted at the seat of constriction. The difficulty in deglutition will, however, gradually increase, the patient being first unable to swallow solids, then being reduced to pulpy food, and at last to liquids. After a time, he will not even be able to swallow this; and then it becomes necessary for the Surgeon to feed him by the introduction of a gum-elastic catheter through the stricture, and the injection of a sufficient quantity of liquid or semi-pulaceous nourishment into the stomach twice a day. After a few weeks, the irritation induced by the repeated introduction of the catheter will render its passage more and more difficult, until at last it becomes impossible to get it through the constriction. The patient may

Fig. 745.—Epithelioma of Pharynx and Oesophagus causing Stricture

still be kept alive for some weeks by nutritive enemata, but at last dies of starvation. Even in cancerous stricture of the oesophagus, death seldom occurs by constitutional contamination, or by constitutional contamination, but in the way just pointed out. In some cases the disease extends to the posterior part of the larynx, the mucous membrane covering the arytenoid cartilages and the epiglottis becomes involved, laryngeal stridor and dyspnoea ensue,

and death may result from laryngeal spasm, unless life be prolonged by tracheotomy, which in many cases becomes necessary.

Such is the miserable course and termination of an organic stricture of the oesophagus. But the question now presents itself, Can nothing be done to cure or even arrest this disease?

The **Palliative Treatment** that is usually adopted in these cases consists in the introduction of bougies, and an attempt thus to dilate the stricture exactly as in the case of a constriction of the urethra. In introducing bougies into the strictured part of the oesophagus, there is, however, often a good deal of difficulty in making the point of the instrument enter the narrowed portion of the canal. This is more particularly the case when the constriction commences suddenly; the oesophagus, as is frequently the case, being dilated into a pouch-like sac above it, in which the food is apt to lodge, and the end of the instrument to be arrested, and at the bottom of which a narrow orifice exists, leading into the lower portion of the canal. In these cases, much patience and care may be required in overcoming the difficulty. Besides the ordinary dilatation by gradually increasing the size of the instruments used, I have in some cases seen temporary benefit result from the use of a catheter, surrounded by a tube of vulcanized India-rubber, which admitted of dilatation by the injection of water or air when introduced through the stricture; or from the employment of a tubular instrument, by passing a long small sized bougie through the constriction, and then slipping a gum elastic catheter with a round led terminal aperture over it. It is needless to observe that, in the treatment of stricture of the oesophagus with bougies, no force should be used, lest the walls of the canal be perforated.

From these means temporary relief may result in some cases; but can an oesophageal stricture be thus cured? I believe not. If the stricture were ordinarily fibrous, as in the urethra, permanent relief might possibly be expected. But this form of oesophageal constriction is comparatively rare, and if the disease can be made out to be malignant, but little good, and most probably much harm, will result from the irritation of dilating instruments. We may, therefore, employ dilatation as a means of temporary benefit, but not with the hope of effecting a cure. Should the stricture at last become so tight as no longer to allow the catheter to be passed, and thus to be injected into the stomach, the patient must inevitably die of inanition, unless kept alive by nutritive enemata. By these means I have known the patient prolonged, by a frail tenure it is true, for many weeks. In such cases it is an interesting physiological fact that, although the patients may continue to be moderately well nourished, and do not feel the pangs of hunger, they suffer excessively from thirst.

Has surgery no resource in those cases in which the stricture has become impermeable, and in which neither food can be swallowed nor a catheter passed, and in which, consequently, the most miserable death, death by starvation, is impending? In such cases it has been proposed by Sedgwick to open the stomach, by an incision through the abdominal walls, and thus directly introduce food into the organ. To this operation Sedgwick gave the name of *Gastrostomy*.

Operation of Gastrostomy.—The object of the operation is to expose the stomach, and to make a fistulous opening in that part of it which is in contact with the abdominal wall, and uncovered by the ribs. The operation consists of three stages: 1. The exposure of the stomach; 2. The incision to the lips of the incision in the abdominal wall; 3. The making of an opening into it. The area to be exposed is not large, and corresponds externally to the cartilages of the eighth, ninth, and tenth ribs, above and internally it is bounded by the lower edge of the liver. In the contraindications

state of the stomach the pylorus lies immediately to the right of the middle line; it is advisable, therefore, to make the incision as far to the left as can conveniently be done. Sédillot divided the abdominal wall by a crucial incision, each limb of which was about an inch and a half in length. Further experience has shown that so large an incision is not necessary. Labbé recommends an incision about an inch and a quarter to an inch and a half in length, parallel to the left costal cartilages, and one finger's breadth from their borders, terminating below at an imaginary line drawn between the most prominent points of the convexities of the two ninth cartilages. This incision will be found to divide a few fibres of the external oblique and notch the edge of the rectus; beneath this is the expansion from the internal oblique and the upper fibres of the transversalis, under which lie the transversalis fascia and the peritoneum. Howse prefers a vertical incision at about the same level, passing through the outer fibres of the rectus, which will afterwards exert a sphincter-like action on the opening. In whichever way the abdominal wall is divided, all bleeding must be carefully arrested before the peritoneal cavity is opened. On dividing the peritoneum the stomach may present at the wound, and may be grasped with the fingers and drawn out. If it is not at once seen, the finger must be introduced and the lower border of the liver felt for immediately, below which will be the stomach. When the stomach is felt, it may be drawn up into the wound by the fingers, if possible, if not, by a pair of ring-forceps; vulsellum-forceps must on no account be used. If the omentum presents in the wound, it should be drawn gently downwards until the stomach comes into view. The only viscus which can be mistaken for the stomach is the transverse colon, the left end of which immediately before the splenic curvature may present in the wound. The stomach can be recognized by the thickness of its walls and the extent and smoothness of its surface. The next step is to secure it to the opening. This is best done by carbolized silk sutures passed through the serous and muscular coat only. This is easily accomplished by gently pinching the coats of the stomach between the finger and thumb, when the mucous coat will be felt to slip away, leaving the other two in the grasp of the fingers. The stitches must be passed first through a good thick piece of the stomach, then through the peritoneum, which should be drawn a little forward by forceps, and then through the skin and fat, missing the muscular tissue of the abdominal wall. In this way the serous surfaces will be brought very accurately in contact. All the stitches must be passed before any are tightened; they must be not more than one-sixth of an inch apart, and must be so arranged as to enclose a circular area of the stomach wall about the size of a shilling. Finally the stitches are tightened and the wound dressed, with proper attention to the prevention of decomposition. The patient must be nourished for the next four or, if possible, five days by nutritive enemata. By that time the stomach will have formed firm adhesions, and may be safely opened. This is done by passing a narrow scalpel through the adherent portion of the stomach, and making an opening large enough to admit a No. 10 catheter, into which an India-rubber tube, fitted with a shield or a small tracheotomy tube, may be passed; the orifice of which may be closed with a cork. At first only milk or pancreatized food should be introduced, but, as the stomach becomes stronger, minced meat, bread, and other food may be used.

The chief danger of the operation is peritonitis, but the risk of this has been very greatly diminished, first by the adoption of the method of operating in two stages, and secondly by the use of antiseptics. The advantage of delaying the opening till firm adhesions have formed is clearly shown by the statistics published by C. L. Vitrunga, who has collected altogether the

records of 155 cases of gastrostomy. From these he shows that before the introduction of antiseptic treatment 55 per cent. of the patients operated on died directly from the operation, but since that period the death-rate has been reduced to 27 per cent. If the antiseptic cases are divided into those in which the opening was made into the stomach at the time of the operation and those in which it was delayed till adhesions had formed, we find the death-rate was 55 per cent. in the former and only 17.5 per cent. in the latter. In many cases, although the patient does not die directly from the operation, life is but little prolonged by it, as the stomach seems unable to resume its functions. This most commonly has happened in cases of malignant stricture, in which the operation has been deferred till the patient was in the last stage of exhaustion. In all cases of malignant stricture the most that can be obtained by gastrostomy is the prolongation of a precarious existence which must in a few weeks or months be cut short by the unobstructed progress of the disease. In such cases the advantages and the dangers of the operation should be laid fairly before the patient, but it is not the duty of the Surgeon to urge him to submit to it.

There is, however, one class of oesophageal strictures which are of the most obstinate character, and rapidly fatal by simple occlusion of the tube, without any tendency to malignancy. These are the constrictions that result from the swallowing of corrosive liquids, whether acid or alkaline. In such cases as these, in which speedy death by starvation is inevitable, I think the Surgeon is justified in advising the operation. In a case of this kind operated on by Trendelenburg, the patient was alive and well many years after the operation. He took food by masticating it thoroughly and then blowing it from his mouth into the stomach through a tube fitted to the cannula.

In many cases a good deal of trouble has been occasioned after the operation by the escape of gastric juice from the fistula. This causes great irritation of the surrounding skin apparently by a process of digestion. It may be avoided by not making a larger opening than is absolutely necessary. In the vertical incision adopted by Howse the sphincter-like action of the fibres of the rectus tends in great measure to prevent this complication. Should the skin become sore it may be relieved by being washed with an astringent solution and protected by vaseline.

DISEASES OF THE LARYNX.

The larynx may be the seat of a great variety of morbid conditions. Acute oedematous, and follicular inflammation; ulcerations and other thickenings of the mucous membrane; inflammation and necrosis of the cartilages; and the formation of tumors or polypoid growths in its interior may all occur.

LARYNGOSCOPE.—It is of the utmost importance in the diagnosis, and for the proper treatment of these affections, that a view should be obtained of the parts that are the seat of disease. This can be done only by means of the Laryngoscope.

The introduction of this instrument into practice and its perfection have been a work of time.

It appears to have been invented and first used in 1829, by Bellingoni, who, under the term "Glottiscope," described an instrument consisting of a small mirror fixed to a wire shank, which, being placed against the uvula whilst the tongue was held down, enabled him to view the glottis and upper part of the larynx; more especially when he illuminated these parts by throwing reflected light upon them from a mirror held in his left hand.

Trousseau, and Avery, all made attempts in the same direction. But the celebrated singer Garcia, who, by throwing the sun's rays into the f his mouth from a mirror held in his left hand, and then introducing at's reflector into his mouth, saw the image of his own larynx and its movements in the reflection of the looking-glass. Hitherto, however, laryngoscopy had not been employed in the study and diagnosis of s of the larynx, and it is undoubtedly to Czermak that the merit is having been the first to make this application of the art.

Fig. 746.—Method of using the Laryngoscope with Reflector.

laryngoscope essentially consists of two instruments, a reflector (Fig. 746) which may be attached by a spectacle-frame or an elastic band to the n's forehead, and a mirror (Fig. 747), which is held in his right or nd, according to circumstances.

mode of application and of use is extremely simple, and is illustrated . 746. The patient sits with his back to a good light: that of the sun ery well if it can be obtained, but usually artificial light has to be

Fig. 747.—Throat Mirror.

red. This may be obtained from a moderator or paraffin lamp. The of the lamp should be a little above the level of the patient's ear. The n, facing the light, arranges the reflector in such a way that, whilst e and the patient are in easy positions, a well-defined circle of light the patient's mouth. If, as in many arrangements, the reflector be se eye of the Surgeon, he must so place it that he sees clearly through e in the centre, and can consequently employ both eyes in examining oat. The patient now having the head very slightly inclined back-opens his mouth and puts out his tongue. The Surgeon grasps the tip ongue gently between the forefinger and thumb of his left hand, covered oth or pocket-handkerchief. He must be careful not to drag on the

tongue, but merely to hold it steady; and this is best accomplished by resting the forefinger on the patient's chin. He now takes the small mirror and warms it over the lamp, so that the patient's breath may not condense on it and obscure the image of the larynx. Having warmed it till he sees the cloud of condensed moisture from the lamp disappear, he tests it against his own cheek to feel that it is not too hot, and then introduces it in the following way. The handle being held like a pen, and rather to the left side of the patient's mouth, the mirror is passed in carefully, having its surface parallel to the dorsum of the tongue, until the tip of the uvula rests on it back, and is pushed slightly backwards and upwards by it. Care must be taken, in doing this, that the reflecting surface does not touch the tongue, and so become dirtied, and that the mirror is not passed so far as to touch the back of the pharynx, which in most patients would cause an effort at swallowing. The mirror being in the position above described, the Surgeon will, if he see anything, view the back of the pharynx reflected on its surface; but, by gently and steadily raising his hand, so as to render the angle formed by the surface of the mirror with the patient's body about a right angle, he will bring the opening of the glottis into view. By raising his hand still a little further, he can examine the epiglottis and the root of the tongue. It must be remembered that the image thus produced is reversed in the antero-posterior direction, the parts that appear anterior on the mirror being really posterior; while in the transverse direction there is no reversal.

When the Surgeon requires both hands, as in the application of caustics or in the removal of growths or foreign bodies, the patient must be taught to hold his own tongue, or it must be held by an assistant. The Surgeon then holds the small mirror in his left hand, and the instrument he is using in the throat in his right. Sometimes all view of the larynx is obscured by the patient obstinately arching the tongue in the mouth. It must then be held down by a spatula. In some patients, the fauces are so irritable that the slightest touch causes violent retching. This may be allayed by sucking out for a short time before the laryngoscope is employed. The administration of bromide of potassium for a few days in full doses is said to diminish the sensibility of the fauces, but its action is not certain.

LARYNGITIS—Inflammation of the larynx occurs both in adults and children, though more commonly in the former, from exposure to cold, or the infection of erysipelas, and various other causes. It differs essentially from the croup of children, which is attended by an albuminous exudation, and spreads downwards into the bronchi; whilst in laryngitis there is no such effusion, and the disease is confined to the larynx itself. Laryngitis may not only be of an acute or chronic kind, but the acute form likewise presents two distinct varieties, according to the parts affected, the cause from which it arises, and the condition of constitution in which it occurs. In one, the true **Acute Catarrhal Laryngitis**, the inflammation is seated chiefly in the mucous membrane; in the other, the **Œdematous Laryngitis**, the affection extends to the submucous areolar tissue, within and around the larynx.

In all inflammatory affections of the larynx, whether acute or chronic, there is danger to life; the rima glottidis, that narrow chink through which all the air destined for respiration must enter, becomes readily occluded, and asphyxia consequently results. This may happen either by the swelling of loose folds of mucous membrane about the upper opening of the glottis, or by membranous exudation upon the vocal cords, or by the occurrence of spasm in the larynx. Indeed, there is usually more or less spasm associated with all the acute inflammatory affections of this part of the air tube, and this spasm, being superadded to already existing mechanical occlusion, commonly

proves fatal. These laryngeal spasms do not at first recur oftener than at intervals of half an hour or an hour; but, as the disease advances, they become more frequent, and in any one of them the patient may be carried off. It is of importance to bear in mind that death may occur in these cases, although a considerable portion of the cavity of the larynx continue free. Thus Cheyne states that there are always in croup at least three-eighths of the glottis open for the transmission of air, and that death must consequently result from some cause other than mere mechanical obstruction. This freedom from permanent occlusion commonly occurs in cases of laryngitis; and the immediate cause of death in the majority of instances appears to be spasm, conjoined with defective arterialization of the blood, which causes congestion of the lungs and convulsions.

Acute Catarrhal Laryngitis may arise from exposure to cold, from violent strains of the vocal apparatus, or from extension of catarrh from the nose or pharynx. It is most common in adult males, but may occur in children. One attack predisposes to another. The mucous membrane only being affected, the *symptoms* are not indicative of such early and intense interference with respiration as is met with in the oedematous form of the disease. These are dryness of the throat and hoarseness, with pain varying from mere tickling to a severe sense of constriction. Occasionally there are pain and tenderness on pressing upon the larynx, more especially about the *ponum Adami*. The voice is at first harsh and rough, then stridulous, and finally may be completely lost; there may be some pain and difficulty in deglutition. In simple catarrhal laryngitis there is rarely any serious dyspnoea or spasm; but in children there may be considerable difficulty in respiration, especially if the glottis becomes covered with dried mucus during sleep. There is expectoration of frothy mucus, sometimes tinged with blood, and the act of coughing is accompanied by considerable pain. With the laryngoscope the intensely injected state of the mucous membrane of the larynx can be seen; but this is not accomplished without difficulty, partly from the irritability of the fauces, and partly from the large amount of tenacious mucus which usually surrounds the glottis. In very severe cases the inflammation may extend to the submucous tissue, and be accompanied by exudation into the loose areolar tissue, and the symptoms then gradually merge into those of the oedematous form of laryngitis to be presently described.

Treatment.—The patient should be placed in a warm atmosphere, which should be kept moist by steam carried into the room from the spout of a kettle. This is especially important in children, to prevent the drying of the mucus during sleep. Hot fomentations may be applied to the throat, and the patient should be made to inhale the steam from a pint of boiling water, to which a teaspoonful of compound tincture of benzoin has been added. A free purge will be usually found useful at the onset of the attack, and should there be much pain and cough, small doses of opium should be administered. Should symptoms of dyspnoea appear, indicating a tendency for the inflammation to assume the oedematous form, more active measures must be adopted, which will be described with that affection.

Acute Oedematous Laryngitis may arise as an intensification of simple catarrhal inflammation, as an independent affection by extension from neighboring parts, or as a complication of various chronic affections of the larynx. In many cases it seems to be distinctly erysipelatous in character, occurring as the result of exposure to the impure air of crowded hospitals, to sewer gas, or to the specific infection of erysipelas. In fact, it appears to be at times epidemic, and in its pathological conditions to resemble closely phlegmonous erysipelas of the part, the mucous membrane becoming red, pulpy, and swollen, and the submucous tissue infiltrated with sero-purulent

fluid. (Edematous laryngitis is occasionally met with in fever, especially in scarlet fever, and it is predisposed to in some cases by Bright's disease. It is most commonly met with in adults, being very rare before the age of eighteen. The *symptoms* are usually well marked. The fauces are red, dusky, and swollen; difficulty in swallowing is often an early and prominent symptom, and continues throughout; dyspnoea, often of a spasmodic character, then appears, the lips becoming livid, the nostrils dilated, the features pale and bedewed with perspiration, the eyes watery and bloodshot, and the respiratory muscles are called into violent action; gasping efforts at breathing and sudden fits of increased difficulty in inspiring come on; at the same time, the pulse is feeble, though it continues rapid; and, unless efficiently relieved, the patient will speedily sink. The voice is at first hoarse, but is speedily lost, and there may be some tenderness about the larynx. The dyspnoea is usually peculiar in character in the intervals between the spasms. Inspiration is always more or less difficult, as the swollen edematous parts fall together in a valve-like manner over the opening of the glottis. Expiration, on the other hand, may be comparatively easy. The fatal result is frequently due directly to spasm. The spasms come on early, and are apt to be brought on by speaking or swallowing; but, as the disease advances, the dyspnoea becomes more continuous, until stupor at length supervenes and speedily terminates in death. There is usually well-marked fever and turbulence. If the finger be passed over the back of the tongue, the red swollen epiglottis may be clearly felt. Laryngoscopic examination shows the epiglottis forming a red, semi-transparent roll, usually bent upon itself transversely. It may completely conceal the parts beneath, but in many cases the edematous aryteno-epiglottidean folds may be seen on each side. It is rarely possible to obtain a view of the cords.

The edematous infiltration in this form of laryngitis is confined principally to the submucous areolar tissue around the epiglottis, in the aryteno-epiglottidean folds, and over the arytenoid cartilages. In these situations the tissue is distended with an abundant inflammatory exudation, of an opalescent appearance, so that the swollen membrane may almost completely

occlude the rima glottidis (Fig. 748). It is a pathological fact of much importance, that the effusion does not extend below the true vocal cords, being limited at this point by the direct adhesion of the mucous membrane to the subjacent fibrous tissue, without the intervention of any loose areolar tissue.

Diagnosis.—It is of great importance to recognize edematous laryngitis early, and not to confound it with simple catarrhal inflammation. The laryngoscope is of the greatest use in arriving at a correct diagnosis. It is somewhat difficult to use in these cases, especially if there be much dyspnoea, but supposing even a momentary glance be obtained of the opening of the glottis, the condition depicted in Fig. 748 may readily be recognized. In addition to this, the occasional epidemic character of the affection, the early dyspnoea, and the dusky swollen fauces will point to the edematous variety.

Treatment.—The treatment should be antiphlogistic, though in many cases the constitution will not bear very active measures. Leeching under the jaws and over the larynx. In some cases acupunct. antisept. or acon.

might be of use, but very often the invasion of the inflammation is so rapid that local means must be relied upon rather than constitutional. In many

Fig. 748.—Edema of the larynx.

cases scarification with a hernia-knife, or with a sharp-pointed bistoury, situated within a quarter of an inch of its point, will be found the most ready means of unloading the infiltrated mucous membrane. The operation of scarification may be more accurately performed by using the laryngeal lancet, whilst the glottis is brought into view by the use of the laryngoscope. If no instrument be at hand, the swollen mucous membrane may be efficiently scarified with the forefinger-nail notched with a pair of scissors. After this, inhalations of the steam from a pint of hot water to which twenty drops of carbolic acid or a drachm of compound tincture of benzoin has been added, will be found to give most relief. Hot fomentations must be applied externally and frequently changed. In the early stages ice may be given, but after the swelling has commenced steaming the throat usually gives more relief. If, notwithstanding these remedies, the difficulty in respiration continues to increase, the windpipe must be opened before the lungs and brain become irretrievably engorged. After the proper employment of the means that have been indicated and their failure, the less delay there is in opening the air-passage through the crico-thyroid membrane, the better. The Surgeon should not wait until extreme and continuous dyspnoea has set in; this may never occur, the difficulty in breathing being rather spasmodic than continuous, and in one of the spasms of dyspnoea life may suddenly become extinct. The lungs may become fatally congested, if the difficulty in breathing be allowed to continue too long. The operation adds but little to the patient's danger, but the increased risk is immense if it be delayed to an advanced period. I can truly say that I have seen several cases lost by delaying the performance of the operation, but never one by operating too early. When once dyspnoea with laryngeal spasm has fairly set in, every moment is precious, and the patient may at any time be carried off by the recurrence of the spasmodic seizures. The patient does not die gradually asphyxiated, but is suddenly seized with a spasm that terminates his existence. Macewen has suggested that instead of performing tracheotomy a large catheter should be passed through the larynx from the mouth. He has successfully adopted this in one case, retaining the catheter with surprisingly little inconvenience to the patient till the oedema had subsided.

If the oedematous laryngitis become chronic, sloughing and putrid supuration of the submucous areolar tissue may occur, as in phlegmonous abscesses of other parts of the body, and the patient may die partly from asphyxia and partly from typhoid symptoms, with putridity of the breath and mouth. In these cases the administration of stimulants and tonics, more particularly port-wine and bark, with free sponging of the part with a strong solution of nitrate of silver, will be urgently required.

Traumatic Laryngitis from scalds, corrosive fluids, etc., has already been alluded to. It usually assumes the oedematous form, and requires the same treatment.

CHRONIC LARYNGITIS.—The larynx is liable to various chronic diseases of a serious character, some of which are incurable, leaving a permanent impairment of the vocal and other functions of the larynx. Chronic laryngitis is usually divided into three varieties, Simple or Catarrhal, Syphilitic, and Tubercular. All forms give rise to interference with the voice, and some to **Asphyxia**, or complete loss of voice.

Simple Chronic Laryngitis.—This affection is common amongst those who habitually exert the voice and from its frequency amongst clergymen is familiarly known as the *Clergyman's Throat*; it is also of frequent occurrence amongst singers, but may be met with in all classes of the community. In some cases it is the result of a previous attack of acute laryngitis, and it is **pre-disposed to** by gout and alcoholic excesses. The voice at first becomes

number of cases. Some of its advocates, however, not content with curing in this way disease that is visibly seated in the throat, state that the morbid condition extends down the trachea into the bronchi, and that it is necessary to follow it in these situations. They accordingly speak of passing the probang or brush between and beyond the vocal cords, and of sponging and mopping out the interior of the larynx and the lower parts of the air-tube, and of applying the caustic solution to them, as if this were a proceeding that could be adopted with as little difficulty as passing the sponge into the nares. I cannot believe, however, that this practice, though commonly spoken about and professedly employed, is ever in reality carried out.

The utmost that can be done is that, guided by the laryngoscope, a small brush may be momentarily passed between the vocal cords, but the spasm so caused renders it impossible to do more. Other instruments have also been passed beyond the true cords, and warty growths have been in this way removed from the cords themselves; but the moment they are touched, spasm occurs. The most that can be done is a sudden touch of a brush or snatch with a forceps or hoop of wire. Any more deliberate proceeding is impossible.

Inhalation of the Nitrate of Silver in Powder is occasionally useful in cases in which the follicles about the opening of the glottis are much enlarged. It is most conveniently done by mixing it, in proper proportions, with some innocuous impalpable powder, such as ground and dried sugar. The strength may vary, one part of nitrate of silver being mixed with twelve, sixteen, or twenty of sugar. A small quantity of the powder so prepared should be put into the end of a thick glass tube, which has been bent nearly at right angles about one inch from its extremity. The Surgeon, placing his finger over the orifice of the straight part of the tube, carries the bent end behind the tongue, over the epiglottis; he then directs the patient to make a sudden inspiration, and at the moment of his doing so takes away his thumb, so as to allow the powder to be drawn out of the tube and into the air-passages along with the current of inspired air. In this way the nitrate of silver may, in some cases, be very conveniently applied to the whole of the affected mucous surfaces without the irritation produced by the friction of the sponge.

Injection of the Solution of Nitrate of Silver may easily be done by means of the instrument that is here delineated (Fig. 750), and which I

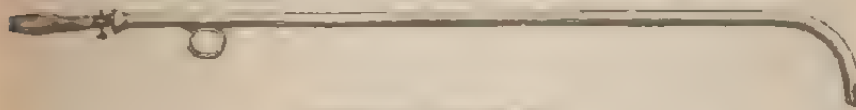

Fig. 750.—Laryngeal Syringe.

have had constructed for this purpose. It consists of a silver tube, perforated at the end, and having a small piston moving in it with a sponge attached to its lower surface. The instrument is charged by dipping the end in the solution, and then drawing back the piston-rod. It is then passed into the pharynx, or between the lips of the glottis, and the fluid is injected into the air-passages or upon the inflamed surfaces in a number of fine streams, by pushing down the piston and compressing the sponge. By means of this *laryngeal syringe* the nitrate of silver can be applied to any part of the pharynx without irritating the tender mucous membrane by the contact of a rough body; and, by applying its nozzle to or between the lips of the glottis, the fluid may be readily thrown down into the interior of the larynx with the greatest certainty and ease. In those cases in which it is wished

to apply the solution of the nitrate of silver to the air passage. I prefer using this simple instrument to the ordinary sponge or brush, as mere pressure of which upon a tender mucous surface may be a source of irritation. When the mucous membrane behind the velum, or that of the posterior nares, is affected, the solution may readily be applied to these parts by turning the end of the instrument upwards, and then injecting it directly on to the affected surfaces.

In whatever way the caustic is used, its application should be repeated about every second or third day, in order to insure its full effects. In some instances, however, advantages may be obtained by using it every day, and others, again, a longer interval is required than that just stated.

Syphilitic Laryngitis.—According to Mackenzie, syphilitic disease forms about 3 per cent. of all affections of the larynx. In the early exanthematic stage of syphilis, slight hyperæmia, with a little hoarseness, is not uncommon, but it is usually so slight as to pass unnoticed. In the secondary stages, condylomata or mucous tubercles may be met with. They can be recognized only by the laryngoscope, by means of which they can be seen forming smooth grayish elevations, usually on the epiglottis or the arytenoid fold of mucous membrane. These may be followed by superficial ulceration. The most common and most characteristic of the syphilitic affections of the larynx are those met with in the tertiary stages of the disease. The pathological changes observed are the same as in other parts—diffuse overgrowth of the connective tissue or gummatus infiltration and the formation of isolated gummata. The subsequent softening of the gummata gives rise to wide-spreading, destructive ulceration, and should the patient recover and the ulcers heal, cicatricial contraction follows, sometimes to such an extent as almost to close the opening of the larynx. The parts first affected are usually the epiglottis and the aryteno-epiglottidean folds, and from these points the ulceration extends inwards towards the glottis. Sometimes the distinct gummata may be seen as pale yellowish elevations on the mucous membrane, and should softening and ulceration follow, the yellowish adherent slough may possibly be recognized. Syphilitic ulceration not uncommonly leads to complete destruction of the epiglottis, and in the later stages necrosis of the cartilages frequently occurs. The disease is usually associated with similar ulceration in the pharynx. The symptoms are those of chronic laryngitis, with mucopurulent expectoration and gradual loss of voice. Gradually increasing dyspnoea is not uncommon from contraction of the opening of the glottis.

Diagnosis.—Syphilitic ulceration of the larynx is recognized by the history of syphilis and the presence of other manifestations of the disease, by the rigidity of the affected tissues, by the early affection of the epiglottis, the gray surface of the ulcers, or the presence of adherent yellow sloughs, and by the fact that the ulceration commences in the peripheral parts, and spreads towards the central. The rapidity with which the destruction of tissue takes place serves to distinguish it from epithelioma.

Treatment.—The usual constitutional treatment of syphilis must be adopted. Locally a solution of bichloride of mercury (gr. ʒ to ʒi) may be applied with a sponge or brush, or a preparation of half that strength may be used as a spray. Iodoform mixed with twice its bulk of starch may be blown into the larynx by the method already described, or by means of the special instrument constructed for this purpose. When healing is taking place, a solution of nitrate of silver may be of use, but it is not so efficacious as in simple chronic laryngitis. Should the dyspnoea become a marked symptom, tracheotomy must be performed.

Tubercular Laryngitis is usually met with only in advanced disease of the lungs, but occasionally it is the earliest sign of phthisis, and the disease may run its course and terminate fatally without the lungs being extensively affected. This variety is sometimes spoken of as *Laryngeal Phthisis*. The earliest symptoms are merely those of chronic laryngitis. As it advances the voice is lost, there is constant cough, with frothy mucopurulent expectoration and great pain. Deglutition becomes gradually more and more painful, till at last the patient can scarcely be induced to swallow, and death takes place gradually from exhaustion. Laryngoscopic examination may at first show but little, but before long a peculiar swelling is observed in the mucous membrane covering the arytenoid cartilages and the neighboring parts of the aryteno-epiglottidean folds. This gives rise to two pyriform swellings of sufficient size to meet in the middle line posteriorly. It is this swollen mass projecting backwards that causes the pain and difficulty in swallowing. Numerous small ulcers then appear, first in the central parts, and subsequently extending to the peripheral. The under surface of the epiglottis may be early affected. These ulcers gradually coalesce and extend, forming crenulated sores, destroying the vocal cords and neighboring parts. There is seldom serious dyspnoea, as the sores have no tendency to heal and contract. In the later stages, if the patient survive sufficiently long, necrosis of the cartilages may take place.

The *Diagnosis* is made by the presence of disease of the lungs, the peculiar swelling over the arytenoid cartilages, by the multiplicity of the ulcers and their comparatively superficial character, and by the fact that they appear first in the central parts of the larynx and spread towards the peripheral.

The *Treatment* of this affection belongs rather to the physician than the Surgeon. Local treatment can at most give some slight relief. Mackenzie recommends soothing inhalations, such as the compound tincture of benzoin, or the insutlation of one-eighth of a grain of morphia diluted with starch, twice a day. The dyspnoea is rarely such as to necessitate tracheotomy. If the inability to swallow, partly from pain and partly from the food finding its way into the larynx, becomes such as to threaten death from starvation, the patient may be fed without difficulty by an œsophageal tube.

Complications of Chronic Laryngitis.—In all cases of chronic laryngitis there is a tendency to *acute inflammation* supervening on the chronic disease. The affection may then prove fatal by the induction of œdema glottidis, often coming on with great rapidity. *Necrosis of the Cartilages of the Larynx* is most commonly a complication of the more advanced stages of tubercular laryngitis, and less frequently of syphilitic disease. It has been known in rare cases to follow typhoid fever, and still more rarely to occur without any evident cause. It gives rise to copious expectoration of large quantities of fetid puriform sputa, often streaked with blood, and occasionally containing masses of necrosed and usually calcified cartilage. In many cases abscesses form outside the tube, and after much irritation and distress open externally; and not unfrequently they are met with to such an extent, as to undermine and disorganize the greater portion of the tissues of the anterior part of the neck. Where they correspond to the necrosed patches of cartilage, they give rise to aërial fistulae, through which bubbles of air escape during respiration. Tracheotomy is sometimes required in these cases.

In cases of long standing and incurable laryngeal disease, either syphilitic or tubercular, it has been proposed by Bryant to perform tracheotomy with the view of giving the diseased organ rest, and thus giving time and opportunity for the inflamed and ulcerated mucous membrane to heal; the opera-

tion being performed here, not for the relief of laryngeal obstruction, or with the view of rescuing the patient from impending death from asphyxia, but with the object of aiding other curative means in an otherwise intractable disease. This suggestion appears to be founded on sound pathological principles, and is of peculiar importance when we consider that patients suffering from chronic laryngeal disease are never safe from the sudden supervention of *oedema glottidis*. Whenever acute inflammation supervenes in these cases, with a tendency to oedema about the glottis, the patient should be narrowly watched, as he may readily be carried off by the sudden swelling of the lips of the rima, or by the supervention of spasm. In cases of this kind, the air-passage may have to be opened to allow respiration to be carried on; and this operation must not be delayed until the patient falls into an asphyxial condition.

NERVOUS AFFECTIONS OF THE LARYNX occur both in children and in adults. In *children* the affection, commonly called **Spasmodic Croup**, comes on suddenly and runs its course with great rapidity. The child is seized, often without previous warning, with difficulty in breathing, uses violent efforts to inspire, becomes black in the face and convulsed, and has in rare cases been known to die before anything can be done for his relief; but ordinarily he gapes and gasps a few times, and eventually recovers himself with a long, deep-drawn whooping inspiration. In cases of this kind, the *Treatment* at the time of the fit consists in dashing cold water in the face, in exposing the body to a current of cold air, and in using friction to the extremities. If asphyxia occur, artificial respiration must be kept up either through an opening made in the windpipe or by the mouth.

In the *adult*, these spasmodic affections of the larynx may come on either from pure hysteria, or from irritation of the laryngeal nerves by the pressure of tumors or aneurisms upon them. In other instances, they arise from the presence of some local inflammatory mischief about the glottis. In the hysterical form of the affection the ordinary remedies for hysteria, together with cold douches, will be of essential service. In some cases, however, the obstruction to respiration is so great, that the Surgeon may think it necessary to have recourse to operation. When the disease arises from irritation of the trunks of the nerves, such a procedure may give relief, but the occasioning cause is usually in itself of a fatal character.

Paralysis of the Larynx, either unilateral or bilateral, is occasionally met with. When unilateral, it arises usually from pressure on the recurrent laryngeal nerve by an aneurism or other tumor. The abductor muscles of the cords are usually affected first. The vocal cord on the affected side then remains stationary in the adducted position. If only one side is affected, it causes some alteration in the voice, but no serious dyspnoea. If both sides are affected from any cause, serious dyspnoea results, necessitating tracheotomy for its relief. Many other forms of paralysis of the muscles of the larynx are met with, but their consideration belongs rather to the physician than the Surgeon.

TUMORS OF THE LARYNX. Simple Tumors.—*Papillomata* form the most common simple tumors of the larynx. They appear as cauliflower-like growths of all sizes up to that of a walnut. They may be single and pedunculated, or multiple and sessile, spreading widely over the upper opening of the glottis. Their most common seat of origin is the vocal cords. They are met with at any age, but are more common after thirty than before. In structure they resemble similar growths elsewhere, being composed of processes of vascular connective tissue covered with a layer of epithelium. The epithelium is that normal to the part, being, as a rule, squamous, though columnar epithelium is said to have been occasionally observed. *Fibromata*

are much less common. They form rounded or smoothly lobulated pedunculated growths, springing usually from the neighborhood of the vocal cords. They are almost invariably single. They are composed of ordinary fibrous tissue, covered with a squamous epithelium. *Myxoma*, *Lipoma*, and *Naroid Tumors* have been met with, but are of extreme rarity. *Cysts* arising from retention of the secretion of the mucous glands occasionally develop in the neighborhood of the epiglottis or false vocal cords. They form smooth, shining, rounded projections. *Polypus of the Larynx* is a term applied to any simple pedunculated growth, and has no pathological significance.

The simple tumors of the larynx cause alteration in the voice, slight cough, discomfort, and dyspnea, varying in degree with the size of the growth. Their true nature can be recognized only by careful examination with the laryngoscope.

Treatment.—These growths may be removed by one of two methods—the endo- or the ecto-laryngeal. There appears to be a general consensus of opinion amongst laryngologists that the endo-laryngeal method should always be attempted in the first instance. Should it fail, then the larynx may be opened and the growth removed from without. The endo-laryngeal method consists in removing the growth through the glottis by means of instruments

Fig. 751.—Endo-laryngeal Forceps.

specially designed for the purpose, guided by the laryngoscope. The instruments most commonly used are forceps, by which the growth can be seized and torn from its attachments; but in some cases, especially when the growth is of some size and distinctly pedunculate, wire snares or small écarteurs may be of use. In some cases, the destruction of the growth may be brought about by simply crushing it with a strong pair of forceps. These operations require practice both on the part of the patient and the Surgeon. The patient must be taught to keep steady, to hold his own tongue, and to tolerate the presence of the instrument. For this purpose, it is often necessary to train him for a week or two before any real attempt is made to remove the growth. The smaller papillary growths will sometimes disappear under the application of nitrate of silver; in such cases, therefore, the Surgeon should not be in a hurry to attempt operative interference. The accompanying drawings (Figs. 751, 752, 753) show various forms of forceps which may be used in these operations.

Should the endo-laryngeal operation fail or be impossible, the growth must be removed by an ecto-laryngeal operation. Mackenzie lays it down as a cardinal rule that no operation of this kind should be undertaken unless there is danger to life from dyspnea or dysphagia.

The operation most commonly performed is that known as **Thyrotomy**. It is advisable in most cases to perform a preliminary tracheotomy about a fortnight before undertaking the removal of the tumor. When the patient has quite recovered from this, and feels no further discomfort from the tube,

thyrotomy may be undertaken. The operation is thus performed: An incision is made accurately in the middle line from the thyroid cartilage to the cricoid cartilage. The cartilage is then carefully divided with a knife, and if it be ossified, with a fine saw. The alæ are then held apart with thumb hooks, and the interior of the larynx is fully exposed. A small piece of sponge may then be passed into the trachea so as to plug the opening above the tube, lest blood should pass into the lungs. The morbid growth may then be removed with scissors, and the surface from which it grew treated with nitrate of silver. After all bleeding has ceased, the sponge is removed and the parts accurately brought together, and the trachea tube is retained until the patient can breathe through the glottis with ease. Mackenzie has

Fig. 752. -Endo-laryngeal Forceps.

Fig. 753. -Endo-laryngeal Forceps.

published the results of 48 cases, collected from various sources. Of the 8.33 per cent. died, in 31.25 per cent. the operation was followed by persistent dyspnoea, requiring the use of the canula, and only 14.58 per cent. resulted in a perfect cure.

Tumors affecting the upper opening of the glottis or the epiglottis have also been removed by a transverse incision in the thyro-hyoid space. Mackenzie recommends that the incision should be made along the lower border of the hyoid bone, partially dividing the sterno-hyoid and sterno-thyroid muscles and the thyro-hyoid membrane. The head being thrown well back, sufficient space may thus be obtained to allow of removal of the epiglottis or a tumor situated in its immediate neighborhood. This operation is seldom required, as simple growths in this region can usually be removed from the mouth.

Malignant Tumors of the Larynx.—Both true carcinoma and sarcoma are met with in the larynx, but the former is far more common. The form of carcinoma met with is almost invariably squamous epithelioma. Cylindrical epithelioma has, however, been observed, and scirrhous glandular cancer said to have been seen. When sarcoma occurs in the larynx it is most com-

monly spindle-celled, less frequently round-celled or mixed. Butlin, who has collected the records of 23 cases of sarcoma, states that half the cases were spindle-celled. Malignant growths in the larynx may be intrinsic or extrinsic, that is to say, they may commence in the interior of the larynx, or spring from surrounding parts and secondarily invade it. All malignant growths in this region tend to assume a papillary form (Fig. 754), though they are rarely polypoid. They are most commonly single. The symptoms they give rise to are those of interference with speech and respiration, with some cough and expectoration, often mixed with blood. In the carcinomatous growth the glands are early affected. The situation of the tumor and its size are usually determined without difficulty by the laryngoscope; but it is not easy in many cases to determine the nature of the growth. For this purpose a piece of the growth can sometimes be removed with the laryngeal forceps, and submitted to microscopic examination. Death in such cases is necessarily inevitable, either by asphyxia or by constitutional infection, if the disease be left to run its course; and up to a comparatively recent period the Surgeon had no other means of prolonging life than by the performance of tracheotomy. Of late years, however, Operative Surgery has added extirpation of the entire larynx to its other triumphs.

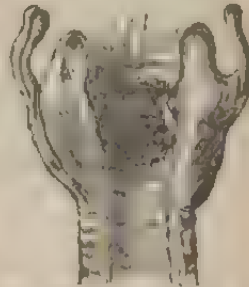

Fig. 754. Epithelioma in Larynx.

Extirpation of the Larynx.—Excision of the larynx, or *laryngectomy*, in part or in whole has been somewhat extensively practised of late years. The first case in which this formidable operation was undertaken was that of a man 35 years of age affected with syphilitic stenosis of the larynx. Dr. P. Heron Watson in 1866 excised the larynx, in this case the patient dying three weeks afterwards of pneumonia. In 1873, Billroth operated in a case of carcinoma of the larynx. The patient survived the operation, but died in a few months from recurrence of the disease. Since this time the operation has been frequently practised. Dr. Solis Cohen has collected the details of 65 cases of complete extirpation of the larynx. The practicability of the operation without causing the death of the patient has been fully demonstrated.

The diseases for which the larynx has been extirpated are chiefly sarcoma and epithelioma. Of the 65 cases in Dr. Cohen's tables, the operation was only done in 4 for non-malignant disease, in 5 for sarcoma, and in the remaining 56 for carcinoma.

Of the 4 non-malignant cases 2 died. The 5 in which the operation was done for sarcoma all recovered. And 2, those of Bottini, of Turin, and Caselli, of Reggio-Emilia, were alive 64 and 2 years respectively after the operation. These cases are the more remarkable, as in Bottini's the man not only recovered, but was able to return to his work as a postman and walk eight miles a day. In Caselli's case the sarcoma extended far beyond the larynx, and this Surgeon accordingly performed the remarkable operation of extirpating not only the larynx but a portion of the pharynx, the base of the tongue, the soft palate and tonsils. The patient, a girl of 19, was alive and well two years after this most formidable procedure. These two cases are the most successful on record, for, as Cohen most truly observes, the history of the remaining 56 presents a much more gloomy account. Of these 56 no less than 42 died either from the direct effects of the operation or from rapid recurrence of the disease—14 only recovering, and of these

only 6 have been reported as alive one year or more after the operation. 22 out of the 42 deaths occurred within the first fortnight, chiefly from shock and pneumonia. Indeed, pneumonia appears to be the great danger during the earlier period after laryngectomy. But the influence of shock is also apparent in the death-rate, and this is not surprising when we reflect that many of these operations occupied from one to three hours in their performance.

These results are by no means encouraging. There would appear to be some prospect of advantage from laryngectomy in certain cases, especially when the disease is recognized early and is intrinsic, and more especially if it is sarcomatous. In extrinsic malignant disease of the organ it is very doubtful whether it is a justifiable procedure. In such cases there is not only the imminent risk of a directly fatal result, but the absolute certainty of a speedy recurrence of the disease.

Laryngectomy, indeed, appears to offer no advantages over tracheotomy in such cases. By tracheotomy the patient is saved from the danger of immediate suffocation with little risk to life, and his subsequent existence will probably endure as long as it would in the face of the inevitably speedy recurrence of the carcinoma after complete extirpation of the larynx. The operation is clearly unjustifiable when the cervical glands are widely implicated, so as not to admit of thorough removal.

The operation must be varied somewhat according to the extent of the disease, but the following plan recommended by Foulis is applicable to most cases. A vertical incision must be made accurately in the middle line from the body of the hyoid bone to the second ring of the trachea. The soft parts are then to be turned off the larynx, all bleeding vessels being ligatured as they are cut. When the larynx is fully exposed and all bleeding arrested, the cricoid cartilage is drawn forwards with a sharp hook and the trachea divided, care being taken not to wound the œsophagus. The trachea is then at once plugged with a large vulcanite or leaden tube, slightly conical in shape and completely filling the passage. Several such tubes of different sizes should be at hand. The larynx is then drawn forwards and separated from the œsophagus and the lower part of the pharynx, the edge of the knife being carefully turned towards the parts to be removed. When all hemorrhage has ceased the wound may be partly closed, the tube being retained in the trachea. In the after-treatment the patient must be fed by means of a tube passed down the œsophagus. When the wound has contracted Gussenbauer's artificial larynx, containing a reed for the production of vocal sounds, may be introduced. If the disease is not found to be so extensive as was expected, part of the larynx may be saved, as, for example, the upper part of the thyroid cartilage.

CHAPTER LIX.

OPERATIONS ON THE AIR-TUBE AND ON THE CHEST.

LARYNGOTOMY AND TRACHEOTOMY.

THE windpipe may require to be opened to allow the formation of a temporary breathing aperture, in consequence of obstruction of the larynx by causes that are speedily removable; or it may be necessary to establish a permanent opening in the air-passage in those forms of chronic laryngeal disease, in which the obstruction depends upon alterations of structure which are not remediable.

Among the conditions requiring *temporary aperture*, may be mentioned all acute inflammatory affections of the larynx that give rise to obstructive oedema of the glottis; also traumatic conditions, such as the impaction of masses of food in the gullet, inducing asphyxia, and not capable of being immediately removed; scalds of the rima glottidis; the presence of foreign bodies in the air-passage; and oedema of the glottis from wounds of the thyro-hyoid membrane.

The establishment of a *permanent aperture* in the air-passage is especially required in chronic diseases of the larynx, attended by thickening of the mucous membrane, by abscess, or by necrosis of the cartilages—in fact, by all such conditions as cause obstruction not admitting of removal; so also, in cases of epithelioma or warty growth of the larynx, a permanent opening below the obstructed point may be required.

Opening the Windpipe in Membranous Laryngitis.—By membranous laryngitis is meant any form of inflammation of the larynx, accompanied by a coagulable exudation from the mucous membrane, forming a false membrane upon it, whether diphtheritic or not. It is not the place here to enter into the disputed point of the identity of croup and diphtheria. The exhaustive report of the able committee appointed by the Medico Chirurgical Society in the year 1879 clearly demonstrates the fact that inflammation of the mucous membrane of the larynx with membranous exudation may arise, not only as a result of diphtheritic contagion, but as an accompaniment of measles, scarlatina, or typhoid, and occasionally from "various accidental causes of irritation—the inhalation of hot water or steam, the contact of acids the presence of foreign bodies, and a cut throat." It seems possible also that a similar condition may arise from simple exposure to cold. To all these cases the term membranous laryngitis may be indiscriminately applied, as it merely expresses an anatomical fact without implying any theory. The committee made the excellent suggestion that *croup* should be used merely as a clinical term implying laryngeal obstruction, occurring with febrile symptoms in children, and not as indicating a special disease, of the existence of which there is no definite evidence. When the disease is evidently zymotic, and when the larynx is affected by extension from the throat, the term "diphtheria" is applied to it by common consent. Membranous laryngitis, from whatever cause arising, is a most fatal disease in childhood, at least 90 per cent. of those attacked dying, and a considerable proportion of the minority that escape owing their lives to the performance of tracheotomy. In acute catarrhal laryngitis, unattended by membranous

exudation, tracheotomy is scarcely ever needed, the disease yielding to milder methods of treatment.

The question as to whether the windpipe should be opened in membranous laryngitis has been much discussed. Were the disease limited to the larynx, and did death result from simple laryngeal obstruction, there could scarcely have arisen any question as to the propriety of performing the operation. But in the great majority of cases of all kinds, and in all those of zymotic origin, there are two distinct sources of danger: 1, that arising from asphyxia dependent on laryngeal obstruction; and, 2, that which is due to the extension of inflammation below the larynx into the bronchi and lungs. By tracheotomy we can doubtless remove so much of the danger as arises from the laryngeal obstruction; but we cannot remove that which is dependent on the often concomitant broncho-pneumonia. In fact, the question as to the performance of tracheotomy in these cases must be answered by the amount of laryngeal obstruction and the extent of pulmonary implication. If the child be in danger of death from laryngeal obstruction and spasm, timely tracheotomy will undoubtedly rescue it from this immediate danger and will be a proper operation; but if extensive broncho-pneumonia already exist, it will be worse than useless, and should on no account be practised. In cases in which the disease is evidently true diphtheria, and these undoubtedly form the vast majority, there is yet another danger. The windpipe may be opened, and the immediate occurrence of death from asphyxia warded off, but the zymotic disease remains and runs its course, the patient ultimately, in a large proportion of cases, dying of exhaustion or of the sequelae of the disease. Even though the relief afforded by operation be only temporary in the majority of cases, yet it is obviously proper where the danger from laryngeal asphyxia is imminent, that the Surgeon should rescue the patient from instant peril, and give him his only chance of prolonging or preserving life by opening the windpipe.

It has been very justly observed by Sir W. Jenner that by opening the windpipe in these cases, we save the patient from so terrible a death as that by asphyxia; and, even if life be ultimately extinguished by the disease, temporary ease will have been afforded, and death will occur in a less distressing manner; and that, if only one life in a hundred could in this way be saved, we should be justified in having recourse to the operation. Sir W. Jenner has made the important observation, that if the larynx be not invaded by the end of the first week of diphtheria, so as to require the windpipe to be opened, laryngeal obstruction rarely, if ever, occurs.

I have frequently performed the operation myself, though rarely with ultimate success, and this I believe is the general experience of other Surgeons. The operation was strongly advocated in France, more particularly of Trousseau, many years ago, when it was regarded less favorably in this country. But even in Paris it was not a very successful procedure; thus it appears that, at the Hospital for Sick Children in that city, the operation was performed in 215 cases in five years, and that of these only 47 were cured. Unless we assume that the disease, as occurring in Paris, is different from that we meet with here, it may fairly be doubted whether an operation which is in itself dangerous could have been necessary in many of the instances, and whether a large proportion of the children might not be recovered under ordinary medical treatment and without having recourse to surgical operation.

The propriety, or rather the necessity, of the operation being now universally recognized, it remains to consider the indications for performing Trousseau strongly advocated early tracheotomy before collapse of the larynx had taken place to any extent, or the patient had become exhausted by it.

struggle for breath; and nothing is more certain than that the operation is rarely successful if performed *in extremis*. It may be taken as a rule that, when the voice is lost or nearly lost, and there is evident laryngeal obstruction gradually increasing, the sooner tracheotomy is performed the better. The degree of obstruction is estimated by the recession of the chest-walls during inspiration. If the lower ribs and epigastrium sink in with each inspiratory effort, it is wiser not to delay the operation.

The prospect of saving life after opening the windpipe in cases of diphtheritic asphyxia will greatly depend upon the age of the patient. Under two or even three years of age, recovery is extremely rare; as age advances, the chances of life proportionately increases, and in adults the prospect of recovery is considerable. In many cases the patient will get great temporary benefit from the operation, and will appear to be doing well for several days, perhaps for eight, ten, or fourteen; and then, to the great disappointment of the Surgeon, he will die, not from the effects of the operation, but from blood-poisoning or from extension of the disease to the bronchi and lungs.

In other forms of laryngeal obstruction not dependent on membranous laryngitis, there can be no question as to the propriety of the operation. No patient ought ever to be allowed to die from simple laryngeal obstruction, whether that be spasmodic or dependent on organic disease, without an attempt being made to save life by opening the windpipe. It is as unpardonable for a Surgeon to allow a patient to die of laryngeal asphyxia without an attempt at relief by opening the windpipe, even though life appear to be extinct, as it would be to let him die of hemorrhage without attempting to control the bleeding vessel.

Necessity for Promptitude.—When it has been determined to open the windpipe for acute disease, more especially supervening on chronic laryngitis, the less delay there is in having recourse to operation, the better; as the patient may at any moment be seized with laryngeal spasm, and be carried off. The operation ought always, however, to be completed, even though the patient have apparently expired before the windpipe has been opened; for resuscitation may, even in these extreme cases, be effected by artificial respiration. When life hangs on so slender a thread as it does in urgent cases of laryngeal obstruction, the first touch of the knife may cause a spasmodic seizure that may give rise to apparent death. It has twice happened to me to operate under such circumstances, and in both cases to be fortunate enough to save the patient's life. I was called many years ago to an elderly woman who was apparently dying from the supervention of acute upon chronic laryngeal disease. I lost no time in making an incision into the crico-thyroid membrane, but at the first touch of the knife she sank back, apparently dead. I immediately completed the operation, and introduced a large silver tube, through which the lungs were inflated; in the course of a few minutes, voluntary respiration recommenced, and the patient eventually recovered. She has never, however, been able to breathe without the silver tube, which she wears in her windpipe up to the present time. In another case to which I was hastily summoned by my friend Mr. Tweed, I found the patient, a young woman, in the last stage of asphyxia from acute disease of the larynx. I immediately proceeded to operate. As the patient's neck was short and thick, and the veins excessively turgid, there was profuse hemorrhage on the first incision being made; while we were waiting a minute or two until this would cease before opening the windpipe, the patient fell back and apparently expired. I lost no time in plunging the scalpel into the crico-thyroid membrane, and cutting down through the cricoid cartilage, so as to make a free aperture into the air-passages. On endeavoring to set up artificial respiration, I found the air-passages clogged with inspissated mucus,

which prevented the entrance of air into the lungs; the life of a feeble creature being at stake, and dependent on the immediate and full establishment of artificial respiration, I felt that there was only one thing to be done—to empty the chest of the matters loading it, and that this must be done instantaneously. I accordingly applied my lips to the wound, and sucked out three or four mouthfuls of blood and mucus, when I had the satisfaction to see that air could be made to enter the lungs. After artificial respiration had been kept up for some time, the heart began feebly to act, the face became less livid, and the circulation was reestablished; the patient eventually did well, and is now alive and in good health.

OPERATIONS.—In opening the windpipe the Surgeon has the choice of two situations in which he may make the aperture; either in the crico-thyroid membrane by **Laryngotomy**, or in some part of the trachea in **Tracheotomy**. Besides these two established operations, some Surgeons have performed a third—**Laryngo-tracheotomy**, by opening the crico-thyroid membrane, and dividing the cricoid cartilage with the upper ring of the trachea.

Whichever operation is performed, so soon as the windpipe is opened the patient is seized with an attack of spasm and convulsive cough, often attended by much struggling and distress, during which the whistling sometimes is heard as the passing of the air through the new passage is very loud and hurried. The patient, however, soon recovers, and then breathes naturally and easily, the signs of asphyxia disappearing.

The windpipe may require to be opened either by laryngotomy or tracheotomy for the following conditions: L.—Laryngotomy: T.—Tracheotomy.

1. Acute laryngitis with oedema of the glottis in the adult (L.).
2. Chronic oedema of the glottis with suffocating spasms (L.).
3. Syphilitic or other ulcerations of the glottis with chronic oedema (L.).
4. Membranous laryngitis in children (T).
5. Membranous laryngitis in adults (L.).
6. Necrosis of the cartilages of the larynx with obstructive thickening of tissues (T or L).
7. Epithelioma of the epiglottis and other growths obstructing the laryngeal orifice (L.).
8. Tumors in the larynx (L.).
9. Scald of glottis by boiling water or acids (T or L, according to age of patient).
10. Foreign bodies impacted in the larynx (L.).
11. Foreign body in the trachea or bronchus (T).
12. Impaction of foreign substances in the pharynx (T).
13. Asphyxia from any cause by which the glottis is mechanically closed (T or L, according to the age of the patient).
14. Accidents in operations about the head and face by which blood accumulates in the pharynx (L.).
15. As a preliminary step in certain operations on the bones of the face attended by much hemorrhage (T).
16. Laryngeal spasm or paralysis from compression of the inferior laryngeal nerve by aortic aneurism (L.).

LARYNGOTOMY is an easy operation. The crico-thyroid membrane almost subcutaneous, and may readily be reached by making a vertical incision in the medial line, between the sterno-hyoid, about an inch in length, and then a cross cut through the membrane with an ordinary scalpel. The air-passage having thus been opened a silver tube, curved on the flat, may be readily introduced and retained by tapes around the neck. The most troublesome result that can occur in this operation is the wound of a small

artery, the crico-thyroid branch of the superior thyroid which crosses the membrane. I have never seen any trouble arise from this; but, should it occur, the hemorrhage would readily be arrested by the application of pressure or ligature.

In cases of extreme urgency, it is recommended by some Surgeons that laryngotomy be performed by a transverse instead of by a longitudinal cut through the superficial structures in order to save time. In this opinion I do not agree; little if any time is saved, and peril may ensue by cutting across the branches of the anterior jugular veins—thus leading, as I have seen, to profuse hemorrhage, equally embarrassing and dangerous. There is, moreover, some risk of the formation of an acrial fistula. In all cases the longitudinal cut answers perfectly, and the crico-thyroid membrane can be opened by it in less than five seconds.

TRACHEOTOMY consists in making an opening into some part of the trachea, by exposing the tube and cutting across two or three rings.

There are three situations in which the trachea may be opened; above, underneath, and below the isthmus of the thyroid body, which usually crosses the air-tube opposite its second and third rings. Above the isthmus, the trachea is comparatively superficial, being covered merely by the skin and superficial fascia, the deep fascia, and the sterno-hyoid muscles. Beneath the muscles will be found a strong fascia, which comes downwards in front of the larynx from the hyoid bone and divides above the thyroid body, enclosing its isthmus between its two layers. This fascia is of some importance, as it is difficult to push the isthmus downwards so as to expose the upper rings of the trachea without notching this transversely. Below the thyroid gland the trachea recedes from the surface and is overlapped by the sterno-hyoid and sterno-thyroid muscles, beneath which is some loose areolar tissue in which lie the inferior thyroid plexus of veins, which are of large size, together with some tracheal branches from the inferior thyroid artery, and in rare cases an irregular arterial branch ascends from the aorta in front of the trachea to the thyroid body—the thyroidea ima. Beneath the deep fascia but superficial to the muscles on each side, lie the anterior jugular veins. These are variable in size, become larger below, and sometimes communicate by a branch crossing the line of the tracheotomy wound. The carotid arteries also are in close relation to the trachea on each side, being more especially in danger at the lower part of the neck. Opposite the episternal notch, the windpipe is crossed by the left innominate vein, which has been seen by Macilwain lying high at the very point where tracheotomy is usually performed. A glance at these important relations will suffice to indicate the difficulty that must in many cases occur in exposing and opening the trachea. This difficulty is greatly increased when the veins of the neck have become turgid in consequence of the pulmonic obstruction. It will be seen also that the trachea is less covered, and may consequently be much more readily reached above, than below, the isthmus of the thyroid gland. Though some Surgeons, as Velpeau, for instance, have recommended the opening to be made in the lower part of the tube, no advantage whatever is gained by so doing, whilst the difficulties of the operation are very seriously increased; and in practice it is almost invariably opened at its upper part, usually through the first and second rings.

The patient should, if possible, be placed on a table in a good light. In operating on an adult, it will be found sufficient in most cases to support the patient's shoulders with pillows, while the head is thrown as much back as practicable. In children, a small firm pillow must be placed under the neck, so as to throw the trachea as much forwards as possible. A stocking stuffed tightly with towels will usually be found to answer the purpose admirably.

An assistant should be seated above the head of the patient; it is his duty to hold the head steady with his wrists, while with a blunt hook in each hand draws the wound open during the operation. At the same time he must keep the chin exactly in the middle line to serve as a guide to the Surgeon. The hooks must never be entrusted to separate assistants, as they would certainly displace the wound from the middle line. If another assistant is present he may give the anæsthetic and sponge the wound. The Surgeon stands to the right side of the patient.

If it be intended to open the trachea *above* the isthmus of the thyroid body the incision must be commenced at the upper border of the cricoid cartilage and carried downwards directly in the middle line for an inch to an inch and a half, according to the age and size of the patient and the amount of subcutaneous fat. After dividing the integuments, the interval between the sterno-hyoid muscles must be found, and these drawn apart. Any vessels that present themselves should be avoided as carefully as possible, and held on one side by the assistant, who has charge of the blunt hooks. After the muscles have been drawn apart, the isthmus of the thyroid body comes into view, and above it is the fascia that supports it and covers the trachea. The *upper* border of the cricoid cartilage should then be felt for; it can be recognized by its forming a slight projection above the level of the trachea, which can be readily felt with the finger-nail. If the parts are well in view, the trachea may be best exposed by the plan recommended by Rose. The layer of fascia in front of the trachea which supports the isthmus is picked up with a pair

Fig. 745.—Operation of Tracheotomy.

of forceps at the lower border of the cricoid cartilage, and carefully lifted transversely for a distance sufficient to admit the handle of the scissor beneath it, by means of which the isthmus is pushed downwards and the upper three rings of the trachea clearly exposed. The trachea is then fixed with a sharp hook and drawn forwards to steady it while the operation is made. It is usually recommended to insert the hook in the middle line immediately below the cricoid cartilage, but the plan devised by J. M. Rose will be found more convenient. In this, the hook is inserted about an eighth of an inch from the middle line parallel to the intended incision, its point being made to reappear so as to puncture the trachea in two places and get a firm hold on it. The opening in the trachea is then made, the knife being held by the blade about half an inch from its point, so that it is possible to transfix the trachea and puncture the œsophagus. The incision must be made from below upwards, and should include about three rings of the trachea. The tube may now be easily inserted by drawing the upper opening well forwards with the hook that has been inserted parallel to

while the other is depressed with the end of the tube. If this be done, it goes in without any difficulty. It must then be retained by tapes round the neck.

If the trachea is to be opened *below* the isthmus of the thyroid body, the incision must commence immediately below the cricoid cartilage, and be carried downwards for at least an inch and a half. The muscles are exposed and separated as in the previous operation. In this situation the sternohyoids will probably come into view after the sterno-hyoids have been drawn aside. The isthmus, having been exposed, must be drawn upwards with a blunt hook. At this stage of the operation, the large veins forming the inferior thyroid plexus must be carefully avoided, and if the wound be very deep, it is safer to use the scalpel to a limited extent, dilating the deeper parts of the wound with its handle or with a director. In young children the thymus gland will appear in the lower part of the incision, and require to be pushed downwards.

Opening the trachea *beneath* the isthmus is seldom necessary, but should it be unavoidable, the tissue of the thyroid body may be divided with but little bleeding if the knife be kept accurately to the middle line. *Laryngo-tracheotomy*, in which the cricoid cartilage is divided with one or two of the upper rings of the trachea, is occasionally performed intentionally, but more often accidentally, in young children, the cricoid being mistaken for a ring of the trachea. The accident, if such it can be called, is not productive of any injury to the patient.

The question as to the safety of the administration of chloroform in these operations often occurs. I believe that it may always be given safely except in cases of extreme syncopal asphyxia, where, as sensibility no longer exists, it is unnecessary. Laryngeal inflammation and obstruction are always associated with so much spasm, more particularly in children, that it will often be found that the patient respire more easily and fully whilst under the influence of chloroform than before its inhalation was commenced; and, as the anaesthesia materially facilitates the operation by doing away with his writhings and strugglings, I invariably have recourse to it when I perform tracheotomy on children. In laryngotomy in the adult it does not appear to me to be necessary.

Difficulties and Accidents.—This operation is often attended by extreme difficulty, and not unfrequently by much danger.

The difficulties occurring in tracheotomy are chiefly referable to four heads: 1. Difficulty in Exposing the Trachea; 2. Profuse Hemorrhage; 3. Difficulty in Opening the Trachea; and, 4. Trouble in Introducing the Trachea-tube.

1. The *Difficulty in Exposing the Trachea* increases greatly as the incisions approach the sternum, and is especially great in stout, short-necked persons. The want of an assistant to hold the wound open adds greatly to the difficulty of the operation. This may, however, be overcome by the use of the ingenious "Automatic Retractor" devised by R. W. Parker (Fig. 756). The accidents in this part of the operation arise very commonly from taking the guides incorrectly. In their anxiety to open the trachea above the thyroid body, young operators are apt to make the incisions too high. The Adam's apple of a young child, especially when covered by much fat, is scarcely to be felt, and the hyoid bone is sometimes mistaken for it. Owing to this error, I have more than once seen the thyroid cartilage partly divided, and in one case an opening made even in the thyro-hyoid space. The mistake is avoided by taking the sternal notch as the guide, and making the incision in a child reach to about a finger's breadth above it. Insufficiency of the incision is a frequent source of difficulty. Even in the smallest

children it should never be less than one inch in length. Deviation from the middle line is a common cause of accident, leading to wounds of the thyroid body or even of the carotid artery, or to great difficulty in finding the trachea. It may be the fault of the assistant, who should keep the chin exactly in the middle line as a guide to the Surgeon. In very young children an inexperienced assistant may even draw the trachea on one side with the blunt hook.

Fig. 786.—Automatic Retractor.

2. The **Hemorrhage** may occur either from arteries, from veins, or from the thyroid gland. Arterial hemorrhage is less frequent and troublesome than the bleeding from other sources. When it occurs, it happens chiefly from the wound of some anomalous branch, or from that of the small tracheal vessels. Desault has, however, mentioned a fatal case, in which death arose from a wound of the carotid. The arterial anastomosis of the isthmus of the thyroid body may, if this part be enlarged, occasion some difficulty in the performance of the operation; but the main source of danger is unquestionably the *venous bleeding*. Not only are the plexuses of veins of large size, more particularly where they cover the lower part of the trachea, but they become immensely gorged by the asphyxia that necessitates the operation. Hence, when they are wounded, the bleeding may be so abundant as scarcely to be controllable, and may very greatly retard the after-steps of the operation. Many Surgeons of authority in these matters advise that the windpipe should not be opened until all, or nearly all, the bleeding has ceased: lest the blood, entering the bronchi and lungs through the aperture, asphyxiate the patient. But in this way much valuable time may be consumed, and the patient may be fatally exhausted by a tedious and prolonged operation, and by the loss of an unnecessarily large quantity of blood. The hemorrhage in this operation is almost entirely venous, and is, in a great measure, dependent on the distention of the veins of the neck, which occurs in asphyxia as the result of the accumulation of blood in the right cavities of the heart, consequent upon the obstructed circulation through the lungs; and the bleeding will continue so long as that obstruction remains unmoved. But as the respiratory process is reestablished, this obstruction to the pulmonary circulation diminishes, the cardiac cavities become unloaded, the venous turgescence of the neck subsides, and the hemorrhage proportionately lessens. This I have repeatedly found in asphyxia artificially induced in animals; and I have often seen it in the human subject, in cases in which it has become necessary to open the windpipe at once, without waiting to arrest hemorrhage. Hence, except in those instances in which an arterial twig or large venous trunk has been wounded, and which must of course be secured, the occurrence of bleeding, though tolerably smart, need not deter the Surgeon from opening the windpipe; as the relief afforded to respiration will induce a corresponding and rapid diminution in the venous turgescence of the neck, and in the consequent flow of blood from the wound.

It is important to bear in mind that the risk of hemorrhage is not entirely avoided by the use of blunt instruments. The veins are very thin walled

and easily torn, and I have seen very troublesome bleeding caused in this way by the incautious use of a director. The difficulties arising from hemorrhage are very greatly increased by an insufficient incision. There is seldom any trouble in arresting the bleeding if the wounded vessel can be clearly seen. Sir Spencer Wells's forcipressure forceps will be found invaluable under these circumstances, as the vessel can be seized and the forceps left attached till the operation is completed. Should blood accidentally enter the trachea in such quantities as to threaten suffocation, it must be sucked out either by the mouth applied to the tube, or by an aspirator tube passed down the trachea. As in diphtheria it is extremely dangerous to suck the tube, it is advisable, when performing tracheotomy, always to have an aspirator at hand in case of need.

3. Another difficulty in tracheotomy sometimes attends the process of **Opening the Trachea** after it is exposed. In consequence of the convulsive breathing of the patient, the sterno-mastoids are put upon the stretch, thus

Fig. 757.—Trachea-hook Director.

increasing considerably the depth of the wound in the neck; and, at each short and gasping respiration, the air-tube is rapidly jerked up and down, approaching to and receding from the surface in such a way that the scalpel cannot be thrust into it with safety. In order to do this with the least risk, a sharp-pointed hook should be passed between two of the rings, and the tube, being thus fixed, opened by cutting upwards (Fig. 755). Or the hook, being grooved along its convexity, as Edwards recommends (Fig. 757), is to be introduced under the cricoid cartilage, and the air-tube pulled up and opened by sliding the scalpel along the groove of this hook-director. I

Fig. 758.—Cutting Trachea-hook.

have found it advantageous in some cases to open the trachea with a cutting hook, such as is here represented (Fig. 758). By means of an instrument of this kind, the trachea is first fixed and then divided without danger to the patient.

The only accident likely to happen at this stage of the operation is wound of the œsophagus. This is avoided by steadying the wrist on the sternum while making the incision, by drawing the trachea well forward with the sharp hook, and by holding the knife by the blade so that not more than half an inch projects beyond the finger and thumb. I have heard of a case in which, for want of these precautions, not only was the œsophagus wounded but at the post-mortem examination the mark of the knife was found upon the bodies of three of the cervical vertebrae.

4. After the trachea has been opened, the next point is to **Introduce a proper Tube**. In doing this, special care must be taken not to push the tube into a sort of pouch which always exists at the lower angle of the wound, between the trachea and the deep fascia of the neck. This error is not only embarrassing in the highest degree to the Surgeon, but dangerous to the patient by the delay it occasions, by the compression exercised on the

trachea below the opening into it, and by the suction of blood into the aperture in the air-tube. It is best avoided by expanding the tracheal opening with the dilator (Fig. 761), and passing the tube between the blades of that instrument, or by adopting the method already described of inserting the sharp hook parallel to the line of incision instead of above it. In passing the tube into the trachea some difficulty may be experienced, owing to the elasticity of the sides of the incision in the windpipe, in consequence of which one of them is apt to be doubled in under the end of the instrument. This may be avoided by introducing the sharp hook in the manner described above, or by the use of Fuller's bivalve tube introduced closed (Fig. 759), and then expanded by slipping a canula into it (Fig. 760). If the rings of the trachea be very rigid and unyielding, the silver tube may most conve-

Fig. 759.—Bivalve Tube closed.

Fig. 760.—Bivalve Tube with Canula introduced.

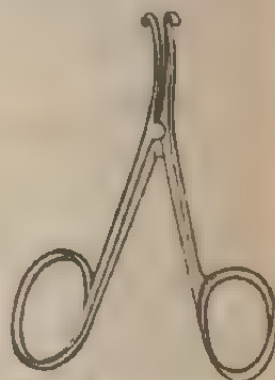

Fig. 761.—Trachea dilator.

niently be introduced by expanding the incision by means of the trachea-forceps (Fig. 761), and then passing it between or under their blades.

Some Surgeons prefer, instead of the scalpel, to open the trachea with cutting forceps, or with a trocar carrying a canula in the shape of a trachea-tube, which is then left in the air-passage; these instruments, though ingenious and in some respects useful, do not appear to me to be so safe or easy of management, especially in children, as the scalpel and trachea hook.

Trachea-tubes should be of such a calibre throughout as to admit of respiration being carried on through them, without any effort on the part of the patient. Many of those that are to be met with in the instrument-makers' shops, though very wide at the mouth, are far too narrow and contracted at the lower aperture to allow a free and unimpeded passage for the air of respiration, being made very conical in order to admit of easy introduction, and to occlude the opening in the windpipe completely, so as to prevent the entry of any blood by the side of the tube. The disadvantage attending this mode of construction may in a great degree be remedied by having a longitudinal opening like the large eye of a catheter cut in the side of the tube, immediately above the inferior aperture.

One great difficulty which the Surgeon has to meet in cases of tracheotomy or laryngotomy, is to keep the tube from being clogged and obstructed by mucus. It is usually stated that the tube may be kept clear by the occasional introduction of a feather, of a piece of sponge fixed to a stick, or a bit of lint wrapped round a probe. In this way it is true that the frothy mucus that collects in the tube may be readily enough cleared away; but

this simple means will in very many cases be found to be quite ineffectual in removing another kind of mucus that in certain conditions rapidly accumulates to a considerable extent within the tube. On examining a trachea-tube that has been worn for but a few hours, it will be found that its interior becomes gradually lined by a coating of dry, gummy, and very tenacious mucus, which is so firmly adherent to the metal that it must be detached by means of a pen-knife or pointed probe; or, what is better, by pouring boiling water through the tube. This tenacious mucus, collecting in largest quantity at the inferior aperture, and at the curve of the trachea-tube, may block up its calibre to a very great and dangerous extent, whilst the mouth of the tube appears to be perfectly pervious and free. Though feathers and pieces of stick armed with sponge or lint have been introduced from time to time, these, passing over this dry mucus, are quite unable to detach it from the side of the tube, and bring away merely the sputa and more frothy mucus.

Obré devised a very simple means to remedy this inconvenience. It consists in the trachea-tube being made of uniform calibre throughout, and having an interior tube accurately fitted to it, and projecting about one-eighth of an inch beyond the lower extremity of the outer tube. It is in the projection of the internal tube beyond the lower end of the external one that the great utility of this contrivance consists. If the two tubes be of the same length, or still more, if the innermost tube be the shorter, a plug of mucus may be left at the end of the outer canula, on the withdrawal of the inner tube. But if this be the longer of the two, the end of the outer tube will be effectually cleared every time it is withdrawn, which may be done as

Fig. 762.—Trachea-tube, Side view.

Fig. 763.—Trachea-tube, Front view.

Fig. 764.—Laryngeal tube.

often as any mucus collects, without in the slightest degree disturbing the patient. The two tubes are fixed by means of a button, attached to the edge of the outer one (Figs. 762, 763). The bivalve trachea-tube (Figs. 759, 760) is constructed on the same principle, the inner tube being longer than the outer; and it possesses the additional advantage of being readily removed for the purposes of cleaning, and as easily replaced. When used for laryngotomy, the tube may conveniently be curved on the flat (Fig. 764); the longest diameter being lateral instead of antero-posterior, thus being adapted to the form of the aperture in the crico-thyroid membrane.

It sometimes happens that, in consequence of the tube becoming detached from the shield, it slips into the trachea, where it acts as a foreign body. Cases of this kind have been related by Walters, and by J. W. Ogle. The removal of the tubes was effected by means of forceps. For the prevention of such an accident, it has been suggested that the trachea-tube should be formed in one piece, instead of in two pieces soldered together.

When a trachea-tube has been worn for any length of time, it will almost always be found that ulceration has taken place in the trachea at some point as the result of pressure. The discharge from this ulcerating surface and the increased secretion caused by the accompanying irritation, add greatly to the difficulty experienced in keeping the tube from becoming choked. To overcome these difficulties, Marrant Baker has employed a tube made of India-rubber, such as is used in the manufacture of the India-rubber catheter. It has sufficient rigidity to prevent its collapsing, but not sufficient to give rise to irritation or to cause ulceration. It is to be introduced after the first twenty-four hours, a silver tube being used till then. The tube is large but the ease with which it can be removed and reintroduced is so great that there is no difficulty in keeping it clean; in fact, the irritation produced in so doing is said to be less than that caused by the removal of the inner tube of any ordinary double trachea-tube. Baker has found, from

experience in a considerable number of cases, that it is worn with much greater comfort to the patient than a rigid tube.

Fig. 745. Baker's Tracheotomy-tube.

R. W. Parker has pointed out that the ulceration caused by the point of the canula is in great measure due to the fact that the ordinary quarter-circle tubes do not correspond with the natural direction of the trachea; he has therefore devised an angular tube to overcome this difficulty. It is fitted with the *marble collar* invented by Roger, of Paris, which was found to be more comfortable to the patient than a rigid shield.

Tracheotomy in Children is never easy, and is at times a dangerous operation. The difficulty of the operation arises more particularly in infants and very young children from the shortness of the neck, and the depth and small size of the trachea. Before the age of puberty, this tube is usually thickly covered by a quantity of loose granular fat, containing many vessels and is of small size, so that a slight deviation of the incision to one side may readily lead the Surgeon astray, and into dangerous proximity with the carotid arteries. The danger of the operation results from the size of the venous plexuses in connection with the thyroid body. In performing this operation in young subjects, chloroform should always be administered. This may be done with safety, even though the most urgent asphyxia be present; the difficulty of respiration, being in a great measure spasmodic, is relieved by the anæsthetic. If chloroform be not given, the struggles of the child will seriously embarrass the operator. The dangers and difficulties of the operation are avoided only by attention to the advice already given, to keep accurately to the middle line, to avoid operating too high, mistaking the hyoid bone for the pomum Adami, to make a free enough incision, and above all to avoid needless hurry in cases in which asphyxia is not imminent, and to do the operation by a careful process of dissection, rather than by irregular tearing with blunt instruments.

Comparison of Tracheotomy and Laryngotomy.—On comparing tracheotomy, as ordinarily performed, with laryngotomy, I think there can be little doubt that the Surgeon should give the preference, in all cases when it is practicable, to the latter operation on account of its greater simplicity, safety, and rapidity. When the windpipe is to be opened for the extraction of a foreign body, tracheotomy should be performed in preference to laryngotomy, as the latter operation does not provide a sufficient opening for expulsion or extraction. In children the larynx is so little developed that tracheotomy must always be done. In all cases in which the obstruction

respiration is produced by inflammatory effusion into the submucous areolar tissue, or oedema glottidis, whether dependent upon idiopathic or erysipelatous laryngitis, or chronic disease of the larynx, or upon the irritation and inflammation excited by swallowing boiling water or the stronger acids, in my opinion, laryngotomy is the operation that should be preferred in the adult; and this opinion is based on the following reasons.

1. As in laryngotomy the air-tube is always open below the seat of obstruction, there can be no necessity to make an aperture further from the seat of disease. In laryngitis, whether that affection assume the acute or the chronic character, the obstruction to breathing is in a great measure mechanical, and depends upon the infiltration of the submucous areolar tissue of the larynx, and partly of the large plane of this tissue, which lies behind the larynx, and which, by expanding, as it were, into the pharynx, obstructs deglutition, and afterwards, by the extension of this swelling and infiltration to the lips of the glottis and the interior of the larynx, causes an impediment to the entrance of air into the bronchi. But, as has been pointed out by Sir Prescott Hewett, this submucous areolar tissue terminates at the true vocal cords, where the mucous membrane becomes directly applied to the subjacent fibrous structures; the swelling and consequent mechanical impediment are hence confined to the limits of the thyroid cartilage, and any opening made below this will clear the lowest limit of the disease, which is always accurately and almost mathematically bounded below by the vocal cords. Hence an aperture in the crico-thyroid membrane is quite as effectual as one in the trachea.

2. Laryngotomy is a far safer operation than tracheotomy. On this point I need scarcely dwell; a glance at the anatomy of the parts concerned will be sufficient to establish it. The crico-thyroid membrane is nearly subcutaneous, and no parts of importance can be wounded in opening it, if we except the small crico-thyroid artery which crosses it, and which might be cut across, but from which I have never seen any trouble arise. The trachea, on the contrary, is not only deeply seated, but covered by a large plexus of bloodvessels, which when rendered turgid by the asphyxiated condition that exists when an operation is required, pours out a large quantity of dark blood, and thus seriously embarrasses and delays the Surgeon at a time when the life of the patient depends on the speedy admission of air to his lungs.

3. Laryngotomy can be much more quickly performed than tracheotomy. This I look upon as an inestimable advantage in many of the cases requiring operation; a few seconds more or less being sufficient to turn the balance either in favor of life or of death. The rapidity with which laryngeal obstruction—partly mechanical and partly from spasm—sets in, is sometimes so great, more particularly when an acute inflammation supervenes on chronic disease of the larynx, that life may be extinguished before the Surgeon has time to open the windpipe, if he endeavor to do so by tracheotomy. In extreme cases, as where the lungs have become slowly engorged, the action of the heart is already enfeebled, and a sudden spasm occurring at the glottis, will at once place the patient beyond recovery. But even though life appear for the moment extinct, it is the imperative duty of the Surgeon to open the air-passage as speedily as possible, and to endeavor, by means of artificial respiration, to recall the flickering spark; and it is impossible to experience a greater satisfaction in the exercise of our profession, or to witness a greater triumph of art, than in thus snatching a patient out of the very jaws of death.

An objection has been urged to laryngotomy in these cases, that it does not allow the patient to wear a tube without much irritation being induced

This, however, I have not found to be the case in my practice. I have two patients who have worn silver tubes in this situation a considerable number of years, in one case as many as twelve, and in whom no special irritation has been occasioned by them.

The conditions which necessitate an opening in the windpipe, and the operation adapted to each, have been already given (p. 672).

After-treatment of Laryngotomy and Tracheotomy.—In all cases after the windpipe has been opened, the patient should be placed in a well-warmed room, the air of which should be kept moist by means of steam. A flat piece of muslin folded two or three times may be laid over the opening of the tube to exclude dust. If the operation have been performed for some temporary obstruction of the glottis, such as the impaction of a foreign body, the tube may be taken out as soon as the cause is removed, and the wound allowed to heal by granulation.

The after-treatment of tracheotomy for membranous laryngitis requires special attention, as the success of the operation depends almost entirely upon it. The objects in view are, 1st, to provide a warm moist atmosphere, in order to diminish as far as possible the risk of bronchitis; 2d, to keep the tube open and free; 3d, to hasten the separation of the membrane and limit its extension; and, 4th, to remove the tube at the earliest possible period.

A warm moist atmosphere is best provided by placing the child in a bed over which a sort of tent of sheets is reared, supported by pieces of annealed iron attached to the legs of the bedstead. One side of this tent must be left open, and through this opening a current of steam must be introduced from a kettle, to the nozzle of which a tin tube is attached. The best apparatus for this purpose is the "croup-kettle," invented by R. W. Parker, which supplies a current of warm air mixed with the steam, thus efficiently maintaining ventilation as well as warmth and moisture. By its means the temperature can be easily regulated, so that there is little risk of weakening the child by over-heating. 2. The tube must be kept clean by frequently removing the inner part and washing it with warm water and cleaning the inside with a feather. If it is caked inside with dried mucus, this will be better removed by a solution of carbonate of soda. After the fourth day the whole tube also may be removed and cleaned once every twenty-four hours. The patient must be constantly watched day and night, and any mucus that appears at the orifice of the tube during efforts at coughing must be wiped away with a sponge. 3. To hasten the separation of the membrane and to prevent its extension various substances may be administered by inhalation. Acting on the theory that the formation of the membrane is dependent on the micrococci which are invariably found in it, quinine, carbolic acid, creosote, and eucalyptus inhalations have been recommended. Carbolic acid, creosote, and eucalyptus oil may be administered by adding a few drops to the water in the kettle, from which the steam is being supplied. Quinine may be given by means of a spray from a Siegel's apparatus, the solution used containing about four grains to the ounce. Solvents may be used in the same way to soften the membrane; the best of these is carbonate of soda (gr. xx to 3j). Lactic acid also has been recommended, but it does not seem to be superior to the soda solution. These substances in spray may be used every two or three hours, the child being wrapped in a macintosh and at the time to avoid wetting the clothes. R. W. Parker, believing that in all cases of membranous laryngitis the disease is at first local, and that the general symptoms are due to the absorption of the unhealthy products of the local process, insists very strongly on the necessity of clearing these away both at the time of the operation and afterwards. Before inserting the tube he recommends that the incision in the trachea should be held open with

hooks or a dilator, while all membrane within reach is removed by means of a feather which has been previously soaked in a solution of carbonate of soda. In order to clear the larynx the feather may be passed upwards into the mouth. This apparently severe treatment has in his hands proved very successful, no fewer than 8 out of 16 cases thus treated having recovered.

4. The removal of the tube should always be accomplished as soon as possible. It is often difficult to determine when this can be safely done. Many tubes are made with an opening at the upper part, so that the patency of the glottis can be ascertained by placing the finger over the external opening and observing the effect. The return of the voice, more or less perfectly, when the outer opening is closed, is usually a sign that the tube may be safely removed. In rare cases there is much delay in getting rid of the tube, owing to a persistence of the laryngeal obstruction. This may be due to adhesions in the larynx, which may be broken down by an instrument passed upwards from the wound. In other cases it seems to result from paralysis of the laryngeal muscles. Centric contraction in the site of the opening in the trachea is a rare complication. In most cases the tube can be removed without ill-effect in about a week.

The feeding of the patient must not be neglected, even if considerable persuasion be necessary to make the child swallow. Food should be given about every two hours, and soft solids will often be taken more easily than liquids.

SURGICAL OPERATIONS ON THE CHEST.

TAPPING THE PLEURAL CAVITY.—The operation of **Tapping the Pleural Cavity** is required in cases of hydrothorax, empyema, and hemothorax. The point of selection is a spot in the fifth intercostal space on the lateral median line. This point is crossed by a line drawn horizontally round the body from the nipple to the spine.

As it is of great importance in cases of *hydrothorax* to exclude the air from the pleural sac the operation is now almost invariably performed by the aspirator. The original aspirator, as invented by Dieulafoy, slightly modified (Fig. 93, vol. i. p. 254), will be found the most convenient instrument, as it can be converted into a siphon at will. The ordinary bottle-aspirator (Fig. 766) will, however, usually answer the purpose well enough. The air having been exhausted from the bottle by means of the air-pump, and the stopcock closed, the chest is tapped in the way to be presently described with the aspirator-trocar; and the cock in its side being turned on, the fluid rushes into the exhausted bottle to fill up the vacuum.

Other instruments also have been designed for the purpose of preventing the entrance of air during the operation. Of these the two most efficient are the "*piston-trocar*" (Fig. 767), or Thompson's "*siphon-trocar*" (Fig. 768).

If the "*piston-trocar*" (Fig. 767) be used, the tap should be closed as the stylet is withdrawn, and an India-rubber tube attached to the end of the canula. The tap being then opened, the fluid flows along this into a vessel containing a 1 in 20 solution of carbolic acid. If the *siphon-trocar* be used the fluid is allowed to run off by the elastic tube, the end being in the same way immersed in an antiseptic solution.

In the absence of all special instruments, the chest may be safely tapped with a common trocar by the simple method suggested by Reybard. A piece of thick linen or cotton rag free from holes is made into a funnel, the narrow end of which is tied tightly round the canula immediately below its expanded end. The funnel is then thoroughly soaked in carbolic oil (1 in 10). When the trocar is withdrawn the funnel of oiled rag hangs down

from the end of the canula, and serves to direct the fluid into a vessel to receive it, and at the same time it forms an efficient valve which prevents the entrance of air during inspiration.

Whatever plan be adopted, the side of the chest, the operator's hands, and all instruments used must be carefully washed in a solution of carbolic acid.

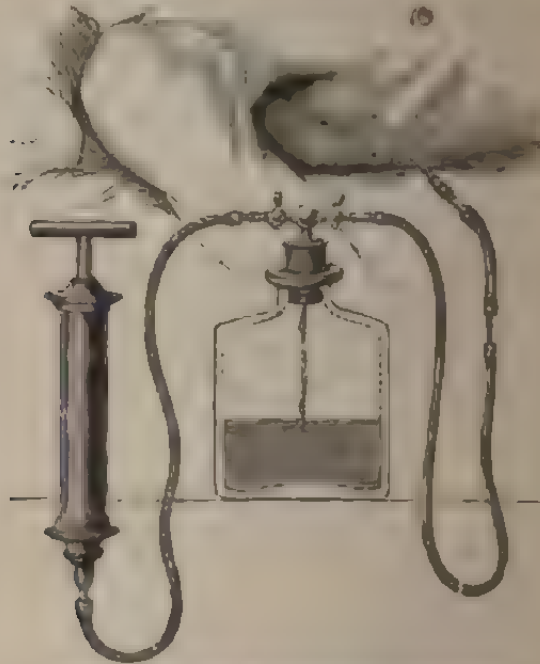

Fig. 766.—Tapping the Chest by the Bottle-aspirator.

(1 in 40). The *lower* border of the sixth rib is then felt for, and if a trocar is being used, a small incision may be made through the skin, parallel to it, in the mid-axillary line. The point chosen should correspond to the interval between two digitations of the serratus magnus. If the aspirator is used, no incision is required. The skin is then drawn upwards till the point chosen in the skin corresponds to the upper border of the rib, and the point

Fig. 767.—Piston-trocar for Tapping the Chest.

of the trocar is then slipped over its margin and thrust sharply and firmly into the pleural sac, so as to make sure of penetrating the thickest pleura and any layer of false membrane, which if the instrument were pushed slowly on, might be thrust before it. By thus passing the trocar immediately

the rib any risk of wounding the intercostal artery or nerve is avoided, drawing up the skin before so doing the superficial opening and the intercostal muscles and pleura do not correspond, and thus the trocar is efficiently closed. After the withdrawal of the canula the incision is covered with some dry cotton-wool and collodion, or by an adhesive plaster, and will usually unite without trouble. After tapping the lung will expand and fill up the cavity previously occupied by the fluid.

If a siphon-trocar is used, the details described in vol. i. p. 253, must be attended to. It must be remembered that when the vacuum is moderately great the lung is being expanded by the pressure of the atmosphere with

Fig. 768.—Tapping the Chest by the Siphon-trocar.

equal to fifteen pounds to the square inch. This may possibly cause injury by rupture of adhesions, and even cause hemorrhage from the vessels. Therefore, the patient complains of severe pain after a certain amount of fluid has been withdrawn, the operation must be at once brought to a stop, and repeated after an interval of a day or two, if necessary.

The importance of antiseptic precautions such as have been described in a simple case of hydrothorax, is very great. If they are carried out, tapping may be repeated several times without evil result; if they be neglected, the hydrothorax is very prone to become converted into empyema.

Surgical Treatment of Empyema.—When the fluid in the chest is purulent, it is generally acknowledged that the patient's chance of recovery is small, except by surgical interference. The consideration of general symptoms indicating the presence of pus in the pleura belongs to medicine rather than to surgery, and need not be discussed here. In all cases of doubt

the diagnosis may be readily made by means of the aspirator. The presence of pus having been determined, there should be no delay in resorting to it. The longer it is left, the more firmly the lung becomes bound down by adhesions, and the probability of its perfect expansion becomes less. Moreover, the pus may burrow beyond the limits of the pleural cavity, finding its way downwards into the iliac fossa, or more rarely into the abdominal cavity, and thus add greatly to the gravity of the case. In a certain proportion of cases empyema may be cured by simple aspiration. It is advisable, therefore, always to attempt this before proceeding to the operation of opening the pleura by an external incision. If after withdrawing the fluid the temperature falls, the general symptoms improve, and the fluid reaccumulates slowly, aspiration may be repeated with some hope of success. If, however, the relief is very slight and temporary, it is wiser at once to open the pleura and drain the cavity.

The operation of opening the pleura for empyema, though one of the most ancient in surgery, was until recently so unsatisfactory in its results that it was resorted to only in the last extremity. The fatal result that so frequently followed was due to septic fever and prolonged suppuration consequent upon imperfect drainage and decomposition of the retained fluid. With the view of preventing the accumulation of pus and diminishing the risk of septic poisoning Goodfellow and De Morgan adopted the use of Chiessignac's drainage-tubes with considerable advantage; but it was not until the introduction of efficient antiseptic treatment that the operation became really safe and successful. In discussing the operation the following points have to be considered: 1. The best point for making the opening; 2. The method of making it; 3. The form of tube; 4. The dressing and after-treatment; 5. The removal of the tube; 6. The results; and 7. The subsequent treatment of the cavity should the lung fail to expand.

1. *The best point for the opening* is the subject of considerable difference of opinion. Many Surgeons, following the ordinary rule of opening an abscess at its most dependent part, make the incision as far back and as low down as possible, the point chosen being either immediately below or a little distant from the angle of the scapula, in the seventh, or even as low as the mid-axillary costal space. The advantages of this situation are, however, very doubtful.

A patient suffering from empyema usually does not lie flat upon his back but inclined towards the affected side, so as to allow the freest possible room for the sound lung. An opening in the mid-axillary line with the patient more dependent while the patient is confined to bed, and at least equal to when he is in the erect position. Moreover, the ribs posteriorly are crowded together, making it difficult to insert the tube, and are thickly covered by the muscles, necessitating a longer incision and more discomfort to the patient after the operation. Another and more serious objection is that as the chest expands it first comes in contact with the chest walls posteriorly, the two pleural surfaces meeting last in front of the mid-axillary line. An opening made too far back is liable to become early overlapped by the expanded lung, and drainage is thus seriously interfered with, or a sinus difficult to heal may be left running forwards towards the anterior part of the chest. In cases in which the expansion of the lung is imperfect the diaphragm may rise up and obstruct the opening if it be made too low.

John Marshall has pointed out that immediately outside and below the junction of the fifth rib with its cartilage, is a point in the chest wall at which, from the comparative absence of superjacent muscles, the pleura is but slightly supported externally, and through this he believes an incision tends naturally to point. This point is above the origin of the external oblique, external to the insertion of the rectus and internal to the origin of

the serratus magnus. It is covered by the outer edge of the pectoralis major, and is beyond the anterior limit of the external intercostal muscle. That an empyema may perforate the chest at this spot is undoubted, but according to most authorities it tends to point higher up in the second or third space. Marshall, arguing from the excellent results that usually follow the opening of an empyema pointing in front, suggests that the opening should always be made on the thin point above mentioned. The only objection to this is that the ribs are somewhat closer together here than they are a little further back. The facts adduced by Marshall may, however, be said to demonstrate that openings made far back and low down do not present the advantages usually assigned to them, and that better results will probably be attained by making the incision more nearly over that part of the cavity which is the last to be closed by the expansion of the lung. The space between the fifth and sixth ribs, an inch to an inch and a half in front of the mid-axillary line, will probably be found the best in most cases. The interval between the ribs is wide enough here to admit a large tube readily, the covering of soft parts is not too thick, and the drainage obtained is efficient, and there is little risk of the opening becoming obstructed either by the expanding lung or the diaphragm. In cases of localized empyema the incision must, of course, be made over the collection of pus.

2. *The method of operating.* The operation should be performed with the strictest antiseptic precautions, including, if possible, the carbolic spray, which adds greatly to the certainty of preventing putrefaction, as it is almost impossible to prevent the entrance of air during inspiration. If the opening is made in the fifth space, it is not necessary in ordinary cases to remove a portion of a rib. The incision should be made about an inch and a half in length parallel to the upper border of the sixth rib, exposing it clearly. Any superficial vessel that bleeds may then be secured. The intercostal muscles and pleura are then punctured with the scalpel, guided by the left forefinger in the wound, immediately above the rib, so as to avoid the intercostal artery. The blade of the knife must be parallel to the rib. A pair of dressing-forceps may then be introduced and the wound stretched by expanding the blades, after which the tube may be at once inserted.

If the opening is made further back, or if, from partial absorption of the fluid part of the pus, the ribs have fallen together so as to leave an insufficient space for the introduction of the tube, a piece of the rib must be removed. Some Surgeons prefer always to remove a portion of rib, asserting that by this means a better opening is provided, but in the majority of cases it does not seem to be necessary. Should it be required, the operation is thus performed. An incision from two to three inches in length is made directly upon the rib, the periosteum of which must be divided in the long axis of the bone. The wound is then held widely open with the blunt hooks, and the periosteum stripped from the exposed part of the rib with an elevator, which must not be too sharp. No difficulty will be found in turning the intercostal artery out of its groove at the lower border. A curved elevator or a broad, flat director is then passed completely under the rib from below upwards, and the bone divided in two places with a saw or properly constructed bone-forceps, and about one inch of its length removed. The pleura should not be wounded up to this stage in the operation. All bleeding having been arrested, the pleura may be opened and the tube inserted. If it be preferred, the operation may be performed by a T shaped incision, but this usually presents no advantage over the simple longitudinal. The removal of a piece of rib is not accompanied by any difficulty or danger. Necrosis rarely follows, not more often, apparently, than after the simple insertion of a tube between the ribs. New bone rapidly forms from the

periosteum, and, after a time, the continuity of the rib is restored, and sometimes a mass of bone fills the intercostal spaces. The operation may, therefore, be undertaken without hesitation whenever it seems to offer the greatest advantage.

3. *The Tube.* The ordinary India-rubber drainage-tube should be used, but care must be taken that there is no hole in the part corresponding to the chest walls, as granulations are apt to sprout up into it and obstruct the lumen. It must be provided with a shield, lest it slip into the pleural cavity. The best form is that suggested by E. B. Baxter. It is thus prepared: In the middle of a piece of sheet India-rubber, about a sixteenth of an inch thick, and one inch and a half to two inches square, a round hole is cut of the same size as the drainage-tube. The tube is then passed through for a sufficient distance, and split into four pieces sufficiently long to reach to the four corners of the shield, to which they are attached by silver wire. The remainder of the tube on the other side of the shield must have holes cut in it at intervals, as in an ordinary drainage-tube. The tube must vary in diameter with the size of the patient. It should always be as large as can conveniently be passed between the ribs, but, as the discharge increases, a smaller size may be substituted. It need never be more than two or three inches in length. Nothing is gained by putting eight or nine inches of tube into the pleura; it cannot suck the fluid out, and only causes needless irritation.

4. *The dressing and after-treatment.* The most efficient dressing is eucalyptus gauze. Should it cause irritation, eucalyptus gauze may be substituted for it. Should this not be at hand, an efficient absorbent dressing may be made of salicylic or iodoform-wool, carded oakum or carbonized jute, covered with a piece of oiled silk, or some other impermeable material, to prevent the discharge from soaking through too soon opposite the wound. The dressing should be conducted under the carbolic spray, but, if this cannot be done, the entrance of impure air can be prevented with a little care, by covering the opening immediately with a piece of rag soaked in some antiseptic solution as the dressing is removed, and drawing it out again from under the fresh dressing as it is applied. For the first few days daily dressing is required, but the intervals may be gradually increased. It is seldom a valuable to leave it for more than a week, even if no discharge appears at the edge. In ordinary cases nothing is gained by washing out the cavity with antiseptic solutions, a proceeding which has been known to cause sudden death in more than one case, an accident the cause of which is quite unknown.

5. *The removal of the tube.* The time at which the tube should be removed is often a difficult point to determine. When the discharge becomes profuse, serious and very small in amount, the tube may at first be shortened to just long enough to retain its position. It is then often forced out by granulations, or by the expanding lung. It is well to examine the chest carefully with a probe before removing the tube, as the space may sometimes be larger than would be supposed, from the amount of discharge. Especially if the opening has not been deterred too long, the wound may be allowed to close after about a month. In adults, in whom expansion of the lung is often less perfect, and whose chest-walls are too rigid to sink in, the cavity usually closes before the cavity is closed, and in some cases recovery never takes place. Long sinuses, very troublesome to dress, are occasionally left. These commonly arise from opening too far back or too deep, or from the prolonged retention of tubes of needless length.

6. *The results of the operation for empyema* are usually as satisfactory as

as they were formerly unsatisfactory. In children, especially if the health is otherwise good, recovery is the rule. The temperature falls immediately after the operation, and unless some complication occurs seldom rises again. If the operation be not too long delayed, complete expansion of the lung usually takes place. This is effected by the gradual adhesion of the two pleural surfaces to each other, commencing in the angle of reflection from the chest-walls to the lung.

Operation for empyema without antiseptic precautions may occasionally be necessary when the means of proper treatment are not obtainable. The Surgeon must then rely on freedom of drainage, by which it may be possible so far to reduce the quantity of decomposable matter in the chest, that the dose of septic products absorbed by the patient shall not be sufficient to cause serious constitutional disturbance. This object is best attained either by making a free incision some inches in length between two ribs, or by the insertion of two tubes, one in the ordinary situation, and one at the lowest possible point in the pleura. The second opening may be made upon a curved probe passed in at the upper wound.

7. In cases in which the cavity continues after many months, or even years, to discharge, showing no signs of diminishing either by contraction of the chest walls or expansion of the lung, the operation of division of the ribs corresponding to the unclosed space, or of removal of an inch or more of bone from each, has been often attended with satisfactory results in many cases. The operation can be done as already described, portions of two ribs being removed from each incision.

TAPPING PULMONARY CAVITIES.

The operation of tapping vomica in the lungs in phthisical patients could not be done with certainty until the diagnosis of the existence and precise seat of such cavities could be accurately determined by auscultation; for, prior to Laennec's time, the physician could not diagnose a pulmonary cavity from a circumscribed empyema communicating with the lung. Hence the accounts of such an operation given by the older writers on medicine from the days of Hippocrates down to the present century must be received with scepticism. But that the idea had suggested itself at an early period to medical practitioners of treating pulmonary cavities by incision or tapping, there can be no doubt; for, without going back to the earlier medical writers, we find Dr. Barry, in 1727, recommending that phthisical cavities should be opened, with the view of giving a direct exit to the contained matters, and thus, by avoiding violent paroxysms of cough, that the parts may be kept at rest, and be more likely to undergo a cure. The proposal received little attention, and the practice—if ever adopted by others than Barry—died out, until, in 1836, it was revived by an empiric of the name of Ramadge, who appears to have tapped the chest on several occasions in order to let out pus from cavities in the lungs. In 1845 a most able young Surgeon—Storks—performed this operation with success, and with advantage to the patient, in a case of Dr. Hastings. Storks operated by making a long incision upon the upper border of a rib, and then opening up the cavity by means of a pair of forceps, inserting a canula to allow of the escape of the contents. This case attracted little attention at the time, and the operation again died out. Of late years, however, it has been revived, and Mosler, of Greifswald, has been more especially active in its resuscitation. Mosler not only tapped, but injected the cavities with disinfectant solutions.

In a case of Dr. Theodore Williams I operated by Storks's method. The patient, a gentleman 21 years of age, had an enormous cavity at the base of

the left lung. The discharge from this was not only profuse, but most horribly offensive; the patient being unable, even by the most violent and continued paroxysms of cough, to empty the cavity; a large quantity of decomposed muco-pus was always present in it. I made an incision at the upper border of the seventh rib in the lateral mesial line, and pushing a large trocar and canula through the sixth intercostal space, perforated with difficulty some very condensed tissue, probably thickened pleura and formed lung, and then penetrated the cavity. Nearly two pints of muco-pus were discharged, and the patient derived great relief; the cough diminished, and then entirely disappeared. The cavity was washed out with dilute tannic fluid. Immediately on the cavity being opened, a limited pneumothorax followed by extensive subcutaneous emphysema, occurred, but gave rise to no trouble at any moment. This was doubtless owing to a portion of non-adherent pleura having been perforated at the spot selected for the operation. The patient was greatly benefited by the operation, and lived for six months after in comparative comfort.

Dr. Pepper, of Philadelphia, who has published an exhaustive article on this subject, adopts a different procedure. He taps the vomica with a canula and trocar fitted to a syringe, and injects the cavity with dilute tincture of iodine. The results of his practice have in many cases been very encouraging.

Operation.—When the pulmonary cavity is deeply seated, more especially if basic, the operation may be conducted as follows: An aspirator-needle of sufficient size to permit the passage of thick pus, having been thrust through the intercostal space, opposite to the seat of the supposed abscess, and if it penetrate the cavity, indicate by the escape of pus that this has been reached. A horizontal incision about two inches long is then made in the intercostal space. A full-sized flat trocar (Fig 769) is then thrust through the pleura and

Fig 769.—Trocar for Tapping Pulmonary Cavity.

pulmonary tissue: the aspirator-needle, which has served as a guide, being withdrawn. The canula of the trocar, of silver or vulcanite, should bear a broad plate, by which it may be fastened by strings and plaster to the chest wall. As free drainage of the cavity, more especially if it be basic, is the main object of the operation, this may be secured by leaving the canula in the wound; or, if this be too short to serve as a free drain, it may be withdrawn and a rigid tube of some kind substituted. I have found a full-sized flexible prostatic catheter, cut of proper length, to be the most useful.

Should it be necessary to open up the lung substance more freely, this may best be done by means of dressing forceps, as in Hilton's plan of opening deep abscesses. There will be less danger of hemorrhage than if a scalpel be used. No antiseptics are needed when the contents of the cavity are already decomposing; free drainage is all that is required, and antiseptics, if injected, irritate the bronchi and lung.

Should emphysema occur, as I have seen happen very extensively, at the time of the operation, no apprehension need arise, as the air will be absorbed in the usual way.

If the intercostal space is too narrow to admit the trocar, a piece of rib may be removed by the method already described.

TAPPING THE PERICARDIUM.—In hydrops pericardii, attended with imminent danger of death from pressure, it will be necessary to **tap the pericardium**. This may be done by making an incision about half an inch in length through the skin and areolar tissue in the fifth intercostal space, in the cardiac region, and then slowly and carefully introducing a fine trocar at that point where percussion and auscultation have indicated the greatest amount of fluid. The trocar should be passed obliquely; and, as soon as it appears to have entered the pericardium, the stylet should be sheathed and the canula pushed forwards until the serum escapes.

The operation is, however, much more safely done with the aspirator. From experiments made on the dead body, Dieulafoy concludes that it may be performed in the fourth or fifth left interspace, the fifth being perhaps preferable, as it is nearer the apex of the heart and is a more dependent situation. The puncture may be made from 2 to 2½ inches from the left margin of the sternum. The spot having been selected should be marked with ink. If the patient be anasarctous, the interspace must be determined by carefully pressing away the œdema. The needle to be employed should vary with the case. If the diagnosis be certain, No. 2 (one millimetre, or roughly $\frac{1}{8}$ inch in diameter), should be used; but if the diagnosis be uncertain, No. 1, half this size, should be chosen, as with this needle, it is said, the heart may be punctured with impunity. The best form of aspirator to use is one such as is represented in Fig. 93, as needles of such small size are apt to be plugged with small flakes of lymph, and if such an accident occur, they may be cleared again by reversing the syringe and forcing a small quantity of fluid back into the pericardium. Before using the aspirator, it should be carefully tested with some carbolized water to render it aseptic, and to see that the needle is pervious, and the whole apparatus in working order. A vacuum having been created in the aspirator by drawing back and fixing the piston, the needle is to be inserted at the spot determined on. As soon as the opening at the point of the needle is covered, the stopcock leading to it is to be opened, so that the vacuum extends into the needle; and "we now advance, vacuum in hand, in search of the effusion." The needle must be pushed slowly and carefully onwards in a direction upwards and inwards till the fluid appears in the glass tube of the aspirator. The moment this occurs all movement of the needle must cease, and it must be held steadily as long as the fluid continues to flow. Any unnecessary movement may scratch and injure the surface of the heart. If the flow cease suddenly, as if from some obstruction, a little fluid may be forced back as above stated, to clear the needle. After withdrawing the needle no dressing is required to the minute puncture. Over a pint of fluid has been removed by this means at one operation. In inserting the needle, care must be taken not to force it through a costal cartilage, or a small plug of cartilage may be cut out which would effectually close its canal.

CHAPTER LX.

DISEASES OF THE BREAST.

By **Disease of the Breast** is meant an affection of the mammary region not merely of the mammary gland. These diseases may occur in the male as well as in the female. They are necessarily more frequent as well as more important in the latter, the rudimentary mammary gland of the male being little predisposed to such affections in comparison to the highly developed and active organ in the female.

Diseases of the breast, when they occur in the female, are of much interest to the Surgeon; not only on account of their great variety, but from the difficulties attending their diagnosis, and from the importance attaching to the question of operative interference in connection with them.

Diseases of the breast seldom occur before puberty, being most frequently met with either during lactation, when the functions of the gland are in a high degree of development; or towards the termination of menstrua. It is when the organ is necessarily influenced by the changes that are taking place in the uterine system. But there is this important difference between the diseases at these different periods of life, viz., that in the young they are of a simple, in the older woman frequently, if not generally, of a malignant nature. Just before or at puberty, the breast occasionally becomes the seat of inflammation and abscess, in all probability owing to changes taking place in it in connection with the general development of the reproductive system. As the period of puberty approaches, the breasts often swell, become hard, knotty, and somewhat painful, indicative of some commencing change in the generative system. In other cases again, a precocious hypertrophy may take place, frequently attended with severe neuralgia in the pectoral region. When puberty occurs, the breasts naturally enlarge, and often become unequal, and occasionally one undergoes a certain degree of hypertrophy, increasing greatly in bulk beyond the other. These various changes, though often alarming in females, cannot be regarded as of any very serious importance, and seldom require more than the simplest surgical treatment.

ANOMALIES OF DEVELOPMENT.

The mammary gland is subject to certain anomalies in development. Thus, in some instances it has been found to be altogether wanting. So A. Cooper and Froriep both relate instances in which the organ was undeveloped, and in which the ovaries were also deficient. A more frequent anomaly consists in the development of a number of **Supernumerary Breasts**. Birkett has collected fourteen reported cases, in which there were more than two breasts; most frequently there is but one supernumerary gland, sometimes two; and occasionally, though very rarely, three have been met with, constituting quintuple mammae. **Supernumerary Nipples** have likewise been found to occur; two to each breast have been met with, each having a duct opening upon it. Most frequently the supernumerary breast is situated somewhere in the neighborhood of the normal gland, as on the anterior

part of the thorax; and where four are developed, they have been found placed in two parallel rows, one above the other. Occasionally they have been met with in very strange situations; thus they have been seen on the outer part of the thigh, in the groin, and on the back; and children are even said to have been suckled by these abnormal breasts.

NEURALGIA.

Neuralgia of the Breast occasionally occurs to so severe a degree as to constitute a positive disease, either in girls or at a more advanced period of life, when it not unfrequently complicates other more serious affections of this organ. It is especially apt to occur in young, delicate, unmarried females of the hysterical temperament, though it is often met with in strong, ruddy-looking women, who are perhaps subject to neuralgic pains in the back, and in other situations. Most commonly the catamenia will be found to be irregular; and uterine congestion, inflammation, ulceration, or displacement, will be discovered on examination; indeed, I have scarcely ever failed to detect one or other of these conditions in the uterus in cases of neuralgic breast.

Symptoms.—In neuralgia of the breast, the mammary gland may be of its normal size and consistence; but in some instances it is more or less indurated and hypertrophied, owing evidently to chronic inflammatory thickening. There are always much general pain and aching, deeply in its substance, with cutaneous tenderness of its surface, and lancinating or radiating sensations that extend into the axilla and down the arm. These painful sensations are commonly increased before the menstrual period, and not unfrequently alternate in the two breasts.

Diagnosis.—The diagnosis of this affection from more serious mammary disease may usually be effected by attending to the superficial and radiating character of the pain, to the neurotic temperament of the woman in whom it occurs, to its shifting seat, and to the absence of any sign of organic disease in the breast sufficient to occasion it.

Treatment.—The treatment consists especially in attention to the condition of the uterine organs; unless this be done, the disease will prove excessively rebellious and troublesome to manage. By removing by proper remedies any uterine irritation that may be found, this affection will be subdued with far greater readiness than by any purely local plan of treatment. At the same time, anti-hysterical constitutional remedies may be employed; the preparations of iron administered, when necessary; and the local pain relieved by the application of belladonna and opiate plasters, or by hypodermic injections of morphia.

HYPERTROPHY.

SIMPLE HYPERTROPHY OF THE BREAST is not unfrequently associated with very severe neuralgia of the organ. An increase in size, such as naturally takes place during pregnancy, between the fourth and ninth months, will occasionally commence at puberty, and go on until the organ attains an enormous bulk, as in Fig. 789, which represents the breast of a very thin girl of fifteen, who was under my care for this condition. In some cases the breast has been found after death to weigh as much as twenty pounds; and after removal, a breast of this kind, taken from a young woman under thirty, has weighed no less than twelve pounds, being entirely composed of its normal tissues, greatly hypertrophied. In cases of hypertrophy both breasts are usually affected, though one is commonly more so than the other.

When first this morbid condition commences, the breast preserves its usual shape, though it is increased in bulk; but as it enlarges it gradually projects forwards, drawing down the

skin of the shoulders, of the side of the chest, and even of the back, and hanging downwards, until, as in a case mentioned by Bernard, it has been known to reach to the knees.

Treatment.—The treatment of this affection is very unsatisfactory. The general health must be attended to, and an endeavor may be made to excite lactation, and thus to unload the vessels of the breast by the employment of galactagogue remedies. Amputation of the organ should not be performed in these cases, unless the growth attain so great a size as to render life a burden. Then the mass may be extirpated with little trouble or danger.

Fig. 770.—Simple Hypertrophy of Breast in a Girl fifteen years old.

ABNORMAL CONDITIONS OF THE LACTAL SECRETION.

The lactal secretion is occasionally the cause of abnormal conditions in the breast. Thus the milk may appear at *unusual times*, a twelvemonth, for instance, after weaning; it has occasionally been known to be secreted in children, and in some remarkable instances in both old men. In other instances again, after parturition, there is a total **Absence of Milk** either owing to want of development of the gland, or to debility on the part of

the mother. The opposite condition will occasionally occur, and an **Excessive Flow of Milk** may continue, especially in hysterical females long after the child has been weaned. In such cases as these, the *galactorrhœa* may be checked by the application of the extract of belladonna to the breast, aided by the employment of tonics, and the administration of acids.

LACTEAL TUMOR.—It may happen during lactation that one of the lactiferous ducts becomes obstructed, either by its being obliterated by inflammation or occluded by the deposit in it of a small concretion—a *lacteal calculus*. In either case the walls of the duct may be expanded so that at last it constitutes a moderate-sized cyst, fluctuating on pressure, and containing fluid. In some cases, the lacteal tumor has been known to attain an enormous size. Walpy has related a case in which Scarpa drew off ten pounds of milk by tapping a collection of this kind. These tumors may exist for a considerable time. Dopuytren records an instance in which it had existed for ten months, and Cooper one of a year's duration. In these chronic cases the milk usually undergoes changes, becoming creamy, thick, and oily; and in some instances it would appear to leave a solid caseous residue by the absorption of its watery parts. In other instances the milk appears as if diffused through the substance of the gland and its ducts, constituting a spongy semi-fluctuating tumor. Velpeau has pointed out that these lacteal deposits undergo a series of changes, somewhat similar to those

that take place in blood that has been extravasated; becoming absorbed wholly or in part in some instances, in others remaining fluid, and occasionally becoming surrounded by a distinct fibrous wall.

Treatment.—In these cases the tumor may be got rid of, as Sir A. Cooper advises, by making an oblique puncture from the nipple towards it, by means of a trocar and canula, so that a fistulous track may be left, along which the milk is discharged; the child being at the same time weaned, so that the secretion may cease. In most cases it is better to make an opening through the skin and to treat the cyst by drainage.

INFLAMMATION OF THE BREAST.

Inflammation of the Breast may take place at any period of life. In new-born infants redness, and swelling of the breast is sometimes observed, with some discharge from the nipple. It usually subsides without suppuration in a few days. In childhood it occurs as the result of accidental causes, and also just before or at puberty. It is sometimes met with in boys as well as in girls, as a consequence of the general development of the organs of reproduction. In these cases it is easily subdued by the application of glycerine and belladonna ointment. Far more frequently it occurs during lactation in feeble and anæmic women. It is commonly met with during the first month or two after the birth of the child, and seldom occurs during weaning, but may, as Nunn has shown, be the consequence of unduly prolonged suckling, and thus appear at a late period—the tenth or eleventh month. Inflammation may affect any one of the constituents of which the breast is composed, and may be limited to this: thus it may take place in the nipple; in the subcutaneous areolar tissue lying between the skin and the gland; in the gland itself; or in that extensive plane of areolar tissue upon which the gland rests, and which intervenes between it and the pectoral muscles. But, although inflammation commonly affects those different parts, in many cases the whole of the breast appears to be involved, and no distinct implication of any special tissue can be made out.

Inflammation of the Nipple and Areola.—When the nipple and areola are inflamed, these parts become conical, red, and swollen, with much pain, owing to the density of the subcutaneous tissue in this situation. This affection, “the cracked nipple” of nurses, usually occurs at an early period of lactation in delicate women, and especially with the first child. It commences in the follicles of the part, being accompanied by superficial ulceration, abrasion, and fissures, with oozing of a small quantity of thin sero-puriform fluid. There is great pain during suckling—so great, indeed, as to prevent the proper continuance of this act. It is usually attended by a good deal of constitutional irritation. In some instances, the fissured state of the nipple would appear to precede the setting in of inflammation; in other cases the inflammation is the primary condition. In wet-nurses the possibility of the occurrence of a primary syphilitic sore communicated by an infant suffering from the congenital form of the disease must always be borne in mind.

The *Treatment* is as follows. The child must be taken from the affected breast, both for its own sake and the mother's, the milk being drawn off by means of a breast-pump or sucker. The general health must be attended to; tonics given; the infant's mouth examined for aphthæ, which, whether as cause or as effect, are common, and must be treated on ordinary medical principles. If the nipple be not fissured, it should be covered with flexible collodion, or painted with an astringent; a solution of nitrate of silver, catechu, or tannin is the best. If it be fissured, a pointed stick of nitrate of silver must be applied to the bottom of the crack daily, or, if deep, its base may be

divided by drawing a lancet along it. A nipple shield through which the child can suck, will often be found useful in preventing a recurrence after the fissure has been cured.

Eczema of the Nipple.—The nipple and the areola are not uncommonly the seat of very chronic and obstinate eczema. The eruption may extend to the surrounding skin. The cause of this condition is not always evident, and in some cases it is the precursor of cancer of the breast. It not unfrequently attacks both sides. The *Treatment* is, as a rule, very unsatisfactory. The nipple must be carefully washed with tepid water. Glycerine of borax, boracic acid ointment with one drachm of extract of belladonna to each ounce, carbonate of lead ointment, and lead lotion may be tried, and often are of use. Painting the inflamed area occasionally with a strong solution of nitrate of silver may sometimes prove beneficial.

Abscess of the Areola not unfrequently occurs in suckling women, with the ordinary signs of local inflammation, terminating in circumscribed supuration. The *Treatment* consists in the application of warm belladonna or lead lotion, and opening the abscess early. In doing this care should be taken that the cut be made from the centre of the nipple towards the circumference of the areola, so as not to divide the lactent ducts.

Small follicular inflammations and abscesses, varying in size from a pin's head to a cherry, are common in middle-aged women, independently of lactation. They often excite alarm, and occasion some pain. They are usually readily relieved by belladonna and glycerine or warm lead lotion, followed by the touch of the point of a lancet.

INFLAMMATION OF THE BREAST, which, as it generally occurs in nursing mothers, and terminates in suppuration, is usually called **Milk Abscess**. It may occur in three situations; 1, in the Subcutaneous Areolar Tissue, **Supra-mammary Abscess**; 2, in the Gland itself, **Mammary Abscess**; and 3, in the Areolar Tissue between the Mammary Gland and the Pectoralis Major, **Sub-mammary Abscess**.

1. **Inflammation, followed by Abscess, of the Subcutaneous Areolar Tissue of the Breast**, though common during lactation, occurs more frequently than any other form of inflammation in this region at other periods of life, more particularly about the age of puberty. Its symptoms are those of simple acute inflammation, differing in no way from abscess of the kind in other situations, except that it is always distinctly circumscribed.

2. **Inflammation of the Mammary Gland** is the most common form met with. It arises almost always in connection with lactation. Of 228 cases recorded by Nunn, Bryant, and Billroth, 181 occurred during suckling; 47 during pregnancy, and 34 independently of these conditions. It is most common in primiparae, the tendency to it diminishing with each subsequent pregnancy. The right breast is more commonly affected than the left, and occasionally it is double. The causes of the inflammation are by no means certain. It has been supposed to be due to obstruction of a duct, and such an explanation is no doubt a very possible one, but there is no definite evidence in support of it. The fact that it is very frequently preceded by a sore nipple, and suggest the possibility of its being due to extension from this, either by the lymphatics or ducts. It most commonly commences during the first few weeks after labor, or, if that period be passed, towards the end of prolonged lactation, especially in weakly women. Hence it is very common amongst the poorer classes, amongst which it is not rare to find children of ten or twelve to two years old still at the breast. It is rarely met with in mothers who do not nurse their own children, a fact which, as Billroth points out, is quite what opposed to the theory that its common cause is obstruction to the flow of milk. The whole gland is rarely affected, but should this happen, it pro-

rise to great swelling of the breast, with severe aching and lancinating pain, and much constitutional disturbance, with considerable elevation of temperature. Much more commonly one lobe only becomes inflamed, most commonly at the outer or lower border of the gland. The local signs are then proportionately limited, and occasionally the inflammation subsides without reaching the stage of suppuration. As Velpeau has pointed out, one lobule after another may become inflamed, so that a succession of abscesses forms in different parts of the gland. As the inflammation advances to suppuration, the skin is reddened, assumes a dusky hue, becomes glazed, has a peculiar greasy appearance, and pits on pressure. When matter has formed, the tension of the superficial parts with œdema and fluctuation, perhaps deep-seated, determine its presence.

3. Inflammation in the Areolar Tissue between the Mamma and the Pectoral Muscle is of less frequent occurrence than the other forms of mammary inflammation. It arises in some cases apparently independently of any affection of the gland itself; but in most cases, as Billroth suggests, it is probably due to inflammation and suppuration of a deep lobule of the mamma. In whatever way it arises, the inflammation diffuses itself over the whole of the areolar layer, and almost invariably runs into abscess with considerable rapidity, giving rise to severe pain, of a deep, heavy, and throbbing character, much increased by moving the arm and shoulder, and attended by swelling, œdema, and a slight red blush upon the skin. The breast becomes prominent, and is conical and projecting, the whole organ being pushed forwards by the pressure from behind; it is not readily movable on the pectoral muscles, the subcutaneous veins become engorged, and at last abscess forms. It is not always easy in these cases to determine whether suppuration has taken place or not, the depth at which the pus forms rendering it impossible in the early stages to detect fluctuation; its presence may, however, be suspected on the occurrence of deep-seated throbbing pain, subcutaneous œdema, and some superficial redness. The abscess at last points at some part of the margin of the gland, usually at its lower and outer side, to which point the matter seems to gravitate; after a time, however, it will commonly appear at other points of the circumference of the gland, beyond which it always extends, seldom, if ever, perforating the structure. A series of four or five apertures, forming a large circle round the margin of the mammary gland may thus form. It very commonly happens that the apertures through which the pus discharges itself in these situations, degenerate into sinuses, by no means easily closed.

Treatment.—In the treatment of inflammation and abscess of the breast occurring during lactation, it must be borne in mind that we have not a æthemic inflammatory condition to deal with, but that the disease almost invariably happens in delicate anæmic women, weakened by recent parturition. It is, therefore, obvious that antiphlogistic means of an active nature are not admissible; and the best plan of treatment appears to consist in keeping up the strength of the patient by proper constitutional support, at the same time that the local inflammation is checked by topical antiphlogistic measures. The first thing to be done is to prevent, if possible, the occurrence of suppuration; if this can be accomplished, which is, however, rarely the case, much will be gained. In order to effect this, the breast should be supported in a sling, so as to lessen congestion of it; the arm at the same time being fixed to the side, in order to prevent traction of the pectorals and movement of the submammary areolar tissue. If the patient's strength be good, leeches may be applied, but these are rarely required or admissible. Hot fomentations should be assiduously applied from the first, and the whole breast painted with equal parts of glycerine and extract of

belladonna; at the same time the milk should be drawn off by means of a breast-pump or sucker, the child being put to the unaffected breast or weaned, and an occasional saline purgative administered. When suppuration is impending, the application of fomentations may be continued, the patient being allowed a more liberal supply of nourishment, with a moderate supply of malt liquor; and, so soon as matter can be felt, it should be let down upon and let out by an aperture in the most dependent position. The incision must always be in a line radiating from the nipple, so as to avoid needlessly damaging the ducts. It is of great importance that the pus should be let out early, by an opening into the lowest part of the abscess. A good-sized drainage-tube should then be inserted, and some efficient antiseptic dressing applied. If these precautions be not taken, the pus burrows directly, diffusing itself through the areolar tissue, under, beyond, and around the gland, opening at several points, and leaving long fistulous tracks perforating the breast in various directions. When suppuration is going on, the patient's strength must be supported with tonics, the mineral acids, bark, or quinine. Stimulants may be given as required, and plenty of nourishment supplied. Should sinuses form in a case of mammary abscess, they will usually close if the child be weaned, and lactation stopped. Should they not do so, the employment of pressure and the use of stimulating injections, with attention to the general health, will usually in time bring about a cure. In cases of submammary abscess, the incision must be free, and a large drainage-tube should be used. Sinuses of an intractable kind more commonly follow this than the other forms of mammary abscess. In the event of their proving rebellious, it has been proposed to slit them up by free incisions directed towards the nipple; but this is unnecessarily severe practice, and may, I believe, in all cases be avoided. It will often be found that the delay in healing is due partly to the existence of a cavity beneath the mamma which is imperfectly drained by the sinuses. Under these circumstances the orifices of the sinuses should be enlarged with a knife, and the tracks cleared with the finger. They should then be scraped with a sharp spoon to remove the unhealthy granulation-tissue, after which they should be cleaned with a piece of sponge soaked in chloride of zinc solution (gr. 10 to 5i), held by a pair of sinus forceps. A drainage-tube should then be inserted into each, and gradually shortened at each dressing. In some cases healing is promoted by the introduction of a small quantity of iodoform. The most submammary sinuses may usually be speedily made to close by this treatment.

CHRONIC INFLAMMATION OF THE BREAST. Chronic Interstitial Mastitis. A form of chronic interstitial inflammation of the breast, affecting usually only a limited part of the gland, is not uncommonly met with in women past middle life, and is of great importance from the resemblance it bears in its clinical features to scirrhus cancer. The condition was first accurately described by Cruveilhier under the name of *fibrous bodies* (*corps fibreux*) in the breast; and since his time it has received many other names, such as diffuse fibroma or hard elephantiasis (Virchow), Lobular Hypertrophy (Sir A. Cooper), knotty or nodular induration (Billroth), *cirrhose* of the mamma, benign induration, etc. "Chronic lobular interstitial mastitis" is, however, the best name that can be applied to it, as it correctly indicates the nature of the affection.

The pathological appearances are very minutely described by Virchow. In the earliest stage, which is evidently inflammatory, the acini and ducts of the gland show no change beyond a slight increase in the epithelium. The connective tissue of the affected lobule is infiltrated with small round cells, which are most numerous in the immediate neighborhood of the acini. In

the second stage the new cells undergo development into dense fibrous tissue, like that of a cicatrix. This is accompanied, as in similar processes elsewhere, by shrinking of the tissue. The acini and ducts in the affected area are thus pressed upon. The epithelium undergoes fatty degeneration, and is for the most part absorbed, and thus a number of the acini are finally obliterated. Here and there, however, small retention-cysts form, chiefly from the ducts which have been constricted in places by the contracting fibroid tissue, while at the same time there has been a slight increase of secretion owing to the chronic inflammatory process going on in the surrounding areolar tissue. These cysts seldom reach a size larger than that of a mustard seed, owing to the density of the tissue by which they are surrounded. The disease is very commonly limited to a single lobule of the mamma. Occasionally, however, it may be more diffused, and in such cases, when the stage of shrinking is reached, the gland may become shrivelled and considerably reduced in size. The nipple may be retracted as the breast shrinks, thus still further increasing the resemblance to atrophic scirrhus.

The *causes* of the condition are very obscure. It is frequently associated with some menstrual disturbance, and is not uncommonly met with at the change of life. It is most common in women who have borne children.

The *symptoms* consist of the gradual formation of a tough, hard nodule in the breast, usually situated in the peripheral part, tolerably clearly circumscribed, and of rounded form. In size it may vary from a marble to a pigeon's egg, seldom being larger. It may distinctly increase in size at the menstrual periods, and diminish in the intervals. Its surface is often slightly nodular, the nodules being formed by the small, tense cysts already mentioned. If it be grasped and gently pulled upon with one hand while the nipple is held with the other, so as to make the ducts passing from it tense, it can easily be recognized that it is part of the mamma, and not an isolated tumor. On pinching up the skin over it, a dimple may form, as the areolar tissue of the subcutaneous fat is continuous with that penetrating between the lobules of the mamma, which is involved in the interstitial inflammation. A similar nodule may not unfrequently be found either in another part of the same breast or on the opposite side. The disease may be painless, or may be associated with severe neuralgia, worse during the menstrual period. In the early stages there may be slight tenderness, but this is seldom marked, and is often wanting when shrinking is far advanced. There may in some cases be a slight enlargement of the axillary glands.

The *diagnosis* will be considered more specially with reference to cancer and adenoma. When it occurs below the age at which cancer is met with, its recognition does not as a rule present great difficulty. From adenoma it is distinguished by observing its less defined outline, and its connection with the nipple, showing that it is actually an altered piece of the mammary gland, and not an encapsuled tumor. If more than one lobule be affected, the diagnosis is more easy, as all true tumors of the mamma are single. From a simple cyst it can usually be distinguished by its more leathery feel and less defined outline, but the diagnosis is not always possible. When from the age of the patient, the multiplicity of the tumors, the duration of the disease, or from its general features, it can be certainly stated that it is not a cancer, it may be left to time to determine its nature, but should there be the slightest doubt in the mind of the Surgeon that it is malignant, it is his duty to cut deeply into it without delay, and remove a piece for microscopic examination.

No *treatment* exerts much influence on the progress of the disease, but this is of less consequence, as beyond the neuralgic pain sometimes accompany-

ing it, and the mental anxiety it often causes the patient, it is not likely to cause any inconvenience. Blistering, prolonged painting with iodine, and other forms of counter-irritation, produce little or no effect. Rest-cure may be applied to relieve the pain. Pressure may possibly be of service in some cases. Probably the cases of so-called adenoma or cancer cured by pressure were in reality merely chronically inflamed lobules. Should it seriously annoy the patient, the affected lobule may be safely removed. If the breast is widely affected, no operative interference should be undertaken. In operating in these cases the incision should be placed so that if the disease be cancerous the whole mamma may be removed.

CHRONIC ABSCESS OF THE BREAST may assume two forms, the *Diffused*, and the *Circumscribed* or *Encysted*.

Chronic Diffused Abscess of the breast may occur at all ages, in the single or in the married. It usually appears in the submammary areolar tissue, often without any external exciting cause, but as a consequence of impaired health, in strumous or cachectic females, and is often connected with menstrial derangement. It may attain a very large size, and, pushing the mammary gland forwards, it gives the breast a conical, pointed shape. Fluctuation soon becomes apparent, and the ordinary local signs of chronic, cold or congestive abscess disclose themselves. Chronic abscesses in this situation may arise also in connection with caries or necrosis of a rib.

The *Treatment* of chronic diffused abscess of the breast consists in making a free outlet for the pus in a dependent situation, keeping it free with a drainage-tube, and dressing it by some efficient antiseptic method, at the same time that the general health is improved with iron or cod-liver oil.

Chronic Encysted Abscess of the breast is a disease of great importance, inasmuch as it closely simulates various tumors in this situation, so much so, indeed, that it is only with extreme difficulty that the diagnosis is effected in some cases. The breast has in numerous instances been amputated on the supposition of its being the seat of tumor, when it was merely the seat of a very chronic thick-walled abscess. This form of abscess usually commences as the result of pregnancy, whether complete parturition or miscarriage take place; sometimes as a consequence of lacteal inflammation, but usually without any injury or other direct local cause. An indurated, silent swelling forms, and this may gradually soften in the centre, but fluctuation may for a long time be very indistinct, and even absent, being obscured by the thick wall of indurated tissue, surrounding the collection of pus. It is owing to the dense inflammatory induration of the surrounding tissues, that the chronic encysted abscess is so commonly mistaken for a tumor. It is in general not very distinctly circumscribed, and of but moderate magnitude; after a time it remains stationary, during a space of many months, or but slowly increases with but little pain; it is not unfrequently attended with retraction of the nipple.

Diagnosis.—The diagnosis of this form of abscess is of great importance, inasmuch as it has not unfrequently been excised for tumor of the breast. I am acquainted with many instances in which this mistake has been committed. Such an error may, however, commonly be avoided by attending to the following points: 1, that the existence of an abscess is almost invariably preceded by impregnation, parturition, or miscarriage; 2, that there is more or less edema of the subcutaneous areolar tissue covering it, although it is of slow formation and without pain it is not distinctly circumscribed, but gradually forms in an irregular manner into the neighboring tissues; 4, that it is not freely movable, but rather incorporated with adjacent parts; and, 5, that elasticity, or even deep fluctuation, may be commonly felt at one part of it. Should there be the least doubt in the case

the introduction of an exploring trocar, by giving issue to a drop of pus, will always determine its true nature; indeed, this simple means of diagnosis should never be neglected in any case in which there is reason even to suspect the possibility of the apparent tumor of the breast being in reality an abscess.

Treatment.—The abscess should be opened as soon as recognized, and if of sufficient size a drainage-tube should be inserted. Should the mass of indurated tissue surrounding the pus be very large and dense, a free incision carried through it will usually hasten its disappearance.

In all cases of chronic abscess of the breast, but more particularly in the submammary, the arm should be kept at perfect rest in a sling or bandaged to the side.

TUBERCLE OF THE BREAST.—True miliary tubercle has not been observed in the mamma. Cases have been observed of multiple cavities in the mamma with caseous softening contents, but the evidence that these were tubercular is not perfect. Billroth quotes one such case.

SYPHILITIC DISEASE OF THE MAMMA.—**Primary Sores** on the nipple have already been mentioned. **Gummata** have been described in the mamma, and a few cases recorded. Billroth, however, does not regard the evidence of their occurrence as conclusive. There is no doubt that if they do occur they are of extreme rarity.

TUMORS OF THE BREAST.

The study of the various tumors of the female breast, more especially in a diagnostic point of view, is of the first importance to the practical Surgeon; for though it might be supposed that it would be easy, if not to recognize the minutest shades of pathological difference between morbid growths so superficially situated as those of the mammary gland, at all events to diagnose the malignant from the non-malignant affections of this organ, yet in practice nothing is more difficult in many cases; and it not only requires great experience, but almost an intimate acquaintance with the special course and symptoms of each particular disease, to come to a correct conclusion as to its nature. Even with all the light which experience and a careful examination of the characters of the tumor may throw upon the nature of the disease, it will be impossible for the Surgeon to avoid occasional errors in diagnosis.

The first thorough classification of the different varieties of simple tumors that develop in the mammary gland was made by Sir Astley Cooper, and this important department of surgical pathology was subsequently much extended by the researches of Velpeau, Birkett, and Paget. Since the improvements in the methods of investigation have led to a more perfect anatomical classification of tumors, the confusion that formerly surrounded this very intricate subject has been to a great extent cleared up by the labors of Virchow, Billroth, Gross, and others. The microscopic characters of the various tumors of the breast are now accurately determined and generally agreed upon, but confusion still remains in the nomenclature which time alone can remove. In describing the various tumors of the breast I shall follow the order adopted in the chapter on Tumors in general.

NON-MALIGNANT TUMORS.

CYSTS OF THE BREAST are of common occurrence. They occur either as independent tumors, or in conjunction with solid growths. To the former class belong Retention-cysts, Serous Cysts, and Parasitic Cysts; to the latter, the cysts met with in "cysto-sarcoma," and the cysts in soft sarcomata.

1. **Retention-cysts.**—These are formed by the gradual distention of the acini or ducts of the mammary gland. The "*galactoele*," already described (p. 694), belongs properly to this class of tumor. It is produced solely by obstruction to the exit of the natural secretion during lactation. The retention-cysts formed in the mamma at other times never contain milk. The fluid that distends them is usually thick, sometimes almost mucous in appearance, and usually of a brownish-yellow or brown color, and more or less turbid. It is an abnormal secretion from the gland-tissue. In galactoele the sole cause of the condition is obstruction of a duct, but in the cysts we are now considering, abnormal secretion is the primary factor in the production of the disease. The walls of these cysts are composed of a layer of connective tissue of variable thickness, containing usually an abundant supply of capillary vessels. They are lined internally by a layer of epithelium either cubical, somewhat resembling that of the normal acini, or columnar, like that of the ducts. Various modifications also are met with which will be described later on.

As before stated, cysts of this class are frequently met with in lobules of the mamma affected by chronic interstitial inflammation (p. 698). They are usually multiple, and seldom reach any great size. They are also not uncommon in the indurated and atrophied breasts of old women and even met with under these circumstances have been termed "*involution-cysts*."

Retention-cysts arising independently of these conditions, or *glandular cysts* as they are often termed, may be multiple or single. As a good example of the multiple form the following case may be given: A young unmarried woman, in order to quiet a baby she had charge of, put it *on* to her breast. This was followed by some pain and swelling, and a *small* yellowish discharge from the nipple. Some months after, on examining the breast, a number of small fluctuating swellings, the largest about the size of a hazel-nut, could be felt scattered through both breasts. They were not distinct in the neighborhood of the areola. The discharge continued and was a source of considerable annoyance. On pressing the cysts their contents were easily squeezed out through the nipple. The condition remained unchanged for about two years, in spite of belladonna and other external remedies. She then married and became pregnant. As the breast changed the abnormal discharge gradually ceased, and after her confinement she was able to nurse her child without difficulty.

Single cysts of the same nature are not uncommonly met with, and may attain a considerable size. They form rounded or lobulated tumors, more or less imperfectly defined and painless, or nearly so. When their contents can be squeezed out at the nipple they are usually soft and fluctuating. Should the duct become completely or partially blocked either from inflammatory induration of the surrounding tissue, or, as in a case recorded by Rogers in a small papillary growth springing up in its interior, the cyst increases very rapidly in size, and becomes so tense as to be easily mistaken for a solid tumor. The causes of these cysts are uncertain. They seem usually to arise from some injury or irritation of the breast. Butlin, who has recently published some interesting observations on these cysts, states that they usually occur in thirty-five, in women who have borne children, and in several cases appear to have arisen as the result of a blow. In some cases they may possibly be associated with some uterine affection.

Cysts of this kind may become the seat of *intracystic growths* composed of delicate branching papillae, covered with epithelium of the same character as that lining the cyst-wall. These may at last completely fill the cavity, converting it into a solid tumor. These vascular papillae readily bleed and have probably been the source of the bloody fluid which has been described.

as escaping from the nipple in some of these cases. It is possible that these tumors may become malignant, and be the starting-point of a peculiar form of cancer with columnar epithelium, occasionally met with in the breast, to be subsequently described.

2. **Serous Cysts of the Breast.**—These are believed to be formed, as elsewhere, by dilatation of the lymph-spaces of the areolar tissue, the wall of the cyst being formed of the surrounding connective tissue pressed together and subsequently thickened by new growth. The evidence of this mode of growth is not by any means perfect, but it seems the only possible explanation of their structure. Their walls are composed of delicate areolar tissue, lined internally with flattened endothelial cells like those of a lymphatic vessel. The contents are usually clear yellowish serous fluid, but may sometimes be brownish or turbid, from the admixture of blood, and in some cases cholesterine is present. These cysts are usually single, sometimes they are isolated and in other cases multiple. They are usually about the size of a filbert when first noticed, and may remain small for a great length of time, but in other cases they gradually increase until they may contain several ounces of fluid. They then become very tense, so much so in fact that fluctuation is no longer present.

Unilocular cysts of the breast occasionally attain an immense size, at the same time that their walls remain thin and supple. In these cases the skin covering them may become thinned and translucent, constituting the condition which has been termed *hydrocele of the breast*.

The simple serous cysts never develop intracystic growths. In some rare cases calcification of the cyst-wall has been observed.

3. The true *Hydatid Cyst* is extremely rare, but has been met with in the mamma. The simple serous cyst was described by Sir A. Cooper under this name.

The *Diagnosis* of a cyst of the breast may usually be effected by feeling the globular elastic tumor under the skin; the mammary gland being movable and not adherent to any of the adjacent structures. Cysts being connected with the mammary tissue drag upon the nipple when moved away from it. This is recognized by holding the nipple lightly while the tumor is drawn away with the other hand, when the connection between them will be clearly perceptible. In those cases, however, in which the tumor lies deeply, the diagnosis may not so readily be made, more especially from tumors containing cysts or cancer. In fact, nothing is more easy than to diagnose the true nature of a superficially seated, lax-walled cyst; nothing is more difficult than to recognize it when tense and deeply seated towards the under surface of the mammary gland (Fig. 771); for, the whole thickness of the gland intervening between the cyst and the finger, the sense of elasticity is lost and a solid feel communicated, which may readily mislead even the most experienced Surgeon. Whenever the Surgeon has any doubt about the existence of fluid in a tumor of the breast, he should introduce an exploring trocar; when, if the disease be cystic, the fluid will be discharged. If the tumor prove to be solid, no ill-consequences will result from the simple puncture. Several instances have occurred to me in which, from the want of this simple precaution, very excellent Surgeons have condemned as cancerous, tumors of the breast, which proved to be cystic.

The diagnosis of the retention-cyst from the simple serous cyst is not possible unless fluid can be squeezed from the nipple, a condition which of course cannot occur in the serous cyst. If this sign be wanting, the nature of the disease may be recognized in most cases by the character of the fluid. The true hydatid cyst is so rare that it may be practically excluded in making the diagnosis. It may be recognized by the character of the fluid withdrawn

on puncture. This is clear, containing merely the faintest trace of sanguineous fluid, and has a specific gravity of 1003 to 1004. Hooklets may possibly be found in it. Without puncture these cysts cannot be distinguished from the other forms.

Treatment.—The treatment of cysts of the breast varies according to their number and size and the presence or absence of intracystic growths. Small multiple retention-cysts which can be emptied through the nipple sometimes require no further treatment. Belladonna or some form of counter-irritation may be applied externally in the hope of arresting the abnormal secretion, but these means are seldom of much use. If the cyst is larger and cannot

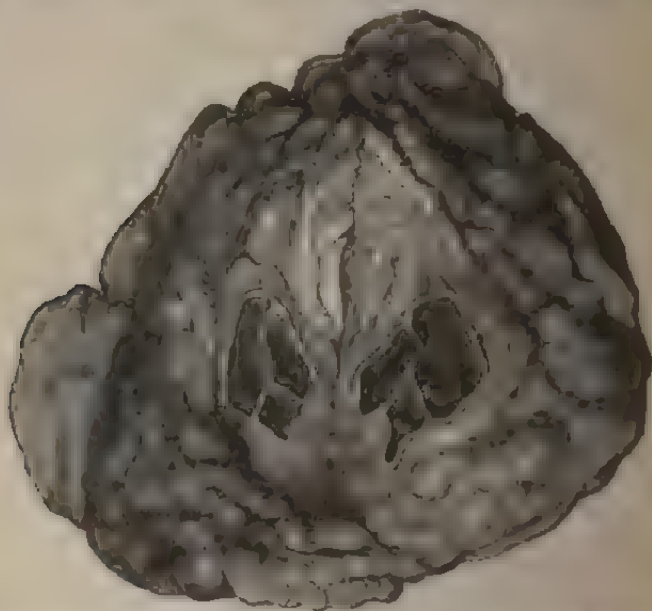

Fig. 771.—Breast laid open after removal, showing Cysts deeply seated in Mammary Gland, mistaken for Scirrhus.

be emptied by pressure, the fluid contents may be let out by puncturing with a small trocar; but a cure cannot usually be effected in this way as the fluid reaccumulates. Occasionally it will suppurate spontaneously and is thus got rid of. If the tumor be single, it may usually be cured by opening it by a small incision, wiping it out with a strong solution of chloroform or zinc or tincture of iodine, and inserting a drainage-tube under an antiseptic dressing for a few days. If it seem to be surrounded by indurated mammary tissue, it is often best to dissect it out and to remove it with the whole of the mamma to which it is attached. On doing this it will often be found that the cyst is not single as was at first supposed, but that several smaller ones are present which have been concealed by the larger one. If the cyst contain intracystic growths, it should be completely removed with the surrounding part of the mammary gland. If the cysts are multiple, they must be treated according to circumstances. If there are but two or three, they may be treated as if single, but if very numerous there is nothing to be done but to remove the breast if operative interference is demanded.

Lipoma.—Fatty tumors have occasionally been met with in close proximity to the mamma, so as to simulate a tumor of the gland itself. A little can

ful examination will usually enable the Surgeon to ascertain that the gland is not implicated. The *Treatment* of these tumors presents nothing peculiar.

Fibroma.—Pure fibroma of the mamma is very rare. One case only has occurred in University College Hospital in the last fifteen years. The patient was a middle-aged woman, and the tumor, which was about the size of a hen's egg, was of stony hardness. It was thought to be a scirrhus cancer, but as there was some doubt, a deep incision was made into it before removing the breast. It was found to be exceedingly dense, creaked under the knife, and no capsule was recognized. After removal of the breast, it was found to be clearly defined and surrounded by a distinct but dense capsule from which it could be dissected out, leaving the mammary tissue untouched. Microscopic examination showed it to be composed of pure dense fibrous tissue, without a trace of glandular structure.

Chondroma and Osteoma.—Tumors of the breast containing cartilage have been recorded, but are of extreme rarity. Billroth mentions a case of a large sarcoma of the mamma in which small nodules of true bone were found.

ADENOMA, ADENO-FIBROMA, ADENO-SARCOMA, CYSTO-SARCOMA.—A group of tumors closely related to each other pathologically, though differing considerably clinically, are included under these names. The essential features common to all are—first, the presence of spaces, either flattened and slit-like or forming distinct cysts, lined with a small cubical epithelium, usually in several layers but occasionally single (vol. i., Figs. 383, 384). The spaces contain a variable amount of fluid, in some cases so small in amount as to be scarcely recognizable, in others distending the cavities into well-marked cysts, seldom exceeding an inch or an inch and a half in diameter. The bulk of the tumor is composed of the interstitial tissue between the epithelium-lined spaces. This tissue varies from fully developed fibrous tissue to the simplest embryonic tissue, and may present every stage between. Thus it may be composed of small spindle-cells with numerous fibres between them, of imperfectly developed fibrous tissue, infiltrated with small round cells, of large spindle-cells, of delicate fibres with stellate cells and mucous intercellular substance, or of various combinations of these structures. Lastly, when the spaces develop into cysts, they often present intracystic growths of great size forming the most marked feature of the tumor. These growths are formed of processes of the interstitial tissue of the tumor projecting into the cyst, and are covered with a layer of epithelium. They are often branched, and may in some cases completely fill the cavity into which they grow. They may sprout from all sides at once, and then form a closely packed foliated mass, without any clear evidence of the mode of growth remaining. In other cases a pedunculated mass springs up from a single point in the cyst-wall, and may project into it, still surrounded by a certain amount of fluid, or may completely fill it, displacing the fluid and being surrounded by the cyst-wall as by a capsule.

In whatever way the tumor grows it remains, as a rule, completely surrounded by a capsule of areolar tissue, and forms no adhesions to the surrounding parts unless it be allowed to reach such a size as to excite inflammation by the pressure and tension it exerts.

Of the causes and mode of origin of these growths little is known. Billroth states that they commence by an overgrowth of the connective tissue surrounding the acini and ducts. But whatever point they may commence in it is evident that in their subsequent development the growth of the epithelium is as essential a part of the process as is that of the interstitial tissue. The presence of the epithelium-lined spaces is not a mere accident

of the growth but an essential feature of it. Those tumors are therefore properly termed adenomata.

The differences in anatomical structure correspond tolerably accurately with the variations in the clinical course of the growth. The more perfect is the development of the interstitial fibrous tissue, the slower is the growth of the tumor; the more embryonic the tissue, the more rapid is its progress, and the greater is the risk of its extending beyond its capsule, invading neighboring parts, and recurring in internal organs, in fact, running the course of a malignant sarcoma; a termination which is, however, very rare in these cases. It not uncommonly happens that the tumor appears first as a small hard nodule, evidently with firm fibrous interstitial tissue, and may remain in this state for many years, scarcely increasing in size; but after middle life it may suddenly take on rapid growth, and when removed its interstitial substance will probably consist of spindle-cells, or of some even more embryonic form of tissue.

The brief anatomical sketch above given will sufficiently explain the various names bestowed upon this class of tumors. When the tumor is of slow growth and firm, it is often called the *Chronic Mammary Tumor*, the name originally given it by Sir Astley Cooper. Abernethy, from the resemblance of the section in some cases to that of the pancreas, termed it the *Pancreatic Sarcoma*. Vidal termed it *partial or lobular hypertrophy of the mamma*. In this country it is most commonly termed the *Simple Adenoma*. The term *Adeno-fibroma* is, however, that which most closely describes its anatomical structure, and is undoubtedly the best (vol. i. p. 358, Fig. 4). When the interstitial tissue is either embryonic or undergoing one of its primary modifications which embryonic tissue manifests in its development into fibrous tissue, in other words, when it corresponds to the structure characteristic of a sarcoma, the tumor is called an *Adeno-sarcoma* (vol. i. p. 359, Fig. 384), and when stellate cells are found, and the tumor secretes or squeezes an abundant glairy mucous fluid, it is often termed *Adeno-cystic sarcoma*. When cysts form a marked feature in the growth, it is commonly termed a *Cysto-sarcoma* of the mamma, but other terms are also applicable. Thus Brodie termed it the *Sero-cystic sarcoma*, and Paget suggested the name of *Glandular proliferous cysts*. The term *Cysto-sarcoma* originally suggested by J. Müller is so generally adopted, that it is, perhaps, most convenient to adhere to it for clinical purposes, therefore, these three forms may be described: the *Adeno-fibroma*, *Adeno-sarcoma*, and *Cysto-sarcoma*, remembering, as Billroth says, that from a purely anatomical point of view the difference between these forms is very slight, and that we should be perfectly justified in considering the *Adeno-fibroma* as the initial stage of the other forms.

The *Adeno-fibroma* is the most common simple tumor of the breast. It is often attributed to blows, squeezes, or lacteal irritation, and is almost invariably met with in young women under thirty years of age; and is also met with in women otherwise healthy. It is often associated with the hysterical temperament, and connected with, if not dependent on, uterine irritation and sexual excitement of an irregular kind. This tumor is generally of small size when first perceived, and may remain stationary for many years; it may slowly increase, and at last attain a considerable bulk. In other cases it may very rapidly grow to a great size. In a case on which I operated six years ago, the tumor had continued for eighteen years about the size of a walnut, but in the course of six months it increased to an enormous magnitude, and on removal weighed nearly five pounds.

This tumor usually commences as a small, movable, finely nodulated growth, attached by a pedicle to one side of the mammary gland; it is hard

and incompressible, often appears isolated, and is not generally painful, but in anæmic women may be the seat of intense neuralgic pain; it increases slowly, without discoloring the skin or becoming attached to it, and is frequently many years in attaining a moderate size. It is often floating, as it were, in the substance of the gland, into which it can be pushed back. This tumor is sometimes mistaken for a cancerous growth, and the diagnosis is often as difficult as it is important, though in many cases the comparative youth of the patient, the mobility of the mass, the absence of all implication of the skin and glands, and its accurately circumscribed character will indicate its true nature. Cysts and chronic interstitial inflammation of a lobule are often mistaken for adenoma, and in many cases the distinction is very difficult. The diagnosis is made by the more accurate circumscription of the fibro-adenoma, and by its being usually clearly separable from the mamma, and not connected with the nipple by a cord of ducts which can be felt on drawing the tumor away from the nipple while that is gently held between the finger and thumb.

On examination after removal, an adenoma appears to be irregularly lobulated, is enclosed in a capsule of areolar tissue, and its cut surface is found to present a bluish- or grayish-white color, which after exposure to the air, assumes a rose tint; and on pressure, drops of a thick mucous or serous fluid are often seen to exude. On examination with a lens, its lobulated structure is often very apparent, so much so, that it has been compared by Virchow to the section of a cabbage. This is more clearly seen after it has been a few days in spirit.

Adeno-sarcoma.—An adeno-fibroma, though usually very chronic in its progress, may at times assume extreme rapidity of growth, so as to simulate even cancer. This happens usually in those cases in which the tumor has remained in a quiescent state from an early period up to about the middle of life. In cases in which the disease develops for the first time between the ages of 35 and 40 it may grow quickly from the first. In these cases it will grow with extreme rapidity, attaining in a few months a size equal to that of a walnut, or even larger, and simulating in this respect the progress of an epithelioid tumor. These rapidly growing adeno-sarcomata are painless, and as a rule, however large, continue perfectly movable, free from deep adhesions, or from glandular implication: the skin covering them is healthy, tanned, and unadherent, the nipple projecting usually very prominently. The tumor itself will be felt to be nodulated, semi-elastic, not stony, and somewhat rounded in outline. After removal its section is lobulated and glistening something resembling a mass of rice or sago-jelly, often having cysts interspersed through its substance.

Painful Mammary Tumor.—It occasionally happens that an adeno-fibroma becomes the seat of very severe and paroxysmal neuralgic pains, attended with very considerable cutaneous sensibility, and it has then been termed the *painful mammary tumor*. This condition most frequently occurs in early life and in women of an irritable and delicate constitution; it is commonly associated with disorder of the uterine functions, the pain increasing at the catamenial periods.

Treatment of Adeno-fibroma and Adeno-sarcoma.—If the tumor be firm and small, and shows no tendency to further increase, it may be let alone, unless it be a source of mental disquiet to the patient. If it assume the form of the painful mammary tumor, the treatment must have special reference to the removal of the neuralgic condition. This is commonly best effected by the internal administration of alteratives and tonics, more particularly the preparations of iron and zinc, with cod-liver oil if necessary; and by theunction of an ointment of belladonna or aconite into the affected breast.

In many cases the application of a few leeches from time to time, especially in the vicinity of the axilla, will lessen the neuralgia more effectually. If these means fail, the tumor must be removed.

Adeno-fibromata are said to have occasionally disappeared, and in some instances to have been spontaneously absorbed after marriage or during pregnancy. The internal administration of Plummer's pill and the compound decoction of aloe, and the external application of leeches, followed by the inunction of iodide of lead ointment, and the employment of pressure either by means of Arnott's elastic air-cushion or by Tanchou's plan, are said to have caused the absorption of these tumors. Tanchou's apparatus consists of a pad to which a spiral spring is attached, and which, being compressed by a proper arrangement of bandages across the chest, will keep up a steady and continued pressure upon the tumor. It is less expensive and more portable than the air-compressor, and has the advantage, that it can be used in conjunction with absorbent ointments, which cannot be used with the air-cushion, as the grease entering into their composition destroys the mackintosh, out of which it is made. I have employed this kind of apparatus in several cases in the breast with great advantage. It is probable, however, that these cases were not true adenomata, but indurated lobules of the breast due to chronic interstitial inflammation, a condition which was formerly not clearly distinguished from adenoma. There is no doubt that the cases of mammary cancer cured by the same means, were also in reality lobules of the mamma indurated by chronic inflammation.

The only efficient treatment of an adeno-fibroma, or an adeno-sarcoma, is its removal by excision. In doing this it is not necessary to remove the whole of the breast, but it will be quite sufficient to extirpate the tumor itself, or at the most the small lobe of the mammary gland connected with it. This may always be done without difficulty by a single incision. In the majority of cases, as soon as the capsule surrounding the tumor is opened, it can be shelled out without further use of the knife. There are usually no vessels to tie. In removing a tumor of this kind there are two important points that should, if possible, be attended to. 1. The gland should not be incised through its whole thickness, so as to open up the areola, which is interposed between it and the pectoral muscle. If this be interfered with, infiltration of blood or of pus into it may occur, and deep abscess may form under the breast, or at the lower edge of the gland, leading to very troublesome consequences. 2. The wound must not be tightly closed; it should be very thoroughly drained. Unless this be done, the discharges are retained, and if allowed to decompose, burrowing of unhealthy matter in the submammary areolar tissue will take place, leading to extensive suppuration behind the mammary gland, often of a most troublesome and tedious character.

In cases of adeno-sarcoma which have been allowed to attain a very large size before removal, it will generally be necessary to extirpate the whole of the mammary gland, which will be found either involved in the tumor or in an atrophied but otherwise healthy state. It is surprising with what ease these tumors can often be removed, even when they have reached some pounds in weight. They rarely form any deep attachments, and adhere to the skin only when the tension has become so great as to set up inflammation.

Cysto-sarcoma.—These tumors are composed of dense white lobulated or foliated structure, resembling that of the adeno-fibroma. This mass is studded throughout with a number of small cysts, varying in size from a pin's-head to an inch and a half in diameter, and usually containing a serous fluid. The larger cysts contain lobulated, branching, intracystic growths, most commonly sprouting from one side only, and forming pedunculated

projections into the cavities. These intracystic growths are not always present. This form of tumor is usually met with in women of from thirty to thirty-five years of age, and is often attributed to injury. It occurs most frequently in women who have borne children, and is possibly a remote consequence of some inflammatory process occurring during lactation. On examining a breast affected in this way, it will be found that the tumor is hard,

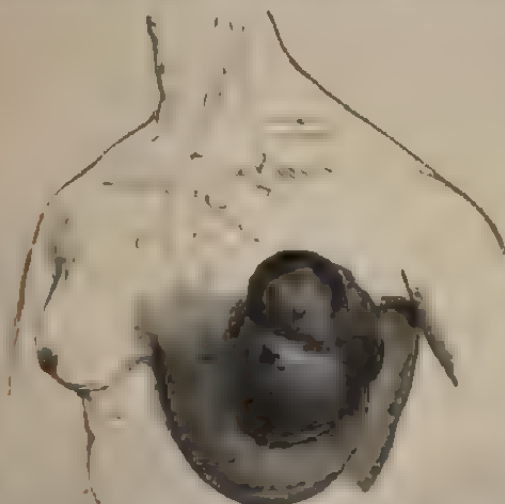

Fig 772.—Cysto-sarcoma of Breast

hard, and solid to the feel; on careful examination, however, its surface may be felt to be finely nodulated; and, occasionally, a larger cyst than usual, recognized by its elastic feel and globular shape, may be found protruding. The disease is slow in its growth, and does not implicate the adjacent cutaneous or areolar structures; hence, the tumor is movable on the pectoral muscles, and the skin is unattached to it. The axillary glands, too, are not enlarged. The nipple will usually be found to be normal in its shape, and not depressed. If one of the larger cysts be laid open, or if the pressure of the intracystic growth causes inflammation and ulceration of its capsule, this may at last be perforated, and a fungous mass will sprout through it, presenting many of the ordinary symptoms of a malignant growth; being irregular, dark-colored, bleeding readily, and increasing rapidly in size. When such changes as these have taken place, the tumor assumes a formidable character, and will rapidly prove fatal by exhaustion. A cysto-sarcoma may attain an immense magnitude and weight. They have been met with of six, eight, or even twelve pounds weight; but by far the largest is one described by Velpeau, which weighed forty pounds.

The eventual development of fungating sarcomatous tissue in these tumors must not be overlooked. A tumor of this kind may remain benign for many years, and remain so generally throughout the greater portion of its structure; yet after removal soft sarcomatous masses may be found sprouting from into some of the cysts. In the case from which the drawings Figs. 771, 772 were taken, the tumor had existed for more than twenty years before removal having commenced at the age of twenty-eight; but after amputation soft fungating growths were found at the bottom of some of the cysts. The constitution was uncontaminated throughout.

There is no *Treatment* for these tumors but early and complete removal. If taken early enough, the mamma can usually be saved, but when the growth has passed a certain size, this is no longer possible.

Sarcomata of the Breast.—The mammary gland or its immediate neighborhood is a frequent seat of sarcoma. By far the most common form met with is the spindle-celled sarcoma, usually of the large celled type. Sometimes the firmer forms of spindle-celled sarcoma, with small cells and a varying amount of fibrous stroma—the old recurrent fibroid—is met with in the region. Small round-celled sarcoma, alveolar sarcoma, and giant-celled sarcoma, are also met with in this region, but are all rare. The structure of these various forms of sarcoma has already been fully described in the chapter on Tumors (vol. i. p. 959).

Fig. 773.—Ulcerated Cystic Tumor of Breast of 20 years' duration.

Fig. 774.—The same Cystic Tumor 12 years later with fungating sarcomatous growth.

Most sarcomata of the breast are distinctly encapsuled by a layer of fibrous tissue in the early stages of their growth, but later on they tend to spread beyond this, and infiltrate the surrounding structures.

Sarcomata are difficult to distinguish from the softer forms of adenofibroma, and are practically indistinguishable from the adenocarcinoma after removal. Usually, they develop in women after thirty. They are soft, elastic tumors, smooth on the surface, and uniformly rounded in outline. They may be deeply buried in the substance of the gland, but more frequently they are situated at one side. They are painless and movable over the pectoralis major until they have reached a considerable size and they show no tendency to infect the lymphatic glands.

Sarcomata here, as elsewhere, may develop cysts in their substance from softening or from hemorrhage. These accidental cavities must not be confounded with the cysts of a cysto-sarcoma. Sometimes the whole mass may be so soft as to be indistinguishable from a collection of fluid. In a case of this kind under my care, a small puncture was made; nothing but blood escaped, and in a few weeks a fungating sarcomatous growth protruded from the opening. The breast was removed, and the growth was found

be an exceedingly soft sarcoma, the structure of which was to a great extent broken down by hemorrhage. These tumors present the most typical examples of recurrent sarcomata. It may be stated broadly, that the softer the sarcoma the more rapidly will it recur. In one case, in which I removed a very large tumor of this kind, weighing about four pounds, with the whole of the involved and atrophied mammary gland, from a lady forty years of age, in 1859, recurrence took place in 1861, and again in 1863, 1864, 1865, and 1868. The recurrent tumors were developed at some little distance from the original cicatrix, and proved on careful examination to be sarcomatous. The general health continued perfectly good throughout, and there was no infection of the lymphatic glands. She died of paralysis some years after the last operation. In these cases, this absence of all glandular implication or of constitutional affection from secondary growths in the viscera will indicate the benign character of the disease; the peculiar local malignancy not being associated with any tendency to general infection. In such cases as these, the tendency to recurrence will often gradually wear itself out, and after several operations have been performed at intervals of months, or a year or two, the disease will cease to be reproduced, and a cure will be thus established. The result is not, however, always so favorable. Instances are not wanting in which the tendency to local reproduction of the sarcoma has been so active that it outran all possibility of complete extirpation, and eventually destroyed the patient. Moreover, whenever a sarcoma is not only exceedingly rapid in its growth, but recurs after removal, suspicions of general malignancy not unnaturally arise, as two of the most frequent and important elements of such a condition, exuberant vegetative activity and local return, exist. In a case under my care a few years ago, I removed a sarcoma about the size of a hen's egg from the mamma of a middle-aged unmarried lady. The tumor was distinctly encapsuled, and was easily dissected out. It was soft in structure, and yielded a glairy fluid from the cut surface, and was composed of large oval and spindle-shaped cells, with scarcely any intercellular substance. A few months after, five small, soft tumors sprang up around the cicatrix. The whole breast was then removed, but the patient died a year afterwards from a large secondary growth implicating the sternum.

The *Diagnosis* of sarcoma of the mamma from the softer forms of adenofibroma and adeno-sarcoma, is not possible in many cases before removal. It may be suspected when the tumor is uniform in outline, free from lobulation, of rapid growth, and commences after the age of thirty-five. From cancer it is distinguished by its softness, its more rapid growth, its more definite circumscription, and the absence of glandular affection and of retraction of the nipple. Should the sarcoma from the first infiltrate the surrounding tissues, the diagnosis becomes much more difficult, as the growth closely resembles some of the softer forms of cancer.

The *Treatment* of sarcoma of the breast is early and free removal. Nothing else can be of the slightest use. Before commencing the operation, it is well to obtain the patient's consent to complete removal of the breast if necessary. The tumor may then be exposed and dissected out. If it be firm and distinctly encapsuled, it may be removed without taking away the whole mamma, the capsule, if possible, being removed with it; but should it be soft, ill-defined, very vascular, it is safer to remove the whole gland at the same time. Should recurrence take place, the breast must be fully removed, and the operation may be repeated as often as local recurrence takes place, so long as there is no evidence of secondary growths in the viscera.

Sanguineous Cysts are occasionally met with in the mamma. These are of various kinds. As before stated, retention-cysts with papillary growths

within them may become filled with blood, which may be squeezed from the nipple by pressure on the tumor. Very soft sarcomata, also, may be broken down by hemorrhage into their substance as to be mistaken for blood-cysts. A peculiar form of cancer, to be subsequently described in which it seems to arise rather from the ducts than the acini, may also present numerous cysts filled with blood. Lastly, any form of cyst may become filled with blood as the result of an injury.

Fetal Remains have, in some rare cases, been met with in the breast; these, however, are rather matters of pathological curiosity than of practical importance.

CANCER OF THE BREAST.

Glandular cancer, that is to say, cancer the cells of which belong to the type of glandular or spheroidal epithelium, is the form commonly observed in the mamma. Its three varieties, scirrhus, encephaloid, and colloid are met with, but the first occurs with far greater frequency than any of the other forms. The encephaloid form of the disease occurs with some frequency; but colloid is very rare. Cancer of the breast, whatever form it assume, is invariably primary; it may affect one lobe only or be infiltrated into the whole gland, and it may commence in or immediately beneath the nipple, or so early affect the skin and spread so widely in it as to appear to have originated in that structure. Most frequently one breast only is affected, but in some cases both are implicated.

Scirrhus.—Scirrhus is the form of cancer which is commonly met with in the breast. It may occur in several ways; either affecting the nipple, invading the skin, primarily developing in the form of an intra-mammary tumor, or infiltrating the whole substance of the organ. It most commonly commences as a circumscribed tumor of small size, at first, perhaps, smooth and round, hard and indolent in its character, with little or no pain, it is readily movable, may be situated in one lobe, and is attached perhaps to the rest of the gland by a distinct pedicle. As it increases in size, it becomes hard, knobby, and irregular, perhaps presenting a finely granular feel, and becoming fixed to the gland and subjacent parts. When the disease begins as scirrhus infiltration of the breast, the mass is from the first hard, ragged, irregular, nodulated, and heavy; often somewhat square in shape and easily accompanied by adhesions to the skin and the subjacent parts. In these cases, the development of the scirrhus mass is accompanied by a corresponding atrophy of the mammary gland, which becomes shrivelled and disappears entirely. In some instances, rather large cysts may form in connection with the scirrhus mass. In a woman, whose breast I once removed for what was supposed to be cystic sarcoma, but which proved after the operation to be a scirrhus tumor, the mass contained several cysts as large as cherries, filled with dark or greenish fluid, and projecting from its surface; and in a lady under my care for scirrhus of the breast, a tumor as large as a pigeon's egg, containing sanguinolent fluid, formed on the surface of the tumor.

As the swelling increases in size, it has a tendency to be more fixed to the subjacent parts, becoming adherent to the pectoral muscles and incorporating with the areolar tissue at the border of the axilla. The tumor also begins to form a distinct external projection, and becomes more irregular in shape; it is the seat of severe pain, more particularly at night; and in some cases covered by a plexus of blue and dilated veins. The ordinary symptoms of cancerous cachexy now appear, and the disease then makes still more rapid progress.

The tumor may in some cases remain for a great length of time without

implicating the **Skin**: but most commonly, after it has existed for a few months, this tissue becomes more or less involved. Instead of being loose and movable over the surface of the cancer, it will be found, on being pinched up between the fingers, to dimple at one part, where it may be felt to be attached by a kind of cord-like process to the tumor beneath it. After a time, that portion of the skin which first became fixed in this way acquires a reddish or purplish color, and is covered with thin scaly epidermic desquamations, and becomes permeated by a number of small ramifying vessels. A crack or fissure eventually forms in this: a small exudation of serous fluid takes place, which dries into a scab; under this, ulceration sets in, which speedily assumes the ordinary characters of a scirrhus ulcer, having hard, elevated, and everted edges, a grayish-green or foul surface, and discharging a quantity of very fetid pus. In some cases ulceration may take place at several points, and thus the whole surface of the breast becomes converted into one immense chasm, which may extend even up into the

axilla.

The skin, when affected, often assumes a red, glazed, hard, and brawny character, being shining, and as if greasy upon the surface, having its pores enlarged, and enveloping the side of the chest in a kind of stiff solid casing, attended usually by much pain, considerable oedema of the arm, and an aggravated form of constitutional cachexy; ulceration at last takes place in this hardened mass, and then speedily destroys the patient. In other cases, the cancerous development seems to expend its energy chiefly upon the cutaneous structures. The tumor of the gland is small, atrophic, and implicates the nipple. The cancerous infiltration rapidly spreads into the surrounding integument, which becomes early contaminated, assuming a hard, leathery character, or feeling brawny and infiltrated; often without discoloration, but presenting a hypertrophied appearance, the pores being enlarged, and the interstices between them increased. In other cases, the infiltrated

Fig. 275. - Ulcerating Scirrhus Cancer of Breast.

skin assumes a brownish or purplish color, and is covered by rough desquamating crusts, so as to resemble the bark of an old tree. This diseased state of the integuments will extend very widely, without ulceration or further development of the tumor situated in the gland. I have in this way seen the integuments of the whole front of the chest, from the clavicles to below the mammae, and from one axilla to the other, infiltrated, hard, and leathery, of a brownish-red color, forming a stiff cuirass, as it were, but without ulceration. This condition is very chronic; and it is remarkable that in it the axillary glands are not infiltrated, or the constitution rendered cachectic, at nearly so early a period as when the disease more extensively implicates the mammary gland.

Another way in which the skin becomes involved is by the formation of a scirrhous tubercle or nodule in it towards the outer or axillary border of the mamma, the gland beneath being implicated to but a limited extent. It is probable that in these cases the disease commences in an outlying nodule of the gland situated immediately beneath the skin. Occasionally small nodules and tubercles spring up in the skin around the spot first implicated. They are of a reddish-brown color, slightly elevated, smooth on the surface, and very hard. By the confluence of these the condition above described of wide spreading implication of the skin may arise.

The Pain is in many cases but trifling in the early stages of the affection so much so, indeed, that it is the tumor, often accidentally noticed, that excites alarm; as it increases, however, the suffering becomes severe, more particularly at night, is greatly aggravated by handling the diseased mass, and chiefly extends up to the shoulder and down the arm. The pain usually becomes most severe about the time when the skin is first implicated, but, as the cutaneous infiltration goes on, it gradually lessens, owing probably to the destruction of the cutaneous nerves.

Retraction of the Nipple commonly commences about the same time that the skin is implicated. It is most marked in the atrophic forms of scirrhous. It is due to the shrinking and contraction of the older parts of the growth, which forms so characteristic a feature of scirrhous (vol. i. p. 140). As this takes place the ducts passing from the affected part of the gland to the nipple become dragged upon. The depression may be at the same time increased by the projection forwards of the general mass of the breast, so that the nipple may become completely buried. This sign has received more importance than it deserves in connection with cancer, as it does not occur in all cases of malignant disease, and is occasionally met with in simple mammary tumors.

The **Axillary Glands** usually become enlarged early in the disease, and may attain a greater size than that of the original tumor; and on dissection a kind of indurated cord may in some cases be felt extending in the course of the lymphatic vessels, from the edge of the pectoral muscle to the axilla. After a time, the supraclavicular glands may likewise become implicated. In fact, the whole of the glandular structures in the vicinity of the shoulder undergo cancerous infiltration. When this is the case, the pressure upon the axillary vein may occasion oedema of the arm and hand. The glandular infiltration usually increases rapidly after the skin has become implicated. In some cases, when the glands become affected, the virulence of the disease appears to expend itself upon them, the tumor of the breast ceasing to enlarge, or even wasting, whilst the secondary glandular deposits in the axilla become greatly developed. It is probably in this way that the supposed cases of primary scirrhous of the axillary glands have arisen.

As the scirrhous extends, it may gradually implicate the subjacent muscular tissue, the ribs, and at last the pleura, giving rise eventually to hydrothorax.

After the affection of the lymphatic glands, secondary growths make their appearance in the **Viscera and other parts of the body**. The period at which this takes place varies in different cases. As a rule, it may be stated that the softer the tumor and the younger the patient the earlier will the viscera be implicated. The most common seat of the visceral tumor is the liver; after that, but at a considerable interval, comes the lung and then the bones. In the brain, kidneys and other organs secondary growths are occasionally met with, but are less common. Among the bones, the ribs, the vertebrae and the pelvis are perhaps the most frequently affected. In the

last situation it causes death by development of angular curvature, with pressure on the spinal cord. In the long bones it gives rise to spontaneous fracture.

The **Constitutional Cachexy** is, in the majority of cases, not present till after ulceration has taken place or secondary growths have formed in the internal organs. In fact, in a very large proportion of cases the patient has enjoyed exceptionally good health, and appears perfectly healthy in other respects at the time the tumor is first discovered, and may remain so till it has made considerable progress. The implication of the skin is usually an epoch of peculiar importance in scirrhus of the breast, as it is at this period that the pain increases, the lymphatic glands become infected, and the constitution becomes distinctly poisoned.

Duration. The duration of life after the occurrence of scirrhus of the breast varies greatly; so much so, that the disease may be considered as assuming an acute and a chronic form. The acute variety occurs principally in ruddy and plethoric women, and commonly proves fatal in a few months. In those who are of a more feeble and delicate constitution, the disease, as a general rule, takes a slower course. Sir A. Cooper states that the disease, on an average, is from two to three years in growing, and from six months to two years in destroying life after being fully formed. In this estimate, which is probably correct, Wulshe agrees. Paget states that the average duration of life in cases in which the disease is allowed to run its course without operation is four years; but the statistics of Sibley and Von Winiwarter give a period of only from thirty-two to thirty-three months. The average duration of life in cancer of the breast may therefore probably be estimated at about three years. As a general rule, the progress of scirrhus is slower in old people, in whom it occasionally gives rise to a kind of atrophy of the breast, with shrinking of the tumor. There are many instances on record, in which cancer of the breast is said to have existed for a far longer period than this; for ten, twelve, or even twenty-five years, but there must always be a doubt as to the correctness of the diagnosis in such cases.

Pathological Structure.—After removal, scirrhus of the mamma presents considerable variety in appearance. In the majority of instances it occurs as a peculiarly hard, knobbed, and irregular mass, creaking under the knife, when cut, and presenting on section a grayish or bluish-gray, semi-transparent surface, traversed in various directions by bands of a more opaque character, and exuding on pressure a thin milky juice. The section has been very aptly compared to that of an unripe pear. In all slow-growing hard cancers the cut surface becomes distinctly concave, a peculiarity which distinguishes them from all other tumors. In soft cancers this feature is wanting. In many specimens masses of an opaque appearance and yellowish tint may be seen in the midst of the tumor. These are the result of fatty degeneration of the scirrhus structure. In other cases, again, on pressing the tumor, small drops of a thick creamy fluid will appear to exude at various points. This seems to be the inspissated and altered secretion of the gland retained in the ducts. Cysts are occasionally, though rarely, met with in scirrhus of the breast; these are usually small, and contain clear fluid, being deeply embedded in the substance of the tumor; in other cases they may be large and globular, and filled with a bloody or dark-green liquid. The microscopical characters of scirrhus of the breast are such as are represented in Figs. 398 and 399, vol. i.

ENCEPHALOID.—Formerly, when all soft sarcomata were classed as cancers, encephaloid of the breast was described as a disease of moderately frequent occurrence. Now that the term is strictly limited to the softer and

more rapidly growing forms of glandular cancer the disease cannot be said to be common. No sharp line can be drawn between scirrhus and encephaloid; what one Surgeon would term a soft form of scirrhus, another would class as encephaloid. Pathologically the difference between the two forms consists in the relative proportion of the stroma and cells. The greater the proportion of stroma, the harder the tumor. In the softer forms the cells are, as a rule, larger. (Fig. 400, vol. i.)

Soft glandular cancer usually begins deeply in the substance of the breast as a soft globular tumor, which rapidly increases in bulk and infiltrates its whole gland; the integuments covering it are not at first adherent but are usually pushed before it, and speedily become permeated by a largely ramified network of veins. In some cases I have seen the integuments, early in the disease, oedematous and inflamed, so as to mask the subjacent tumor. The mass at first feels as if composed of several soft and rounded tumors, which may communicate an obscurely fluctuating sensation, perhaps causing the Surgeon to mistake the growth for a cystic formation or an abscess with which it is especially apt to be confounded in those cases (rare, it is true, in which the skin is inflamed and oedematous). The breast now rapidly assumes a very prominent and conical form; the skin covering it at its most projecting part becomes thinned and reddened, and at last gives way, leaving a large circular ulcer, from which a fungous mass of grayish or reddish-brown color speedily sprouts up, with a good deal of discharge of a foul, bloody, and offensive character. From this, disintegrated masses are occasionally detached by sloughing. Implication of the glandular structures in the vicinity of the tumor, followed by constitutional cachexy, occurs in this as in scirrhus of the breast, but somewhat earlier. The progress of the disease is always extremely rapid, especially in patients below middle life and otherwise healthy.

COLLOID of the breast is of very rare occurrence. Most commonly only a part of the tumor has undergone degeneration, the remainder presenting the ordinary appearances of soft or hard glandular cancer. I have during the last few years removed two very typical specimens of this form of cancer. In both cases the patients were past middle life. The peculiar feature in each case was that though the tumor had implicated the skin and formed a prominence about an inch and a half in diameter and projecting nearly an inch above the surface, no deep ulceration had taken place, nor were the glands affected. A section of the breast showed, in the greater part of the tumor a coarse alveolar structure, the alveoli being distended with colloid matter. The growing margin of the tumor presented the ordinary appearance of a rather soft scirrhus cancer, and between this and the colloid part every intermediate gradation was recognizable. The nature of the growth was confirmed by microscopic examination.

DUCT-CANCER. VILLOUS CANCER.—Under these names has been described a rare form of tumor which infiltrates surrounding parts, infects the glands, and generalizes like an ordinary cancer. Its structure has been very fully described by Cornil and Ranvier. To the naked eye it may resemble encephaloid cancer, and its section yields an abundant milky juice, but it differs from ordinary cancer in presenting numerous small cysts, some only just visible to the naked eye, and others an eighth of an inch, or even more in diameter. In some specimens these cysts are filled with blood. Microscopic examination shows it to be composed of a well formed fibrous stroma, containing spaces lined with an epithelium tending to assume a columnar form. Delicate villous processes covered with epithelium project from this stroma into the spaces. These villi contain loops of delicate capillary vessels which void the blood so often found filling the spaces. According to Cornil and Ranvier

the greater part of the small cysts can be clearly recognized as dilated galactophorous ducts, and they are of opinion that these tumors are malignant growths springing from these structures. As before pointed out, villous growths may term in simple glandular cysts, and these may bear the same relation to villous cancer that the simple papillary polypus of the rectum does to columnar epithelioma. When these tumors affect the lymphatic glands the secondary growths present the same structure as the primary.

Causes of Cancer of the Breast.—These are usually extremely obscure.

Sex is certainly the circumstance that has the most marked influence on the occurrence of mammary cancer, the disease being, as is well known, almost entirely confined to women; yet instances of this affection in the male breast occasionally occur. Its peculiar frequency in the female may possibly be connected with the great and sudden alternations of the functional activity of the breast in women. The changes impressed upon this organ at puberty and during pregnancy, the various alternations which it undergoes, the inflammatory affections to which it is subject during lactation, the frequent irritation to which it is exposed by sympathizing with uterine derangement, and the diminution in its vital activity that takes place at the change of life, are sufficient to explain the great liability of this organ to disease generally: and may not improbably give a clue to the reason why it is peculiarly the seat of cancer in women.

Age.—The age at which cancer of the breast most frequently occurs is between the thirtieth and fiftieth years. According to Birkett, it is most commonly met with between the ages of forty-five and fifty—a period of life that is popularly looked upon as specially obnoxious to this malady. At these ages, cancer of the breast usually affects the form of scirrhus. When it occurs, as it very rarely does, in early life, it more frequently assumes the encephaloid character. I have, however, removed a scirrhus breast from an unmarried woman twenty-three years of age. In elderly women also, scirrhus is the prevalent form; though I have seen several instances of encephaloid at an advanced period of life, one case in a woman upwards of seventy years of age. Indeed, cancer in either form may affect this organ up to the latest period to which life is prolonged. Married women are said to be more liable than single ones to cancer of the breast; it may, however, fairly be doubted whether they are proportionately so; and it is a common belief, founded, I think, in some degree on truth, that the disease is most common in women who have not borne children.

Injuries inflicted upon the breast, such as blows, squeezes, etc., are commonly referred to, and are greatly dreaded by women, as the causes of cancer. That they might be so in constitutions otherwise predisposed to the affection, does not appear improbable; and that they are so in reality in many cases, I have not the least doubt. The number of instances that have fallen under my observation, in which a blow or squeeze of the breast has speedily been followed by the appearance of a cancerous tumor in it, leaves no doubt whatever on my mind of the truth of the popular belief that associates the injury with the disease, in the relation of cause and effect. *Lactal inflammations* are likewise supposed to tend to the production of cancer of the breast. Of this doctrine, I think that we do not possess sufficient proof; though it appears highly probable that disturbance of the functions of the organ during lactation may predispose to the occurrence of this disease.

The so-called "**Eczema**" of the Nipple was first described by Sir James Esq., as being occasionally the precursor of cancer of the breast. The nature of this affection and its connection with cancer of the breast are alike obscure. **There** are two ways by which the latter may be explained. Thus the local external eczema may be the primary disease, and, traveling up the epithelial

lining of the lacteal ducts, may produce changes in them which determine finally a true cancer of the mammary gland. But there is obviously another explanation, viz., that the primary disease is situated in the acini of the gland, that some modification of nutritive or structural change takes place in them either preliminary to, or of the nature of, cancer, in consequence of which their secretion becomes unhealthy, and that this morbid secretion irritates the mucous cutaneous surface with which it comes in contact. That this explanation is a probable one would appear from a case under my notice in which a lady, having atrophic scirrhus of the right mamma, became affected by eczema of the left nipple. After a time, the axillary glands on this—the left side—became cancerous, and then some induration was detected in the left mamma. Here it seemed probable that the primary disease of the left mamma consisted in a small scirrhus infiltration of it which simultaneously or almost so gave rise to eczema of the nipple on one side and glandular infiltration on the other. Any way, persistent eczema of a nipple in a middle-aged woman must excite the gravest apprehension as a probable precursor or concomitant of cancer of the breast.

The influence of *Heredity* and the *Geographical Distribution of the Disease* have been already sufficiently discussed in the chapter on cancer in general (vol. i. p. 974).

Diagnosis.—The diagnosis of cancer of the breast from other diseases affecting this organ is of the first importance, and is attended by corresponding difficulties. The great point is to determine whether the tumor of the breast be of a cancerous character or not; that the Surgeon should get beyond this, matters little in practice—and, indeed, except in some of the forms of cystic disease of this organ, few practitioners would feel disposed to endeavor to carry their diagnosis beyond this point. The great and essential difficulty in determining the nature of a tumor of the breast consists in the fact of the same signs being more or less common to many growths in this region, a hard, circumscribed, indolent mass, chronic in its progress, with a certain amount of pain, being the usual characteristics presented by all solid mammary tumors; and though, in nine cases out of ten, a tumor presenting these characters, which has existed for a year or more in an elderly woman and has resisted ordinary absorbent and alterative treatment, is scirrhus, in instances of the reverse occasionally occur. Nothing can better exemplify the difficulty of diagnosis in tumors of the breast than the circumstance, which is not unfrequently witnessed, that after the removal of the diseased mass, its section, and careful examination, Surgeons of equal experience will differ as to whether it be malignant or not, and to what class of affection it should be referred; and, indeed, in many of these cases it is impossible to ascertain its precise nature without having recourse to microscopical observation.

It is extremely difficult to lay down any definite rules of diagnosis by which the question as to the malignancy of a tumor of the breast can be solved. In the majority of cases of cystic growth in this region, there is little difficulty; the existence of cysts of sufficient size to be readily felt or seen through the skin being generally characteristic of the non-malignant cystic growths. It must be borne in mind, however, that cases, such as one in which allusion has already been made, may occur, in which cysts are associated with cancerous development.

The diagnosis between cystic sarcoma and some forms of cystic cancer of the breast is not always easy; indeed, it may be impracticable except by microscopic examination after removal. I have had in the Hospital a patient fifty-nine years of age, in whose breast a hard tumor, as large as half an orange, had existed for five years; it was perfectly and freely movable,

connected in any way with the skin; there was no retraction of the nipple, and no lancinating pain. On its upper side, several large cysts could be felt, and seen through the skin. On examination after removal, it was found to be cystic scirrhus, with large cysts of the size of cherries, containing bloody and yellow fluid. The only very suspicious circumstances here were the age of the patient, and the existence of one small indurated gland in the axilla.

In these cases of doubt, the safer plan is always to make an exploratory puncture, and, if necessary, to examine under the microscope the contents withdrawn by the groove in the needle or by the trocar; indeed, if there be the slightest doubt as to the nature of the tumor, this exploratory puncture should never be omitted before its removal is determined upon. I have more than once seen tumors which had been positively pronounced to be scirrhus, and for which amputation of the breast had been recommended, prove to be cystic, and disappear entirely when their contents were withdrawn.

Between cancer and the *ordinary solid tumors* of the breast, more especially the adenoid and adeno-sarcomatous, the diagnosis is often extremely difficult; but we may arrange the chief signs of the two forms of disease in distinct groups, that, by comparing them together, the differences may be more clearly seen. (See Table.)

NON-MALIGNANT TUMORS.	SCIRRHUS TUMORS.
<i>Feel.</i> Moderately hard, nodulated, irregular in shape; occasionally more or less lobed; distinctly circumscribed; sometimes elastic in parts.	<i>Feel.</i> Of stony hardness, knobby and indistinctly circumscribed, or somewhat square, and occupying the whole of the substance of the gland.
<i>Mobility.</i> Considerable, though occasionally there is a deep pedunculated attachment.	<i>Mobility.</i> At first, considerable, but soon lost from adhesion to the deeper structures by a broad attachment.
<i>Skin.</i> Of the natural color throughout, though thinned and expanded with the tumor lying close beneath it. Implicated only in the advanced stage of cystic sarcoma.	<i>Skin.</i> Early implicated; at first dimpled, then red or purple, and in other cases brawny and leather-like, so that it does not admit of being pinched up into folds; or nodulated; purple-red masses form in it.
<i>Nipple.</i> Usually not retracted.	<i>Nipple.</i> Usually retracted.
<i>Veins of the Skin.</i> Not much dilated.	<i>Veins of the Skin.</i> Very greatly dilated.
<i>Pain.</i> Often moderate; if severe, continuous, or of a neuralgic character, much increased by handling.	<i>Pain.</i> Severe and lancinating, especially at night after handling, and when the skin is implicated, but not continuous.
<i>Axillary Glands.</i> Of usual size, or but slightly enlarged and movable. Lymphatics not affected; supraclavicular glands not affected.	<i>Axillary Glands.</i> Enlarged, indurated, and fixed. Indurated mass of lymphatics under and parallel to edge of the pectoral, stretching into the axilla, supraclavicular glands enlarged.
<i>Constitutional Infection.</i> None.	<i>Constitutional Cachexy.</i> As disease advances.

The coexistence of adenoma and carcinoma in the same breast is exceedingly rare, though a case has been recorded by Rushton Parker. In such a case the diagnosis must necessarily be very obscure.

The diagnosis of cancer of the breast from *chronic interstitial induration* of a lobule of the gland is often extremely difficult. Both diseases impregnate the mammary tissue, are ill-defined, hard, and often nodular. The pain may be the same in both, and they may occur at the same age. If the inflamed lobule be near the surface, the skin may dimple over it as in a cancer, and in rare cases there may be an enlarged gland in the axilla. As a rule, however, the inflammatory induration is not so hard as that of cancer, and more than one nodule may be felt perhaps in each breast whereas a primary scirrhous is always single. In the later stages, when cancer has implicated the skin and glands, the difficulty in diagnosis is no longer present.

A similar difficulty often arises in cases of *chronic encysted abscess*. Here the distinct relation of the disease to impregnation and the slight color almost always to be recognized over an abscess will serve to show the nature of the disease.

Rapidity of growth, although always a very suspicious circumstance, is not by itself and without other signs be taken as unequivocal evidence of malignancy of action. I have seen a so-called "chronic mammary tumor" probably a sarcoma, increase from the size of a hen's egg to that of the adult head in less than six months, and after removal not present the slightest evidence of malignant disease, on the most careful examination.

Recurrence after removal, though a very suspicious circumstance, is by no means a proof of malignancy. Rapidly growing sarcomata will recur. This I have seen happen five times in a lady, otherwise in perfect health and without a trace of malignant disease in the system or in the tumor (see p. 711). So also the recurring fibroid tumor has been removed eight or ten times from the breast, before its complete extirpation has been effected.

In cases in which, after carefully applying the foregoing principles of diagnosis, the Surgeon is still uncertain, he may feel tempted to wait until time clears up the doubt and makes the nature of the disease evident. By so doing the only hope of materially prolonging the patient's life, should the disease be really malignant, is lost. In the present day, when our treatment of wounds is so far perfected that a simple incision may be regarded as free from danger and almost free from inconvenience, it is the Surgeon's duty to cut into every doubtful tumor which may by any possibility be a cancer and to remove a piece for examination. In the great majority of cases the naked eye appearances will at once determine the question whether it be a cancer or not, but should there still be doubt a scraping or a small fragment teased out with needles may be put under a microscope, which should be at hand for the purpose, and it is very rarely indeed that any doubts then remain. In such cases it is better to obtain the patient's consent to whatever may be necessary before making the examination, so that no time may be lost and the whole breast immediately excised should it prove to be cancerous.

TREATMENT.—In cases of cancer of the breast, the first question that presents itself to the Surgeon is, whether any plan of treatment short of the removal of the tumor holds out a prospect of cure, or even of relief; and if not, whether the extirpation of the cancerous breast can be undertaken with the prospect of ridding the patient of an otherwise fatal disease, or at least of prolonging her existence. To these questions the remarks made p. 1003 *et seq.*, vol. i., on the general treatment of cancer, may be considered applicable. The management of cancer of the breast, however, involves many special considerations of importance, that it becomes necessary to consider its bearings somewhat in detail.

No constitutional means appear to be of the slightest service in arresting

and still less in removing, cancerous tumors of the breast. The advantages stated to have been derived from the use of arsenic, conium, iron, various preparations of mercury, etc., have not been borne out by experience; and, indeed, it may be stated generally that these and all other known remedies are perfectly valueless in the curative treatment of this disease.

Compression by various means, whether by plasters, as employed by Young: by agaric, as used by Recamier; by the spring-pads of Tanchou; or by the slack air-cushion of Arnott, has been much praised, not only as a palliative, but as a curative means of treatment in this disease; and cases are recorded—which, however, even the warmest advocates of this plan of treatment are forced to admit to be altogether exceptional—in which the employment of this means has been stated to have effected a complete removal of the tumor. But, although I am not prepared to deny that indurated masses in the breast may have become absorbed during the employment of this treatment (and indeed I have had occasion to observe this in my own practice), I think that evidence is altogether wanting to show that an undoubted case of cancer of the breast has ever been cured by this means. And, notwithstanding the high authority with which some of these alleged cures of cancer have been brought before the profession, no positive proof has been adduced to show that the tumor that was observed was really and truly of a cancerous character, and that it may not have been merely the result of chronic inflammation. Every practical Surgeon well knows that it is utterly impossible, in the present state of science, to diagnose in many cases with complete certainty the true nature of a tumor of the breast, and must frequently have witnessed cases in which, after extirpation, the morbid growth has been found to be of a different character from what had originally been supposed. I am acquainted with at least eight or ten cases in which some of the most experienced Surgeons, both in this country and in Paris, have amputated the breast for supposed scirrhus; when, after removal, it was found simply to have been the seat of a chronic abscess with very dense walls. And with regard to a hard, chronic, and indolent tumor of the breast, few Surgeons will hazard a positive diagnosis as to whether it is scirrhus or not, until they have actually seen a section of it. For these reasons, it is impossible not to receive with the utmost hesitation the cases of supposed cancer of the breast reported as cured by the advocates of compression, and not to suspect that the cases recorded by these gentlemen as instances of the successful employment of this plan of treatment may have been simple chronic indurations of the breast and not cancer.

But, though there is no evidence before the profession to prove the utility of compression as a *curative* agent in cancer of the breast, I think that, when practised with Arnott's slack air-cushion, or Tanchou's spring-pad, it is of considerable value as a *palliative* in some of the earlier stages of this disease should the patient refuse to submit to operation; then it may undoubtedly occasionally arrest its progress for a time, diminish the size of the swelling, and lessen the violence of those attacks of lancinating pain which are so distressing to the patient. In conjunction with the pressure, much relief to suffering may be afforded by the use of belladonna plasters, or of atropine or aconite inunctions, together with the internal exhibition of conium and morphia, or hypodermic injections of morphia and atropine.

In the advanced stages of the disease, however, when the skin is involved, the pressure is often unbearable, increasing the pain, and acting as a source of irritation to the patient. In some cases of this kind, in which the slack air-cushion could not be borne, I have seen relief afforded by moderate pressure with thick layers of amadou, supported by an elastic bandage, belladonna or conium in powder being dusted on the innermost layer of amadou.

A very thin gutta-percha shield, moulded to the part, may sometimes be advantageously applied over this, and kept on by turns of an elastic band. When the skin is implicated and very tender, the application of belladonna and lead lotion is of use. When the disease has run into an ulcerated state, the internal administration of conium, so as to blunt the sensibility, and the local application of eucalyptus oil and iodoform ointment, borax and lotion, and solution of permanganate of potash, to lessen the fetor together with the watery extract of opium or of belladonna, will relieve. In cases of this kind, the application of caustics has been greatly vaunted, and portions of the diseased surface may be cleansed or removed by these means. The employment of the various antiseptic dressings that are familiar to a Surgeon is of much service in the advanced stages of ulcerated cancer of the breast, removing fetor, and lessening the inflammatory irritation occasioned by the decomposition of the discharges.

Caustics, applied in accordance with the principles laid down at p. 120 vol. i., may occasionally be advantageously employed in the treatment of cancer of the breast, or when the patient is alarmed at and positively refuses to submit to the knife.

Operation.—The constitutional and ordinary local treatment of cancer of the breast being thus at the most, of a palliative character, the question of operation always presents itself at last. The objects proposed are, in the first place, by the extirpation of the diseased breast, to prevent constitutional infection, and thus permanently to free the patient from her necessarily fatal affection; or, failing in this, to retard the progress of the constitutional infection, and thus at least to prolong existence. How far these objects are attained by amputation of the cancerous breast is a subject of important inquiry to the Surgeon. The operation has been discountenanced by many excellent pathologists; not so much from any intrinsic danger it may possess, for, although occasionally fatal from erysipelas or some other accidental complication, there is nothing specially hazardous about it, so from its being now, as formerly, open to the objection of subjecting the patient to unnecessary pain, all suffering during its performance being prevented by anesthetics, and little inconvenience being experienced at subsequent dressings, which are usually almost painless; but the great objection lies in the fear that the disease will return and run its course as rapidly as the operation as if none had been performed, in some cases perhaps even more rapidly.

The principal points in connection with the operation appear to resolve themselves into two questions: 1. In any case of cancer of the breast, can constitutional infection be prevented by amputation of that organ, and, if so, under what circumstances will this most probably happen? 2. Although the disease may eventually return in the part or elsewhere, may not it arrest the rapidity of the fatal termination? (Ibid. p. 1002 et seq., vol. i.)

To the first question, it is not easy to give a very definite reply. The older statistics upon this point are but of little value, for the following reasons: 1st, that it is only comparatively recently that it has become possible clearly to distinguish, even after removal, the various forms of carcinoma of inflammatory induration from cancer; and, 2d, that until even a no recent period most Surgeons have contented themselves with removal of the diseased mamma, leaving the axillary glands untouched, unless they were obviously affected. We may therefore put on one side the statistics of H. who states that out of 88 cases, there were only 10 relapses and 2 deaths; those operated on by him at least two years before; of Alexander Mac who saw no recurrence in 4 out of 60; of Boyer, who saved 1 in 25.

Macfarlane, who saved none; of Warren, who saved 1 in 3; and Cooper, 1 in 4.

Since the introduction of anæsthetics, and more especially since the recent improvement in the treatment of wounds, the more extensive removal of the affected parts has been largely practised by Lister, Banks, Billroth, Kuster, Volkmann, and many others. These Surgeons advocate the removal of the entire mamma, with as much of the skin covering it as can conveniently be taken away, together with the axillary glands, even when these are not obviously affected. The results obtained so far by this treatment have been most encouraging. Thus Banks has published the records of 46 cases, ten of whom were alive and free from recurrence at periods varying from two to ten years after the operation, and in five more no recurrence had taken place from one to two years after the operation. Kuster states, that in 26 per cent. of the patients operated on by him, no recurrence had taken place three years after the removal of the breast. Billroth states that he had under observation 13 cases, in which no recurrence had taken place within two years of the operation, 5 of which had remained free for four years and upwards, and 4 more for more than three years. In almost all of these the axillary glands had been removed either at the same time as the mamma or in a subsequent operation. These extensive operations under the modern system of treating wounds heal frequently without suppuration. Some stiffness of the arm preventing movements above the level of the shoulder is usually left, but this is of small moment if a greater chance of life is given.

The inference fairly deducible from these cases is that in a certain proportion of cases cancer has been effectually removed by extirpation of the breast, and that the proportion of these cases in the practice of any particular Surgeon is directly proportioned to the freedom with which he removes the diseased structures.

As to the second question—whether as a general rule life may not be prolonged by the performance of the operation—we are confronted with the same fallacy in all the older statistics. Leroy D'Etiolles, Walshe, Cooper, and Brodie, were all of the opinion that life was little if at all prolonged by operation; and although Velpeau, Cadaway, Brodie, and other Surgeons recorded cases in which the patient had lived many years after the operation, most of them were probably cases of sarcoma.

The most trustworthy statistics that we possess on the relative duration of life in cases of cancer of the breast, with or without operation, are those collected by Sir James Paget, Marrant Baker, and Sibley; but even these probably include some cases of sarcoma under the name of encephaloid cancer. Paget states that, of 113 cases, 66 were not submitted to operation; of these the average duration of life was a little more than 48 months. Of 47 operated on, the corresponding average was also a little more than 49 months. In the first two years of the disease, the proportion of deaths was much less in those operated on than in those who were left—being in the former 24 per cent., in the latter 36 per cent. The longest duration of life in cases not operated on was 18 years; in those operated on, a little more than 12 years. Marrant Baker finds that in 84 cases in which no operation was performed, the average duration of life was 43 months; in 62 cases operated on, the average was 56½ months. Sibley finds that the average duration of life in unoperated cases was about 32 months; whilst in those subjected to amputation of the breast it reached 54 months. Thus it will be seen that, independently of the possible chances of a complete cure, the operation holds out the prospect of an average gain of about a year and a half.

There is, however, another point of view from which these operations may be considered; for, even if they do not prolong life, they may greatly im-

prove the patient's condition, and place her in a state of comparative comfort during the remainder of her existence. Thus, she may be suffering so much pain from the local affection, or, if the cancer be ulcerated, may be so much annoyed by the fetor of the discharges, that she may be placed in a position of far greater comfort by having the local source of disease and irritation removed; and, though she die eventually of cancer, it may be with much less suffering to herself and others for her to be carried off by one of our secondary growths in the lungs or liver, than to be worn out by the pain, discharge, and hemorrhages, of a slowly progressive ulcerating cancerous mamma.

The question as to the advisability of operation in any given case of cancer of the breast cannot, however, be determined by abstract pathological reasoning, by reference to scientific principles, or by calculations founded on statistical results. The Surgeon must minutely examine and attentively weigh all the circumstances of the particular case before him, and he must endeavor to distinguish those cases in which the operation may possibly be the means of preserving or prolonging life, from those in which there is no prospect of its being of any service, or in which, indeed, it must inevitably hasten the patient's death. Whatever the value of statistics may be in determining the question, whether in cases of cancer of the breast generally the operation will effect a cure or prolong life, they are not equally valuable in their application to individual cases. When a Surgeon is called on for his opinion respecting the propriety of amputating the breast of the patient before him, it is not sufficient for him to be able to state what the general result of the operation may be, but he must be able to satisfy himself whether the particular instance under consideration may or may not be one of those cases, exceptional, perhaps, in which there is a possibility of extirpating the disease entirely from the system, or at all events of prolonging the patient's existence. In order to do this, it is necessary to endeavor to lay down some rules that may guide us in selecting those cases in which the operation may be advantageously done, and in setting aside others in which we know that it will almost to a certainty hasten the patient's death. And, indeed, in the absence of all such considerations in general statistical investigations into the results of operations for cancer, that deprives them of much of their value as guides in actual practice.

Though nothing can be more unsurgical or improper than the indiscriminate extirpation of cancerous tumors of the breast from all patients who present themselves in whatever stage of the disease; and, though such a practice would doubtless be followed by results fully as disastrous as those that occurred to Macfarlane, Boyer, and others, yet there can be little doubt that a Surgeon who would employ a certain principle of selection would obtain a very different and a far more successful result in his practice. Sir B. Brodie very clearly and succinctly pointed out the most important circumstances by which the question as to the propriety of operating in these cases should be determined. Before doing so, he very justly dwells on the fact that in many cases the operation may fail, and the disease speedily recur through the negligence of the Surgeon in leaving portions of the gland, some of the tumor, or contaminated tissue, and that thus the operation may receive discredit for what is in reality the fault of the Surgeon who performed it.

With reference to operation, cancerous diseases of the breast may be divided into three classes:—1. Those in which it is the duty of the Surgeon to be continuance excision; 2. Those in which the operation is of doubtful expediency; and, 3. Those in which it is the duty of the Surgeon to refrain from it.

1. Cases unfit for Operation.—This class includes cases presenting the following conditions: *a.* Strongly marked constitutional cachexy; *b.* Disease in both breasts; *c.* Secondary deposits in internal organs; *d.* Much enlargement of the glands under, and especially of those above, the clavicle; *e.* Edeema of the hand and arm from pressure on the axillary vein; *f.* Adhesion of the tumor to the ribs and intercostal muscles; *g.* Hard, brawny, and infiltrated skin, of a red-fish-brown color, having a hard, leathery feel, or a greasy, glazed appearance; *h.* Rapid growth of the tumor in a patient with a strong hereditary taint; *i.* An extensively ulcerated and fungating tumor, with marked constitutional cachexy.

2. Doubtful Cases.—*a.* If the patient be aged, weak, anæmic, or very fat, and the tumor large, it is seldom expedient to operate, as the shock may destroy life. *b.* When the skin is merely dimpled in by a kind of pedicle passing from the tumor to its under surface, an operation may be performed, unless other circumstances should contraindicate it; but in such cases it is necessary widely to excise the integument surrounding the attached point. The cancer-cells, as I have more than once had occasion to observe, will have diffused themselves extensively through the neighboring skin, which, to the naked eye and to the touch, has a perfectly healthy appearance, the tumor being surrounded by a kind of halo of cancer-infiltration. *c.* When there is but moderate enlargement of axillary glands, which are so situated as to admit of removal, the operation may be performed. *d.* When the cancer is ulcerated, it is seldom proper to operate; but, if all other conditions be favorable, this even need not, in some special cases, be a bar. As Sir B. Brodie has pointed out, the patient's existence may sometimes in these cases be prolonged, and her comfort materially increased, by removing the diseased and ulcerated mass.

Old age exercises a material influence on the expediency of operating for cancer of the breast. As a rule, I do not think it advisable to do so after seventy years of age, unless the distress from pain or the discomfort from fetid ulceration be so great as to render removal at any risk justifiable. The danger of the operation is greatly increased by advanced age, more especially if the patient is stout; and if recovery take place the expectancy of life after seventy would not be materially, if at all, increased by the extirpation of a disease which would probably recur and prove fatal within two years; the more so, as the progress of cancer at advanced age is often very slow.

Pregnancy is not necessarily a bar to the performance of any necessary operation, even of amputation, on the female breast. In pregnant women cancer when attacking the breast becomes very active, hence its removal should not be too long delayed, if all other circumstances are favorable. Should, however, the sixth or seventh month be reached, it might be as well to delay the operation till after recovery from parturition. But in deciding this question much will depend not only on the rapidity of the growth of the tumor, but on the size of the breast and the moral effect of the operation.

3. Cases favorable for Operation. All cases of cancer of the breast are favorable for operation when recognized sufficiently early, provided the patient is suffering from no constitutional disease, but unfortunately, either from reticence on the part of the patient or hesitation on the part of the medical attendant, the question of operation is frequently not raised until some of the unfavorable conditions already mentioned have appeared. The exclusion of all the cases in which this has happened, will necessarily limit very materially those in which the operation may be undertaken; it can, however, be performed with every prospect of its being advantageous to the patient, if the tumor be of moderate size, slow or nearly stationary in its growth, unconnected with or at least merely attached by a pedicle of the skin,

pretty distinctly circumscribed, movable on the subjacent parts, and not complicated by greatly enlarged glands in the axilla or elsewhere. The tumor has an especially good prospect of recovery, according to BROWN, if the disease be seated in the nipple.

When once a tumor of the breast has been ascertained to be of cancerous character, the sooner it is removed the better, unless one of the special reasons adverse to operation that have just been adverted to should rule. Every day's delay diminishes the chance of permanently relieving the patient. The disease (for reasons stated at pp. 278-281, vol. i.) appears in the early stages often to be entirely local: there is no evidence of constitutional infection, but if the operation be delayed the skin speedily becomes implicated, the axillary glands enlarge, and cancerous cachexy sets in. In all cases of cancer of the breast the whole of that organ ought to be removed, especial care being taken that no bits of mammary structure be left behind; and after removal the under surface and edges of the ganglion ought to be carefully examined, to discover whether the extirpation has been complete. The question of the simultaneous removal of the axillary glands in every case is still an open one, but when we consider how unsatisfactory the simple excision of the gland usually is, it certainly deserves a trial. When the cancer is infiltrated, the whole of the breast and the surrounding cellulose-adipose structures must be very freely removed, as there is then a halo of cancerous infiltration around the morbid mass, in tissues apparently healthy. It may happen that the tumor, especially if scirrhus, is apparently isolated, and situated at one border of the gland, scarcely if at all connected with that structure. Here the question will arise, as to whether the whole of the organ ought to be removed or not. In determining this we must, I think, be guided by the position of the scirrhus mass and the size of the breast. The cancer-infiltration proceeds in the course of the lymphatic vessels. If the cancer be situated towards the sternal or under aspect, however isolated it may appear, it will be found that the mammary gland will certainly have become infiltrated, lying as it does between the tumor mass and the lymphatics. When, however, the tumor is seated at the upper or outer border of the gland; when it appears to be detached from the breast, lying rather in the axilla or below the clavicle than in connection with the gland; when the breast itself is very large and fat, but healthy to the touch without hardness or retraction of the nipple; when there is no sign whatever of deep infiltration—it may then be a question whether it will not be more prudent to extirpate the tumor alone, with the adipose bed in which it lies, and a deep slice of the adjoining mammary gland, than to perform the more serious operation of removing the whole of the breast. In determining on this point we must, I think, be guided by the situation of the tumor, the size of the breast, and the size of that organ. If the tumor be distinctly axillary, if the breast feel perfectly soft and healthy, and the nipple project, there is no reason to fear infiltration by cancer of the central and sternal portions of the mammary gland. I have found on careful microscopical examination of breasts removed for scirrhus at the axillary border, that the above named parts of the gland were entirely free from all sign of disease. If the tumor be small and shrunken, the whole may be removed without any increase of danger; if it be very large, the surgeon best consults the patient's safety by simply removing the tumor with a deep wedge shaped piece of the contiguous portion of the gland; but if there be any hardness or suspicious nodulation about the mammary gland, if the line of demarcation between it and the tumor be not defined, and particularly if the patient be thin, so that the operation is not a very severe one, extirpation of the whole of the breast ought certainly to be practised. However widely the parts are removed I

line of incision usually comes together readily and evenly, owing to the laxity of the integuments in the mammary region.

I have observed in those cases in which it becomes necessary to extirpate tumors of the mammary region, without removal of the gland, that erysipelas has more frequently followed the operation than when the gland, being affected, has required removal.

Return of Cancer after Operation may take place in three situations: in the cicatrix of the part operated upon, in the neighboring lymphatic glands; or in some internal organ or distant part. When cancer recurs in the neighborhood of the previously affected part, it is probably owing to the cancer-cells having become widely disseminated in the skin, the subcutaneous areolar tissue and muscles, or neighboring lymphatic glands, and after the removal of the tumor these cells become the germs of new growths. In these circumstances it may recur in the cicatrix and then implicate the glands; or in the glands without the cicatrix having been previously affected. In local relapse of this kind, it often happens that the disease, so reproduced, runs its course more rapidly than if no operation had been performed; the hyperæmia set up in the part during the healing process appearing to give augmented force to the reproductive energy of the cancerous growth. In some cases it returns in the wound even before cicatrization is completed, the surface then assuming the ordinary character of the cancerous ulcer. In other cases, the cicatrix, some weeks or months after it is fully formed, assumes a dusky red or purplish tinge, becoming hard, stony, and nodulated at points; these nodules being round or oval, often very numerous, and varying in size from a pin's head to a pigeon's egg, studding the whole length and breadth of the cicatrix, and at last running into true cancerous ulceration. In such circumstances, the only hope of prolonging the patient's life lies in the speedy excision of the whole of the diseased structures, or their extirpation by caustics, provided there be no deep affection of the glands, nor evidence of internal secondary growths. But if the axillary glands be much enlarged, either alone or together, with recurrent disease in the cicatrix, or if there be any sign of internal cancer, further operation will be improper.

AMPUTATION OF THE BREAST.—The question of amputation of the breast should always be raised and discussed with more than ordinary regard to the feelings of the patient. A woman looks upon her breast as alike the emblem and the ornament of her womanhood. She shrinks from the idea of its being affected by disease. She suffers acutely in mind when it is invaded by tumor of any kind; the horrid dread of that disease being cancer ever haunts her thoughts, not so much from the fear of the possibly impending operation, but rather from the distress of mind, in many cases amounting to a sense of humiliation, at the idea of the mutilation of which she is about to become the victim.

The operation for the removal of a breast, whether affected with cancer or with other disease, may be performed in the following way: The patient should lie upon a table, with the arm hanging over the side, tied down or held by an assistant. If the tumor be large, and the loss of blood a matter of much consequence, another assistant should compress the subclavian artery on the first rib. The hemorrhage will, however, depend more on the nature than on the size of the tumor. In all cancerous tumors, but especially in the encephaloid, it is considerable, and from many enlarged vessels. In simple tumors, even of very large size, it is often trivial. I have removed a simple tumor of the breast of many pounds weight, and had to tie only one *sputing* vessel. Indeed, nothing indicates more conclusively the enormous activity of cancerous tumors, and the great drain they must exercise upon the system generally, than the large size and great number of their supply-

ing arteries, compared with those sent to a simple tumor many times more than the malignant one. If the veins about the part be much enlarged, measures should be taken to arrest the flow of blood from them, as it can sometimes be dangerously profuse; indeed, South relates the case of a patient who died from this cause during the operation. In all cases a sufficient number of forcipressure forceps should be at hand, which can be left attached to the bleeding vessels until more permanent means of arresting the hemorrhage can be carried out if necessary.

In amputations of the breast for cancer, there are four principal and essential points that must be attended to: 1. To remove the whole of the gland; 2. To remove the nipple; 3. To remove the skin widely, even when apparently healthy; 4. To clear out the axilla if there be any glandular enlargement.

The operation should always be done with antiseptic precautions. The whole breast, side, and axilla should first be thoroughly washed with carbolic lotion, 1 to 20. The direction of the incision through the integument is varied by different Surgeons; some prefer a transverse, others a perpendicular one. I think that no definite plan should be followed, but the direction of the cut made to vary according to the situation and size of the tumor, and the amount of integument that requires removal. In all cases, the tumor should be included. In ordinary cases as a general rule, I prefer an oblique incision following the course of the fibres of the great pectoral muscle. This enables the Surgeon, if necessary, to extend the cut into the axilla for the removal of enlarged glands, and, after cicatrization, allows the movement of the arm without undue traction. An oblique elliptical incision of sufficient length, may thus be made, first below, and next above the nipple, so to include a sufficient quantity of integument (Fig. 776). In some cases

Fig. 776.—Position of Patient in Amputation of Breast.

where the skin is somewhat involved, a transverse incision may be made in addition to this, so as to include the affected integument in a triangular manner. When the tumor is very large and prominent, a double vertical incision may very conveniently include the nipple and the most suspicious part of the skin. The dissection should then be steadily carried down to the pectoral muscle, every bleeding vessel being immediately seized in forcipressure forceps, and the breast removed with the cellular bed in which it lies. When the tumor is of large size, and especially if it be of simple character, this part of the operation may be done very expeditiously by drawing down the mass and touching the areolar tissue with the scalpel, when the whole mass will peel off the pectoral muscle, and can readily be detached. After the

removal of the diseased breast, it and the tumor, as well as the whole interior of the wound, must be carefully examined, to ascertain that no slices of morbid tissue have been left behind: if so, they must be freely cut out; and if, as sometimes happens, the growth be rather firmly adherent to the pectoral muscle or subjacent structures, portions of these must also be removed.

The clearing out of the axilla adds greatly to the severity and immediate danger of the operation. Should there be enlarged lymphatic glands, or should the Surgeon adopt the course of clearing out the axilla even when diseased glands cannot be felt, this may be done by extending the oblique incision upwards as far as may be necessary. It will often, however, be found more convenient to perform the operation in the following way: An oval incision, the long diameter of which is placed transversely to the trunk, may be made to include the breast, and as much skin as it is intended to remove. From the outer end of this an incision may be carried to the outer border of the axilla, in the line of the long diameter of the oval incision. Another incision is carried upwards along the anterior border of the axilla to the arm. The mamma is then removed in the ordinary way, the surface of the pectoralis major being carefully cleaned. Having arrested the bleeding, the Surgeon now proceeds to remove the contents of the axilla as completely as possible, including not only the lymphatic glands, but the fat surrounding them. While doing this the bandage securing the arm must be

Fig. 777.—Incisions required for thoroughly clearing Axilla.

loosened, and the limb given to an assistant, who must hold it in the position most convenient to the Surgeon. The edge of the pectoralis major may be cleaned with the scalpel, care being taken to expose and clean the lower part of the pectoralis minor also, as a few glands almost invariably lie concealed between this and the great pectoral, and may be easily overlooked. In doing this the external mammary artery will be divided. The contents of the axilla are then turned carefully over to the posterior side of the space. In the lower part this may safely be done with the edge of the knife, but at the upper part the handle of the scalpel and the fingers should be used, and any hands which are met with, and appear to contain vessels should be isolated, and a ligature passed round them, after which they may be divided with scissors. By thus working carefully at the upper part of the axilla, the fat and the glands contained in it may be safely separated from the great ves-

vessels which are left exposed often for one or two inches. Finally the whole mass is drawn downwards, and separated from the posterior border of the axilla, care being taken not to wound the subscapular artery and vein, which the enlarged glands are sometimes adherent. Should it be necessary to divide these vessels, they must not be cut too closely to the main trunk. The complete extirpation of the axillary glands is the most difficult part of the operation, but by patient and careful dissection it can be safely accomplished. If the enlarged glands that are readily perceptible are removed without the fat surrounding them, a number of smaller glands are sure to be left behind. Wound of the axillary vein is the most frequent accident to occur in removing glands seated high up. It usually arises from tearing through some small branch just as it enters the main trunk. If the opening be very small, it is easily secured by pinching it up, and applying a ligature round it without occluding the whole vein. Should the wound be more extensive, the whole vein should be tied. Bulstroth states that he has occasion to do this more than once, and that no evil consequences follow, rarely even oedema of the arm. The safety of the patient depends so much, however, on the successful prevention of decomposition in the wound. Should the injured vein be bathed in decomposing discharges, the patient would be exposed to the imminent danger of septic thrombosis and pyæmia, which formerly made Surgeons hesitate to apply a ligature to a vein. Entry of air into the vein is a danger which must be borne in mind when removing glands in close proximity to it. It is best avoided by careful dissection, but should the vein be unavoidably in danger, an assistant should place his finger on it, if possible, on the cardiac side of the exposed part. Wound of the artery is much less common. It is most likely to occur in shaving the subscapular branch away so closely as to leave it connected by a twig in the side of the main trunk. It can best be avoided by not using sharp instruments in this region. Should it happen, the main trunk must be tied on each side of the wound.

The *after dressing* of the wound is of great consequence. A wound as gapes immensely whilst the arm hangs down, will be found to close with the greatest ease when the arm is raised and laid across the chest. If properly dressed, the patient suffers no pain during the healing of the wound, and it is usually complete in about a fortnight; there is no constitutional disturbance of any consequence, and the dressings need not be disturbed more than twice or thrice. Some form of antiseptic dressing should always be applied. The plan that I now usually adopt is as follows:—all bleeding points have been secured by torsion or by ligature with fine carbolized catgut; the wound is thoroughly washed out with a solution of chloride of zinc or of boric lotion. The edges are then to be brought together. If much oedema has been removed, and there is considerable strain in approximating them, this should be done by the introduction of one or two deep button sutures of thick silver wire. The edges are then carefully adjusted, and kept in apposition by means of a sufficient number of points of suture of carbolized catgut or catgut. Efficient drainage must next be secured by the insertion of one or two drainage-tubes of good calibre with a piece of silk attached, so that they may not be lost in the wound. If there is a large bag of skin at the axillary border, this may be perforated and one of the tubes drawn through and fixed in the hole. A large and thick layer of iodo-form wool is next to be laid over the wound and well up into the axilla, which must be carefully packed. Over this a still larger and thicker layer of salicylic acid wool must be placed, taking in the shoulder and clavicle.

This dressing should be confined and supported by turns of a webbing tape well stitched down. It need not be disturbed for several days—a web-

or more—unless the temperature rises above 100° Fahr., or the discharge from the wound soaks through. The deep silver sutures should be taken out about the eighth or tenth day. The catgut stitches often become absorbed. If not, they may be picked out when the wound is healed. After cicatrization is complete the part should be kept covered with cotton-wool for some months, and the patient cautioned not to move the arm too freely. In most cases it will unite by the first intention; for owing to the yielding nature of the parts in this situation, the lips of the cut come into very good apposition, even though a considerable mass has been removed. By some it has been supposed that relapse of cancer is less liable to take place if the wound unite by granulation, than if it come together by more speedy union; of this, however, there is no proof with which I am acquainted.

The mortality from amputation of the breast was never very considerable, and has been greatly reduced by the modern improvements in the treatment of wounds. The circumstances that chiefly influence it are the nature of the tumor, the size of the breast, and the extent of the incision into the axilla. The operation is much more dangerous when performed for the removal of cancerous than of simple tumors; and the danger increases in proportion to the length of time the cancer has been allowed to exist before the operation is undertaken. In proportion as the patient's general health has become undermined by the continuance of the malignant disease, so the tendency to pyæmia and erysipelas increases. Women who have small mammae, with little fat, bear the operation best. The danger of the operation is, for obvious reasons, much greater in women with large breasts, in whom the areolar tissue is loaded with coarse yellow fat. In these reparative action is slow, and there is much tendency to sloughing and to erysipelas. Lastly, the operation becomes dangerous in proportion as the tumor is adherent to the pectoral muscle, and the dissection requires to be carried deeply into the axilla or under the pectoral. The danger here is threefold: 1, from hemorrhage; 2, from the entry of air into a vein; and, 3, from opening up the deep fascia of the axilla, and the risk of the occurrence of deep cellulitis. This last danger is much less if the axilla is thoroughly cleaned out than if a small opening only be made in the fascia and the glands torn out through this. It can be much lessened by the proper use of drainage and antiseptic dressings. When death follows these operations it is most commonly the result of erysipelas or septicæmia.

There are two dangers which attend excision of the breast rather more frequently than other operations; viz., 1st, a congestive form of pneumonia, not dependent on any blood-poisoning, but arising from defective aeration occasioned by the breathing being shallow and restrained either by tight bandaging of the chest, or by the pain induced by the movement of the chest walls in respiration; and, 2d, cardiac thrombosis extending into the pulmonary artery. I have known several instances of death from each of these causes. The first danger can obviously be guarded against; the second cannot.

Axillo-mammary Cancer presents some peculiarities that deserve special consideration. It develops at the outer and upper angle of the mammary gland towards its free border, so that, instead of growing into its substance and remaining embedded in it, it tends to push into the direction of least resistance to its outgrowth, and thus to extend into the areolar space at the lower border of the axillary edge of the pectoralis major, and lie between it and the latissimus dorsi muscle. The tumor feels hard and nodulated, and is rounded in shape. Sometimes it appears to be scarcely attached to the mammary gland. But on closer manipulation it will be found to extend deeply into its substance, which towards the base of the tumor feels hard and thickened. The greater portion of the gland, the median half and much of the lower part, will continue long unaffected by cancerous infiltra-

tion. The nipple is not retracted until a very late period in this form of disease. It and the areola preserve their normal appearance, because the skin above them has become involved and the axillary glands engaged. The manner in which the skin is implicated and the appearance it presents are peculiar and characteristic. It becomes involved early by drawing out below in a transverse direction at the upper and outer border of the mamma where there is a tendency naturally to a fold or crease in the integument. There the skin becomes infiltrated in a transverse line of hard scirrhus, depressed and puckered in, with much feeling of constriction and difficulty in raising the arm from the side. The disease, when once it has reached this stage, will of course make rapid progress both locally and constitutionally.

That these axillo-mammary cancers arise primarily in the breast gland there can be no doubt, although their rapid development beyond its limits may, at first, lead to the suspicion that they have commenced outside it.

It is only towards the upper and outer border of the mamma that these outgrowing cancers seem to develop. I have never seen them at the upper or lower part of the gland, unless the whole of its structure had been previously infiltrated. The operation in these cases should be completely thorough, the whole organ being removed, however healthy the nipple, areola, and some portions of its gland-structure may appear to be. The skin also should be widely removed where implicated, and the disease carried as high into the axilla as safety will permit. Unless thorough extirpation be practised, speedy and rapid recurrence will ensue. In most of all operations for diffused cancer, the wound should be well washed out with a solution of chloride of zinc (1 to 20), so as to destroy any remaining cells.

DISEASES OF THE MALE BREAST.

The **Male Breast**, though rarely the seat of disease, may occasionally come affected in a somewhat similar manner to the mammary gland of the

Fig 778. Scirrhus Cancer of the Male Breast.

female. Cases have been recorded in which it was hypertrophied and in which it has been the seat of an abnormal secretion of milk. In boys about 15 or 16

of puberty it occasionally becomes the seat of *subacute inflammation* often attributed to a blow. This is best treated by the application of a belladonna plaster spread on soft leather with a hole cut through it for the nipple. *Chronic interstitial inflammation*, with enlargement and induration of the rudimentary mamma is occasionally met with, and if a source of much annoyance may justify the removal of the diseased gland. *Cysts and sarcomata* are more rare. *Scirrhus cancer* is occasionally met with. The accompanying drawing (Fig. 778) represents a case of this kind under the care of C. Heath in University College Hospital. These growths require removal by the same kind of operative procedure that is adopted when they affect the female breast, though of a less extensive character.

AXILLARY TUMORS.

CHRONIC STRUMOUS DISEASE of the axillary glands is occasionally met with, forming a large lobed mass under the pectoral muscle. Such a tumor as this may easily and safely be enucleated, and should be removed if it have resisted all ordinary topical and constitutional treatment. It will be found to be infiltrated with tubercle.

SIMPLE TUMORS of various kinds are met with in the axilla. The most common are lymphadenomata of the axillary glands, fatty and fibrous tumors.

Lymphadenoma of the Axillary Glands is met with chiefly in young women, forming a smooth, lobed mass, often reaching a great size. It is

Fig. 779 Fibrous Tumor in Axilla of a Woman.

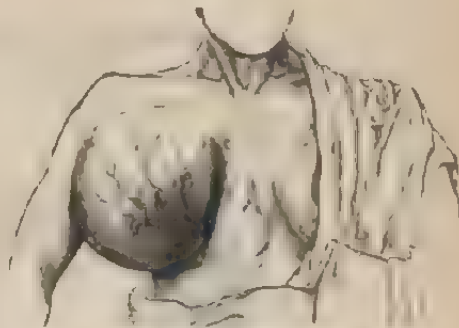

Fig. 780 —Same Tumor, Front View.

usually associated with similar tumors elsewhere, but occasionally the glands of the axilla are alone affected. The enlarged glands form no attachments to surrounding parts, and may be readily removed by enucleation.

Fibromata are sometimes met with in this region, and may attain a great magnitude. A fibroma forms a large, smooth, rounded mass, stretching the muscles and displacing the vessels and nerves, as in Figs. 779 and 780. In this case the tumor, which was of very slow growth, developed between the serratus and the ribs, stretching the muscle over it so as to form a species of capsule to it, drawing the scapula forwards, depressing the chest-wall, and

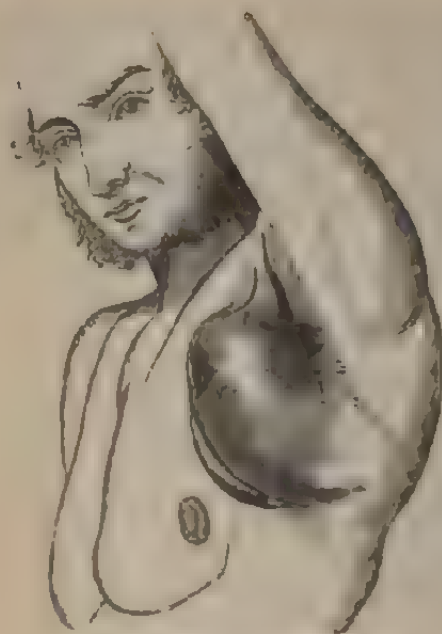

Fig. 781.—Sarcoma in Axilla of a Man.

drawing the axillary vessels back to about three inches below the clavicle. In removing it I was obliged to take away a portion of the expanded serratus as large as the hand. The patient made an excellent recovery, and experienced no difficulty in breathing afterwards.

SARCOMATA of various kinds are met with in the axilla (Fig. 781). Such tumors might, in their early stages, be dissected out, but if they extend high up to the axilla or implicate the skin widely in infiltration, they should, I think, be left, as was necessary in the patient from whom Fig. 781 was taken, when the size of the tumor and its connections precluded the possibility of operation. The removal cannot, indeed, at an early stage be undertaken without great danger. In dissecting as regards for the extirpation of such cases as in Fig. 781, I have had to expose the axillary and subscapular

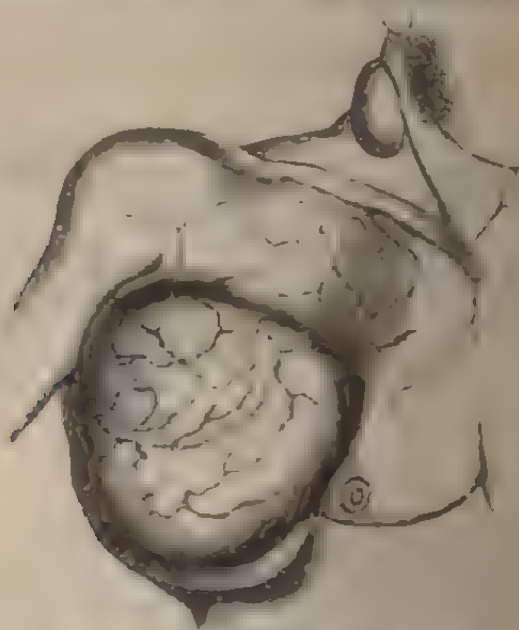

Fig. 782.—Large Sarcoma in Axilla of a Man.

vessels and their accompanying nerves. The growth being usually what widely disseminated, it is difficult to be certain that the whole is not extirpated: hence, recurrence is likely speedily to take place.

DISEASES OF THE ABDOMEN.

CHAPTER LXI.

IN no department of Surgery has there been a greater advance during the last few years than in the **Operative Treatment of Diseases of the Abdominal and Pelvic Viscera**. But a few years ago a wound of the peritoneum, whether accidental or intentional, was regarded as being inevitably accompanied by grave danger to life. The perfection of the operation of ovariectomy, with which the name of Sir Spencer Wells must ever be inseparably associated, led to a more thorough understanding of the causes of death, and established the principles which alone can guide us to success in operative procedures affecting the peritoneal cavity. The systematic use of antiseptics, further put at our command the best means of preventing the most common and most fatal complications of peritoneal wounds, so that at the present time operations on the abdominal viscera are undertaken with little more hesitation, and are attended by as good results, as those of equal magnitude in any other part of the body. Before proceeding to the description of the surgical diseases of the abdomen and their treatment, it will be well to consider briefly the special dangers common to all abdominal operations, and the principles which guide us in avoiding them.

Operations on the abdomen, with wound of the peritoneum, should they prove fatal, usually do so from one of three causes—septic peritonitis and septicæmia, shock, or hemorrhage.

Septic or Diffuse Peritonitis and Septicæmia.—These conditions are so closely associated that it is most convenient to consider them together. Until recently the peritoneum was believed to possess some peculiar tendency to inflammation which rendered a wound of it specially dangerous; the inflammation spreading, as was said, by continuity of tissue. There is nothing to justify such an assumption. The peritoneum becomes inflamed under the same conditions as other tissues, the process is the same, and, as in other parts, it is limited to the area upon which the cause is acting. In the prevention of peritonitis it is necessary, therefore, to consider the causes to which it is due, with a view of excluding them, if possible.

Certain causes of inflammation, as pointed out in the chapter on the Process of Inflammation (vol. i.) are, from their nature, limited in action. To these belong mechanical injuries, heat and cold, and the action of those chemical substances which cannot increase in quantity in the living body, such as mineral acids, saline caustics, and the like. A wound of the peritoneum, therefore, gives rise to inflammation limited to the area injured, and unless some other cause be introduced it has no tendency to spread further. In inflammation of the peritoneum, as in all other membranes lining cavities, the inflammatory products find their way readily to the surface. If the process be of sufficient intensity, an abundant coagulable exudation takes place; the fibrin entangling white corpuscles forms a layer of

"lymph" on the inflamed surface, and the serum drains away into the peritoneal cavity. The peritoneum, however, from its intimate connection with the lymphatic system, is possessed of the power of absorption in the highest degree. The serum poured out at the seat of inflammation is therefore absorbed with great rapidity by the healthy part of the membrane, and, even when the quantity be very considerable the cavity is kept dry. The experiments by which this extraordinary absorbing power of the peritoneum has been demonstrated have been already alluded to, vol. i. p. 827. The inflammatory exudation which covers the inflamed surface glues it to any contiguous area of peritoneum, and adhesions are thus formed which subsequently become vascularized and undergo development into connective tissue by processes identical to those occurring in the formation of fibrous tissue in the walls of the wound. It is by this process that adhesions form between intestines, coils of intestine, and that ligatures, sutures, and other simple foreign bodies become buried and encapsuled. It forms an essential part of the cure of all wounds of the peritoneum, and is often the means of saving the patient's life by preventing perforation of the hollow viscera, or the rupture of collections of pus into the cavity of the abdomen. It is the object of the surgeon to exclude all those sources of irritation which can convert this simple localized inflammation into a diffuse or spreading process.

The causes of spreading inflammations, as already pointed out (vol. i. p. 195), are the chemical products of processes, analogous to fermentation, taking place in the normal fluids of the body, or in inflammatory exudations or other collections of fluid. Without again entering into the evidence for and against the theory, that these processes are directly dependent upon the presence of microscopic organisms, upon which the antiseptic treatment is founded, we may adopt it as a hypothesis to explain the phenomena of septic peritonitis, and to guide us in the prevention of this fatal complication. It will be remembered that according to this theory two classes of micro-organisms exist, the pathogenic or specific organisms which can infect and multiply in the living tissues and blood, and the non-pathogenic or septic, which grow only in dead matter, and are believed to be the cause of organic putrefactive changes. The former we may exclude from consideration here for the sake of simplicity, although it is possible they may take a part in the causation of some cases of diffuse peritonitis.

For the development of septic processes in the peritoneum two conditions are necessary: first, the presence of the putrescible matter, and, secondly, the contact of the organisms with it. The putrescible matter is furnished by the liquid part of the inflammatory exudation, or by extravasated blood. The organisms may reach it either from the external wound, carried in by the surgeon's hands, the sponges, the ligatures, or by the air, or in those cases in which the gut is injured, as in strangulated hernia, they may pass that way from the interior of the intestine through the diseased coats. If the amount of the inflammatory exudation be comparatively small, it is rapidly absorbed by the healthy part of the peritoneum, that no decomposition takes place, the first condition of the process being wanting. If the amount of exudation be in excess of that which can be at once absorbed, an accumulation takes place, which if the cause of putrefaction have been admitted to it, speedily decomposes. The irritating products of decomposition, widely diffused, excite inflammation wherever they go, and thus the whole peritoneum becomes affected. At the same time, there is intense pain, from the absorption of the chemical products of the process. In fact, in a large proportion of cases, this is the immediate cause of death, and it may prove fatal before the local signs of peritonitis become very marked. The

symptoms are those already described (vol. i. p. 907) of acute septic poisoning.

It does not always happen that diffuse peritonitis occurs when the opening in the membrane communicates with a foul wound. Thus, congested omentum in the operation for strangulated hernia was formerly ligatured with a piece of whipcord, the mass being cut off and the stump and ligature left lying in an open wound to which a poultice was applied. Under these circumstances, septic suppuration necessarily occurred, but diffuse peritonitis by no means invariably followed. In those cases, there was a free exit for the discharge from the wound, and the opening into the peritoneal cavity became sealed by firm inflammatory exudation in the first few hours before decomposition set in in discharges, and thus the danger was averted. This is, however, an uncertain barrier, and these exceptional cases do not justify us in neglecting any precaution by which the close contact of septic pus with the peritoneal cavity can be avoided.

The prevention of septic peritonitis and its consequences is carried out on two principles: first, by the use of antiseptics in such a way as to exclude any living organisms from the cavity, and, secondly, by draining the cavity in all those cases in which an amount of exudation is expected, beyond that which will be immediately reabsorbed. Considerable difference of opinion exists as to the relative value of these methods, some Surgeons maintaining that, if antiseptics are properly used, drainage is scarcely ever required; and others that, if the peritoneal cavity be thoroughly cleansed before closing the wound, and drainage be efficiently employed, antiseptic applications are scarcely necessary. It is not the place here to discuss this disputed point. The great majority of Surgeons are agreed upon the value of antiseptics to a certain point, the use of the carbolic spray being the matter chiefly in dispute. Its opponents maintain that it increases the shock by chilling the patient, that when the peritoneal cavity is widely open there is considerable danger of carbolic acid poisoning, and that with careful attention to other antiseptic details it may be safely dispensed with. Its advocates maintain that by careful management the chilling of the body and the entrance of a dangerous amount of carbolic acid into the peritoneum are easily avoided, and that by its use they are able entirely to dispense with drainage—which, to say the least, is an inconvenience—save in a few exceptional cases. The point must still be considered an open one, as excellent results have been shown both by those who use the spray and those who do not. In those cases in which but a small opening is made into the peritoneum, and it is consequently impossible to clean the cavity before closing the wound, and in which, moreover, drainage cannot be efficiently carried out, as in operations for hernia, there can be no objection to using the spray, especially in hospital practice.

Shock is a common cause of death in operations upon the abdominal viscera. It probably arises chiefly from the injury done to the large sympathetic plexuses in connection with these parts. The exposure of the viscera to cold and the loss of blood doubtless aggravate it in many cases.

Hemorrhage is necessarily a source of danger in many cases, but it presents nothing requiring special consideration.

The following are the general rules applicable to all abdominal operations:

1. The room in which the operation is to be performed must not be too cold, especially if the abdominal cavity is to be widely opened and the viscera exposed.

2. In those cases in which it is possible to do so, the bowels should be thoroughly emptied by a purgative the night before, and an enema on the day of the operation.

3. In all operations on the lower half of the abdomen, the bladder should be emptied by a catheter immediately before commencing.

4. The patient, when placed upon the table, should be warmly wrapped up, lest the shock be increased by chilling the body. If the spray machine used, the body must be covered with a mackintosh cloth, or a sheet of fine silk with a hole cut in it, through which the region of the operation is exposed. The under surface of this may be spread with adhesive plaster for one inch round the aperture to keep it in position.

5. The instruments and sponges, etc., and the hands of the Surgeon and his assistants must be cleaned and disinfected with carbolic acid, as already described (vol. i. p. 262). During the operation, all sponges must be squeezed as dry as possible, a twisted towel being used if necessary, and a dangerous amount of carbolic acid be introduced into the peritoneal cavity. They should be washed in warm carbolic lotion to avoid chilling the parts.

6. The sponges should be counted before and after any operation in which they are used inside the abdominal cavity.

7. All hemorrhage from the abdominal wall must be arrested before the peritoneum is opened.

8. If during the operation the intestines are exposed, they should be kept on one side, and retained in the abdominal cavity by a large, flat sponge squeezed as dry as possible after having been well carbolized.

Should they be exposed externally, as in operations for hernia, intussusception, etc., or escape from the abdomen, they must be covered with a wet rag several folds thick, wrung out of a warm 1 in 40 solution of carbolic acid.

9. When the operation is completed, if the abdominal cavity have been opened sufficiently to admit the hand, it must be cleaned with sponges squeezed as dry as possible and passed into the most dependent parts of the cavity, one after another, until they return quite clean. This is a most important part of the operation, and success in many cases depends to a great extent upon the thoroughness with which it is done.

10. In closing the wound, the deep stitches, which should be of carbolized silk, must include the peritoneum, so that the serous surfaces shall be brought closely in contact. The importance of this in securing primary union was demonstrated experimentally many years ago by Sir Spencer Wells. When the abdominal walls are very lax, as after the removal of a large tumor the stitches may be made to catch the peritoneum, the aponeurosis or sheath of the muscles, and the skin and subcutaneous tissue missing the muscular fibres; but if there is likely to be considerable strain, it is better to pass the deep stitches completely through the abdominal wall about three-quarters of an inch from the edge of the wound. Both ends of the deep stitches must be passed from within the abdomen to avoid any risk of puncturing the intestine. All the deep stitches must be passed before any are tightened, and care must be taken while this is being done not to include accidentally a knuckle of intestine between the edges of the wound or under a suture. After the wound has been brought together, finer stitches may be passed bringing the edge of the skin accurately in contact.

11. If it be thought necessary to drain the abdomen, this is done by a large tube of India-rubber or glass passed into the most dependent part of the cavity and brought out at the lowest angle of the wound. The tube must be of such size that all fluid shall escape readily from it. Inefficient drainage is worse than none at all.

12. The dressing should be composed of some efficient antiseptic material. If the wound is completely closed, a thin layer of dressing is sufficient. If it be drained, a thicker mass must be applied to absorb the discharge. If

operations involving the anterior wall of the abdomen, the dressing is most conveniently kept in place by a broad band of strapping, which at the same time supports the abdomen.

13. After most abdominal operations the patient should be kept without food for from twenty-four to forty-eight hours, or in some cases even longer. A small quantity of iced soda-water or barley-water may be given to allay thirst. If the condition of the patient makes it necessary to give food, chicken-broth or iced milk and soda-water is the best, given in small quantities at intervals of about two hours. Small nutritive enemata are often useful. In operations involving the intestine, opium is often necessary to prevent peristaltic movement.

14. If the operation is followed by a high temperature due to absorption of inflammatory exudation from the peritoneum, an ice-cap may be applied to the head as recommended by Knowsley Thornton. If there is reason to believe that the peritoneum is becoming distended with fluid, the patient may sometimes be saved by opening one end of the wound and inserting a tube in those cases in which drainage has not been adopted from the first.

In all abdominal operations success will greatly depend on minute attention to details. The operation must be carefully considered and planned beforehand, and everything that can possibly be required must be at hand. At the end of a severe operation in this region, the patient is often suffering greatly from shock, perhaps hovering between life and death, and a little needless delay from not having everything ready the moment it is wanted, an unnecessary exposure of the intestine for want of a proper flat sponge to retain them, or a failure in some other minor detail, may just turn the scale against him.

HERNIA.

By **Hernia**, in its widest sense, is meant the displacement of an organ from the cavity in which it is naturally contained, by being protruded through an abnormal or accidental opening in its walls; when, however, it escapes through one of the natural outlets of the part, it is not considered hernial. Thus, the protrusion of the brain through an aperture in the cranium, or of the lung through one in the thoracic walls, or of a portion of intestine through the abdominal parietes, is termed a hernia of the organ; but the descent of the bowel through the anus does not come under this designation. Here, however, we have to consider only the hernial protrusions that occur from the abdomen—the common situation of this disease.

A hernia may occur at almost any part of the abdominal wall; though it is far more liable to do so in some situations than in others, being commonly met with at those points where the muscular and tendinous structures are weakened to allow the passage of the spermatic cord in the male, and of the round ligament in the female; or for the transmission of the large vessels to the lower extremity; hence the inguinal and crural canals are the common situations of this disease. It may, however, occur in various other situations, as at the umbilicus, the thyroid foramen, the sciatic notch, in the vagina, the perineum, through the muscular portions of the abdominal wall, the diaphragm, etc.

STRUCTURE OF A HERNIA.—In whatever situation it occurs, a hernia is composed of a **Sac** and its **Contents**.

The **Sac** is the prolongation of that portion of the peritoneum which overlies and corresponds to the aperture through which the hernia protrudes. It is in all cases composed of a *neck* and a *body*.

The **Neck** is usually narrowed, though in some old herniæ it becomes

wide and expanded; it is commonly short, consisting indeed of a ~~small~~ constriction of the sac in this situation, as happens in many forms of femoral hernia; but in other cases it is elongated and narrowed. The neck of the hernial sac usually becomes greatly thickened and of an opaque color, from the growth of fibroid tissue in or upon it from the irritation to which it has been subjected by the pressure of the hernial tumor or the truss, by the incorporation of the subserous areolar tissue lying externally to it, or from the puckering together of its folds, which have been compressed by the aperture in which it lies.

The Body of the sac is usually globular or pyriform, sometimes elongated and cylindrical; it may vary from the size of a cherry to a tumor as large as the head. When recent, it is usually thin and transparent, though in some cases it becomes greatly thickened, having arborescent vessels ramifying in it, and being almost laminated in structure; this is especially the case in old femoral hernie. In other instances, however, it becomes thickened and atrophied as the tumor expands, so that the contents become visible through it. This is especially the case in old umbilical hernia, in which I have seen it as thin as the finest gold-beater's skin.

The sac, though usually forming a perfect inclosure to the hernial contents, occasionally constitutes but a partial investment to them, more particularly in such organs as the cecum or bladder, which are partially covered by peritoneum. In other instances it may be ruptured, or altogether absent. The sac is absent when the hernia occurs as the result of a wound, injury, or abscess of the abdominal wall. It cannot be said to exist in a congenital hernia, and may be absent in creal and in umbilical hernia. Very rarely a double hernial sac is met with, one being protruded from a place placed behind the other. There are instances of three sacs occurring together; and Sir A. Cooper relates a case in which six were met with in the same person.

The abdominal parietes outside the sac undergo important changes. The aperture through which the hernia protrudes usually becomes circular, at the same time, indurated and rounded at the edge, and considerably enlarged. When situated in the movable portions of the abdominal wall, as in the inguinal region, it becomes displaced in old hernie, being dragged down by the weight of the protrusion, usually towards the mesial line. The subserous areolar tissue always becomes greatly thickened, often indurated, so as to constitute one of the densest investments of the sac, and, in some old cases of hernia, closely to resemble omentum. The more superficial structures, such as the integument and fascia, are much elongated and stretched, often tense, and not unfrequently hanging in folds; they are usually thinned, but, if a long time have been long worn, they become thickened and condensed by the pressure of the pad.

Contents.—The contents of the sac vary greatly; every viscera except the pancreas having been found in a hernial tumor. Most frequently a portion of the *Small Intestine*, more particularly of the ileum, is protruded, constituting the form of hernia called **Enterocoele**. The quantity of intestine within the sac may vary from a small section of the calibre of the gut, the mesentery not being included, to a coil several feet in length, with its entire mesentery. After a portion of the intestine has once descended, the protruded part tends to increase in quantity, until, as in some large old hernie, the greater portion has been known to lie in the sac. The *Large Intestine* is rarely found in a hernia, though the caecum is sometimes met with. When intestine has been long protruded, it usually becomes thickened, narrowed, grayish on the surface, and more or less deranged in its functions. The corresponding mesentery becomes thickened, hypertrophied and vascular.

Omentum is often found in hernial sacs, together with intestine; but is not unfrequently met with alone, constituting **Epiplocele**. After having been protruded for some time it becomes thickened, brawny, and laminated, losing its ordinary cellulæo-adipose texture, and becoming indurated. Its veins usually assume a somewhat varicose condition; and the mass of omentum becomes triangular, the apex being upwards at the abdominal aperture, and the base below, broad and expanded. In some cases it can be unfolded; in others, it is matted together into a cylindrical mass. Occasionally apertures form in it, through which a coil of intestine may protrude, thus becoming secondarily strangulated within the sac. In other instances, cysts are met with in it containing fluid. When intestine and omentum together are found in a hernia, the disease is termed an **Entero-epiplocele**; and in these circumstances the omentum usually descends in front of and occasionally envelops the intestine. Besides these, the ordinary contents of herniæ, the stomach, liver, spleen, sigmoid flexure of the colon, bladder, uterus, and ovaries, have all been found in them. In a case described by Scanzoni, the gravid uterus and ovaries were enclosed in the sac of an inguinal hernia.

Adhesions commonly form within the sac in old-standing cases. These may take place between the contained viscera merely, as between two coils of intestine, or between these and the omentum; or they may form between the wall of the sac and its contents, either by broad bands, or else by bridging across from one side to the other, and inclosing a portion of the viscera. In recent cases these adhesions are soft, and may readily be broken down; but when of longer duration, they are often very dense, and are especially firm about the neck of the sac.

Besides the viscera, the hernial sac always contains a certain quantity of fluid secreted by and lubricating its interior. In most cases, this is in but small quantity; but in some instances, when the sac is inflamed, or the hernia strangulated, a very considerable bulk of liquid has been met with; I have seen as much as a pint escape from a large hernia in an old man. When abundant, in strangulated or inflamed hernia, it is generally of a brownish color, though clear and transparent; it is met with in largest quantities in inguinal herniæ.

Hydrocele of the Hernial Sac.—In some instances the fluid becomes collected in a kind of cyst within the sac, formed by the omentum contracting adhesions to its upper part, and leaving space below for the fluid to collect; this condition, represented in the annexed drawing (Fig. 783), has been called *Hydrocele of the Hernial Sac*, and constitutes a somewhat rare form of disease. The fluid is often in considerable quantity; in a case which I tapped some years ago, nearly three pints of dark-brown liquid had thus accumulated, and were drawn off.

If we limit the term *hydrocele of the hernial sac* to those cases in which there is a slow and gradual accumulation of fluid at the bottom of an old hernial sac, which has been cut off from all communication with the peritoneum either by the radical cure of the hernia, or by the adhesion of intestine or omentum to the upper part and neck of the sac, it must be considered a rare disease; and but few cases are recorded by surgical writers. Curling, in his work on the *Testis*, states that, during his connection with the London Hospital, he saw only one case; and the only others with which I am acquainted, besides one that occurred in my own practice,

Fig. 783.—Diagram of Hydrocele of Hernial Sac

are two related by Pott, two by Pelletan, one by Boyer, and one by Lawrence. This disease must not be confounded with the accumulation of fluid in whatever quantity, in strangulated hernia, or in hernial sacs that communicate with the peritoneal cavity. Its distinguishing feature is the accumulation of fluid in a sac that has been cut off from all communication with the cavity of the peritoneum.

An Accumulation of Ascitic Fluid in a Hernial Sac may occur when hernia is complicated with dropsy of the peritoneum. In one case of this kind which occurred in my practice at University College Hospital, the hernia, which was femoral, in a woman, was very tightly strangulated as large as a shaddock, very tense, with distinct fluctuation; the skin over it being much stretched, this was peculiarly evident. On opening the sac, fluid flowed in a jet, as if a hydrocele had been punctured, and about four inches of strangled gut were found lying at the bottom of the sac. After dividing the stricture, serous fluid in large quantity continued to drain from the peritoneal cavity for several hours after the operation.

An Accumulation of Fluid in a Hernial Sac which has been obliterated at its neck is occasionally met with, chiefly in the femoral region. A case of this kind occurred not long ago in University College Hospital. The patient, a middle-aged woman, was suddenly seized with pain in the abdomen and bilious vomiting. On examining the groin a tense rounded tumor was found in the region of a femoral hernia. It was free from tenderness and fluctuated indistinctly. On cutting down upon it, it was found to be an old hernial sac distended with clear serous fluid, but without solid contents. While examining the ring the adhesions at the neck of the sac gave way, and the finger slipped into the abdominal cavity. The vomiting and pain proved to have been nothing more than an ordinary "bilious attack," and the patient speedily recovered.

Loose Foreign Bodies have occasionally been met with inside hernial sacs. They are usually rounded, smooth, and firm; vary in size from a pea to a chestnut; and are mostly single. On section, they are found to consist of a fatty central nucleus with a laminated fibrous envelope, usually of considerable thickness. They are apparently composed of one of the glandular plaques, which has become detached, fallen loose into the peritoneal cavity, and become enveloped in fibrinous layers.

Signs—The signs of hernia, though varying considerably according to the contents of the sac and the condition in which it is placed, present in all cases many points in common. There is an elongated or rounded tumor at one of the usual abdominal apertures, broader below than above, when it is often narrowed into a kind of neck. The swelling usually increases when the patient stands, holds his breath, coughs, or makes much muscular exertion. It can be pushed back into the abdomen on pressure, or goes back readily if the patient lie down, but reappears when he stands up. On coughing, a strong and distinct impulse may be felt in it.

When the hernia is altogether **Intestinal**, it is usually smooth, gurgles when pressed upon, sometimes tympanitic and rumbling and resonant on percussion. It may be returned into the cavity of the abdomen with a distinct slip and gurgle; it has a well-marked impulse on coughing and is usually accompanied by various dyspeptic symptoms, and often with a dragging uneasiness. **Omental Hernia** is usually soft and doughy, moving slowly on pressure into the abdomen, feeling irregular on the surface, and having an ill-defined outline. It occurs most frequently in the middle and is rare in infants, in whom the omentum is short. In **Enterocoele** there is a combination of the two conditions and their signs, but these are

usually so uncertain, that few Surgeons care to predict before opening the sac what the probable nature of the contents may be.

Cæcal Hernia necessarily occurs on the right side only. It is a large, knobby, and irregular tumor, irreducible, owing to the adhesions contracted by that portion of cæcum which is uncovered by peritoneum. The peculiarity of this hernia consists in the sac being absent, or only partial in the majority of cases, the peritoneum being stripped off as the gut descends. When this hernia is large, and partially invested by serous membrane, a sac usually exists at its upper aspect, into which a portion of small intestine may fall, and which may in some cases constitute a second hernia lying above or before the cæcal one, which will be found situated at the posterior wall when this hernial pouch is opened. Occasionally the vermiform appendix and the caput coli are found in the sac, but can rarely be returned. The rule of cæcal hernia having a partial peritoneal investment only, does not hold good in all cases; and instances have occasionally been met with in which this portion of intestine lay in a distinct sac.

Hernia of the Bladder or Cystocele is very rare; and, like that of the cæcum, is usually enclosed in a partial peritoneal investment, though it is not necessarily so. South states that there is a preparation at St. Thomas's Hospital, in which the fundus of the bladder, with its peritoneal covering, has passed into a distinct sac. In some instances the cystocele is accompanied by an enterocele. This hernia is always irreducible, is attended by a good deal of difficulty in urinating, with varying tension, according to the quantity of fluid contained; by squeezing it, urine may be forced out through the urethra, and fluctuation has been felt in it. Urinary calculi have been formed in the tumor, and have been removed by incision through the scrotum, or have ulcerated out.

CAUSES—The causes of hernia are usually sufficiently well marked. In some instances the disease is *congenital*, arising from preternatural patency of the abdominal apertures; in other cases, it occurs at a later period of life, in consequence of some *forcible effort*, as lifting a heavy weight, jumping, coughing, straining at stool, or passing urine through a tight stricture. Such causes as these act especially in tall and delicate people, particularly in those who have a natural disposition to weakness or bulging of the groin. The displacement of the abdominal viscera by a *gravid uterus*, will also occasionally give rise to the disease. Hernia frequently results from a combination of causes; thus, if an aged person of feeble build, or whose abdominal apertures are patent in consequence of rather sudden emaciation, make a violent effort, a hernial protrusion is very apt to occur.

Amongst the most frequent **Predisposing Causes** of hernia, are certainly sex, age, and occupation.

Sex.—Men are more liable to this disease than women, in the proportion of about 4 or 5 to 1. Thus, according to Malgaigne, in France, one man in thirteen and one woman in fifty-two are the subjects of hernia. But, though men are more generally liable to hernia than women, they are less so to certain forms of the disease, especially to the femoral and umbilical. It is to the inguinal that they are particularly subject. According to Lawrence, out of 83,584 patients who applied to the City of London Truss Society, 67,794 were males and 15,790 females. Of 43,214 applicants at the same institution during the eight years 1860-1867, 36,161 were males and 7,053 females. Of these 31,788 males, and 3,085 females had inguinal hernia: 1,373 males, and 3,968 females had femoral hernia.

Age exercises a very material influence upon the frequency of hernia. Malgaigne, who has carefully investigated this subject, finds that in infancy the disease is sufficiently common, owing to the prevalence of congenital in-

guinal and umbilical hernie at this period of life; and that, in the first year after birth, hernia occurs in the proportion of 1 in every 21 children; it then goes on decreasing in frequency, there being 1 in 29 at the second year, 1 in 37 at the third year; until, at the thirteenth year, it has fallen to 1 in 77. Shortly after this, its frequency begins to rise again, and then goes on progressively increasing until the close of life; thus, at the 21st year, there is 1 case in 32; at the 28th year, 1 in 21; at the 35th, 1 in 17; at the 42nd, 1 in 9; at 50, 1 in 6; from 60 to 70, 1 in 4; and from 70 to 75, 1 in 3. In women, according to Malgaigne, hernia most frequently occurs from the 20 to the 50th years.¹ Malgaigne's figures give the ages of the patients as they came under his observation. Kingdon has investigated the question as to the ages at which the hernia commenced. He states that out of 3,278 cases, 5,659, or 60.8 per cent., had commenced before 35, and 3,617, or 39.2 per cent., after that age.

The tendency to hernia is often hereditary, and congenital hernia is common in the children of hernial parents.

Some races of men are less subject to hernia than others. Thus it is less frequent in the negro than in the white man, except in the ventral form.

Occupation.—Those occupations in which the individual is exposed to violent muscular efforts, more particularly of an intermitting character, predispose strongly to the occurrence of hernia; and in these employments the tendency to the disease is often greatly increased by the injurious habit of wearing tight girths or belts round the waist, which, by constricting the abdomen, throw the whole pressure of the abdominal contents upon the inguinal regions. Hernia is also common in men such as railway-drivers, sailors, soldiers, artillery-men, exposed to much jolting in the upright or nearly upright position.

Other Causes.—It is probable also that hernia is predisposed to by the height of the seats of water-closets in common use. In the natural position assumed by man in defecation the femoral and inguinal rings and the lower part of the abdomen are supported by the flexed thighs, whereas at the ordinary water-closet seat the thighs are not flexed much beyond a right angle, and the support is consequently much less perfect. The treatment with which hernia appears for the first time or becomes strangulated after defecation would lend some support to this view. Habitual constipation is a predisposing cause in many cases. Rapid emaciation from any cause was unfrequently followed by hernial protrusion.

CONDITIONS PRESENTED BY HERNIA.—The conditions in which a hernia may be found are very various, and entail corresponding differences in the result and treatment of the affection. When first formed, most hernia may be said to be *Incomplete*, being for a time retained within the orifice of the canal through which they eventually protrude. When they have passed altogether beyond the abdominal walls, they are said to be *Complete*, and this is the condition in which they are usually presented to the Surgeon. A hernia may also be *Reducible*, *Irreducible*, or *Strangulated*.

REDUCIBLE HERNIA.

A hernia is commonly at first *Reducible*; that is to say, it may readily be pushed back into the cavity of the abdomen, protruding again when the patient stands up, holds his breath, or makes any exertion, and having a

¹ Those interested in the statistics of Hernia will find much information, compiled recently by A. Wesselin, de Glessen, in Vol. XI. of *Les questions de Médecine Chirurgicale*, 1890, and in the Reports of Provost-Marshal General of the United States Army, 1876.

distinct and forcible impulse on coughing. Though the hernia contents, in these cases, are reducible into the abdomen, the sac is not; it almost immediately contracts adhesions to the areolar tissue, by which it is firmly fixed in its new situation; though in some cases, as we shall hereafter see, it may be pushed back.

The question as to whether a hernia is of recent origin or of old standing sometimes presents itself in medico-legal practice. In determining this the following points deserve attention: 1. A recent hernia resulting from injury is attended with pain—usually severe—from laceration of the structures of the abdominal wall. 2. When oblique, inguinal or femoral, it may be small, but when direct, inguinal or ventral, it is often large and rounded, the aperture through which it protrudes being irregular and wide. 3. The margins of the aperture in an old hernia are more rounded than in one of recent formation. 4. Recent hernia are intestinal, not omental. 5. They are readily reducible; whilst old hernia are frequently irreducible in whole or in part and omental. 6. After reduction the sac of a recent hernia when rolled between the fingers will feel thinner and softer than that of an old one. 7. Strangulation may occur at the moment of protrusion of a hernia. Hence, although more frequent in old than in recent hernia, its existence does not prove the hernia to be old. 8. In old hernia, if the patient has worn a truss, there will usually be signs of pressure, or of chafing of the skin. Though such signs may be effaced by friction with the hands.

APPLICATION OF TRUSS.—In the Treatment of a reducible hernia, our object is, by the application of a proper truss, to retain the protrusion within the cavity of the abdomen. In order to do this the patient must be provided with a proper kind of truss, adapted to the particular nature of the hernia. In umbilical and ventral ruptures, an elastic pad and belt may most conveniently be used. In selecting the truss, care should be taken that the spring be of proper strength, adapted to the size and power of the individual; and that it be properly shaped, so that it does not touch any part of the abdominal wall, but merely bears upon the points of pressure and counter-pressure. The pad should be convex, firmly stuffed, and of sufficient size to press, not only upon the external aperture, but upon the whole length of the canal. Before applying the truss, the hernia must be reduced, by placing the patient in the recumbent position, relaxing the muscles by bending the thigh upon the abdomen, and pressing the tumor back in the proper direction; the truss should then be put on, and be worn during the whole of the day; indeed, the patient should never be allowed to stand without wearing it. At night, it may either be left off altogether, or a lighter one applied. The patient should be provided with a "bathing" truss, that is, a truss covered with India-rubber, so as to resist the action of the water. It is well that the ordinary truss be covered with linen, so that the leather may be kept clean and unstained by perspiration and the spring free from rust. In some cases, the skin becomes irritated by the pressure of the pad; in these circumstances, an elastic air-cushion may be used, or the parts subjected to pressure may be well washed with spirit-lotion. The truss may be known to fit by testing it in the following way. The patient should be made to sit down on the edge of a chair, and then, extending his legs, opening them widely and bending the body forwards, cough several times. If the hernia do not now slip down behind the pad, we may be sure that the truss is efficient, and will keep the rupture up in all ordinary circumstances.

It is the Surgeon's duty to tell the instrument-maker what form of truss is required, and to see that the instrument supplied fulfils its object. It is always better for the instrument-maker to see the patient and measure him for the truss, but in country practice this is often impossible, and the Surgeon must

then measure the patient himself and order the required instrument. The most important measurement is the circumference of the penis taken halfway between the crest of the ilium and the trochanter major. Most instrument-makers say that this is all they require; but to insure accuracy it is better to send also the exact measurement in the line in which the truss will lie, commencing at the centre of the ring, and passing round the penis halfway between the crest of the ilium and the trochanter, and terminating at the ring again. The Surgeon must also inform the instrument-maker of the nature of the hernia, the side on which it is situated, the size of the ring, the age, sex, and physical power of the patient. He must state, also, if his occupation is such as to necessitate a spring of more than ordinary strength.

RADICAL CURE OF HERNIA.—Various means have been devised in order to effect the radical cure of a reducible hernia. The only plan that is perfectly free from danger, is the compression of a well-made truss. In this way, not unfrequently, the hernia of infants become radically cured; the same result, however, seldom occurs at a more advanced period of life. In order that compression in this way may succeed, it is necessary that it should be applied not only to the external aperture through which the rupture escapes, but to the whole of the canal. It must also be continued for a very considerable time, at least a year or two; and care should be taken that during the treatment the rupture is not allowed to descend. Every time it comes down, any good that may have been derived is necessarily lost again with it, and the treatment has to begin, as it were, anew. Radical cure of a hernia by truss-pressure can be effected only in those cases in which the abdominal aperture has been left congenitally weak or open. Hence it is to be hoped for only in children and very young adults, and only in these two congenital forms of hernia—the umbilical and the inguinal. The continued pressure of the truss-pail in these cases seems to determine the adhesive processes which are necessary for the closure of one of these abdominal apertures. After the cure is supposed to have been effected in this way the truss must be worn for a very considerable length of time, lest by any unfortunate movement the rupture be forced down again.

The Operations that have been devised for the radical cure of hernia are all founded on one of three principles, viz., the excitation of such an amount of peritonitis in the sac, or its neck, as to cause its obliteration, the closure of the hernial aperture by invagination of the sac and subcutaneous tissue, or the complete removal or invagination of the sac with closure of the ring by sutures.

If the accomplishment of these conditions would always prevent the recurrence of the rupture, the radical cure might frequently be undertaken. But it is impossible to look upon the agglutination of the walls of the sac as the closure of the abdominal aperture, or even the removal of the sac, as the sole conditions required. To accomplish the radical cure, it would be necessary in many cases to effect changes in the shape and connection of the abdominal contents, to alter the size of the abdominal cavity, and, indeed, to modify in various ways many conditions independent of those immediately connected with the hernial protrusion. Many of the means of radical cure by which obliteration of the interior of the sac or of its neck is sought to be effected by the introduction of caustics, by scarification, puncture, or injection with tincture of iodine, are attended with so much danger and peritonitis, and are so seldom followed by good results, that their consideration need not detain us here.

The operations that are now practised for the radical cure of hernia are conducted on three principal plans, however much they may be varied in their details by the ingenuity of particular Surgeons.

The first method of treatment consists of invaginating simply a portion of the scrotum, and fixing it in the inguinal canal, where it becomes adherent, and so occludes the aperture of exit. Of this kind of operation, Wutzer's is the best example. The second method of treatment consists in excising a portion of the integumental structures, and then, by means of sutures attaching these and the deeper parts together, and thus leading to the consolidation of the canal. Of this, Wood's operation is the best example. The third method consists of complete or partial removal of the sac and closure of the ring by sutures. The following are the details of these procedures.

Wutzer's Operation.—The late C. W. Wutzer, of Bonn, adopted a plan of radically curing reducible inguinal hernia, combining the two principles on which the older operations were founded, viz., the agglutination of the neck of the hernial sac by the excitation of inflammation in it, and the closure of the inguinal canal by the invagination of the scrotum; and he carried out these objects in a safer and more successful manner than by any of the methods previously employed. His plan of treatment consisted in introducing a plug of the scrotum into the inguinal canal, and fixing it there by exciting adhesive inflammation in the neck of the sac. The details of the operation are as follows: The patient lying on his back, and the hernia being reduced, the Surgeon pushes his index-finger up the inguinal canal as high as the internal ring, carrying before it a cone of the scrotal tissues: a hollow boxwood cylinder, about four inches long (Fig. 784, C), well oiled,

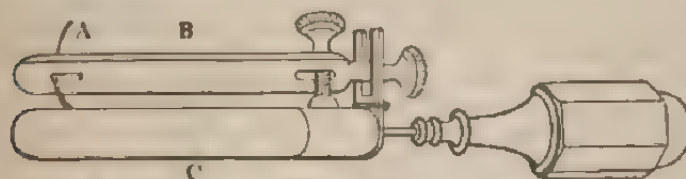

Fig. 784.—Wutzer's Apparatus for Radical Cure of Hernia.

is then pushed up as the finger is withdrawn, so as to occupy its place in the inguinal canal. Along the interior of this cylinder a flexible steel needle, gilt (A), fixed in a movable handle, is then pushed, so as to traverse the invaginated scrotum, the hernial sac, and the anterior abdominal wall, through which its point is caused to protrude. A concave boxwood case (B) is then passed over the projecting point of the needle, and fixed by the other end by a screw apparatus to the cylinder (C), so as to compress the enclosed tissues. The apparatus so fixed is left *in situ* for six or eight days; when, some discharge being established, it is withdrawn, and the invaginated scrotal plug supported by lint introduced up its interior, and by a spica bandage tightly applied. The patient is kept quiet for a fortnight longer, when he is allowed to move about, wearing a light truss for three or four months.

This method of treatment is easy of execution, and appears to have been more successful than any that preceded it. Yet it is open to the objections that attend all plans for the radical cure of hernia, viz., the possible excitation of a dangerous amount of peritonitis, and the want of adhesion between the lower part of the scrotal plug and the corresponding side of the inguinal canal and ring, and consequent failure in the complete occlusion of the canal and in the radical cure.

So far as the first objection is concerned, I believe that very little weight can be attached to it. I have very often performed this operation, and have

never seen the slightest evidence of a disposition to peritoneal inflammation or other local mischief, except abrasion of the skin in one or two cases. With respect to the second objection, there can be no doubt that failures are not unfrequent; but on the other hand successes are not rare, and I have now under observation several cases in which a complete cure has resulted although several years, from two to nine, have elapsed since the operation. It is now scarcely ever practised, being replaced by Wood's operation or some of the various plans of closing the ring by sutures.

Wood's Operation.—In order to secure the more complete obliteration of the canal, and especially the cohesion of the inner and posterior walls, Wood has brought forward another operation, for the following description of which I am indebted to him. The principle of this method consists in the approximation of the tendinous structures forming the boundaries of the hernial canal, by the application of a subcutaneous wire suture through a puncture in the skin. In applying this principle to inguinal hernia, it is to promote the adhesion of the tendinous surfaces, and to protect the spermatic cord from injurious violence, the highly vascular, elastic, and tough tunic of the scrotum is detached subcutaneously from the skin, transplanted by a vagination into the canal and held there by sutures till adhesion ensues to the walls of the canal and to the spermatic cord. The wire is so applied as to obtain a fair hold in two places upon the structures forming the posterior wall, viz., the conjoined tendon and the triangular aponeurosis; and again upon Poupart's ligament and the lower portion of the external oblique aponeurosis forming the anterior wall of the canal. The effect of the suture is to close also the external abdominal ring, the pillars of which are in its grasp. By the close adhesion which is thus produced between the posterior and anterior walls of the canal, the former is made to act as the limb of a valve in preventing the descent of a hernia into the canal. Thus a permanent resistance to the reproduction of the rupture is produced which remains even after the temporarily effused lymph has been reabsorbed. The impulsive force of the abdominal contents tending to protrude at the internal ring, is resisted by the valve-like action of the posterior wall, and is not able to exert itself upon the recently formed adhesions. The need of the truss, except as a temporary adjunct in the cure, is rendered unnecessary by this operation.

Operation.—The patient being laid on his back, with the shoulder raised, and the pubes and scrotum shaved, the hernia must be reduced and held up by an assistant pressing upon the internal opening. The operator standing at that side of the patient which is about to be operated on, makes with a small tenotomy-knife, an incision about three fourths of an inch long through the skin of the scrotum over the lower part of the tumor, i.e., about two inches below the pubic spine. Then the finger being inserted flatwise between the skin and the fascia, is made to separate them around the incision over an area of about a two-inch circle, a proceeding which the loose attachment of the skin easily allows. Then the patient should next be drawn up towards the abdomen, and held tight so as to relax the structures connected with Poupart's ligament. The finger is next passed through the opening in the skin, and made to invaginate the detached fascia through the external ring into the canal, which is best done by using the right hand for the right side, and vice versa, keeping the palm directed forwards. The invagination of the fascia should be continued from as low a point as the cutaneous incision will permit, so as to pass the invaginating finger as much as possible between the sac of the hernia and the spermatic cord. When the finger is in the canal, its point should reach the internal opening of the hernia, and the cord should be distinctly per-

ceptible to it and protected by it. The point of the finger will then be placed behind the lower border of the internal oblique, and must render this point prominent at the surface by being hooked forward. The Surgeon will now be sensible of the edge of the conjoined tendon, raised in relief to the inner side of the invaginating finger, and in contact with its radial border. Next, the needle, stout, blunt-pointed, and curved, mounted on a strong handle, is to be passed along the radial border of the finger as far as just beyond the extreme joint, at which point it is made to pass through the conjoined tendon and the external oblique aponeurosis, till it is seen to raise the skin, which is then to be drawn upwards and inwards as far as possible before the needle is pushed through it. Then a stout copper wire, silvered, about two feet long, and bent into a convenient hook at each end, is hooked on to the eye of the needle; and the latter is withdrawn and unhooked, leaving the lower end of the wire in the scrotal incision, and the upper end in the groin-puncture. The invaginating finger is then placed on the outer side of the cord, behind Poupart's ligament, as far from the border of the external ring as possible, raising the ligament on its point. The needle is then passed along the ulnar border of the finger, and pushed through the external pillar close to Poupart's ligament opposite to the internal ring, the skin being drawn outwards till the point of the needle appears at the former puncture, through which it is then pushed. The upper hook of the wire is then hooked on and drawn down with the needle into and through the scrotal incision. Next, the spermatic cord opposite to the scrotal incision is to be carefully separated from the sac of the hernia by the finger and thumb, placed upon the skin in the same manner as in the operation for ligaturing varicocele. The needle, detached again from the wire, is then passed into the lower angle of the scrotal incision, and made to traverse the tissues between the cord and the hernial sac, and to emerge at the upper angle of the incision. The inner end of the wire is then hooked on to the needle and drawn with it across between the cord and sac. A little care must here be taken to avoid any kink in the wire, which must be drawn down until the part which remains in the wound is quite straight. The ends of the wire are then twisted to the extent of three turns, which it will be found useful, for convenience in removing the wire, always to make in the same direction. Traction is then made upon the wire loop which remains in the groin-puncture. This will be found to invaginate the sac and scrotal fascia, and to close up the pillars of the external abdominal ring. The loop must then be twisted by three firm turns well drawn into the groin-puncture. Then the long ends of the wire, being cut off to a suitable length, are to be passed together through the loop bent down to meet them and hooked on to it. Under the arch thus formed a stout pad of lint is placed, and the whole is held firmly by a spica bandage.

The patient, after the operation, should be placed in bed with the shoulders well raised and the knees bent over a bolster. Any discharge which forms has a free escape downwards, and may be received upon a sponge steeped in some antiseptic fluid. The scrotum should be either suspended in a turn of the bandage, or kept up by a small cushion or strap of plaster.

The wires should be kept in from fourteen to twenty-one days, according to the amount of solid effusion which subsequently occurs. Any pain in the abdomen should be allayed by opiates and fomentations, and by slackening or removing the bandage after forty-eight hours. Pain sometimes results from including the ilio-inguinal nerve, which must not be mistaken for the pain of peritonitis.

Wood had up to 1872 operated in nearly 200 instances, and estimated his successful results in cases of all degrees of severity at about sixty-five per

cent. In young persons the results have been still more favorable and he now confines the operation to patients below the age of thirty, under special circumstances. Three deaths have resulted from pyæmia and peritonitis.

An ingenious operation, much the same in principle as Wood's, has been lately devised by W. Dunnett Spanton. After invaginating a portion of the subcutaneous tissue, of the scrotum and the sac as in Wood's method, instead of passing wires he inserts an instrument like a cork-borer, the point of which is introduced through the skin at the upper limit of the inguinal canal. By rotating the handle the point, guided by the finger at the canal, which at the same time protects the cord, is made to penetrate the same parts as are pierced by the needle in Wood's operation as well as the invaginated subcutaneous tissue, and it is finally made to emerge at the incision in the scrotum. In this way the parts are then brought together and held in position. The instrument is left in for about a week, till some inflammatory swelling is perceptible around it. The instrument must be suited to the size of the patient. Up to 1882 Spanton had operated on 51 cases without an accident, and with most satisfactory results. It is especially adapted to young subjects with recent hernia, especially when of the congenital variety.

Since the introduction of the antiseptic method of treating wounds the old operation of cutting off the sac has been revived with considerable success. In 1871 Sir Joseph Lister reported two cases in which he had cut down upon a hernial sac, and closed the abdominal opening with catgut sutures. This method of operating did not, however, find much favor, as further experience showed that it was uncertain in its results. During the last few years Annandale, Banks, Czerny, and others, have practiced a variety of operations of this type, of which the following are the chief ones: 1. Closing the inguinal ring by sutures without touching the sac; 2. Ligature of the neck of the sac; 3. Suture of the ring with invagination of the sac; 4. Ligature of the sac with excision of the portion below the ligature; and, 5. Ligature of the neck of the sac, excision of the part below the ligature and suture of the ring. Of these various operations the last has proved the most successful, and is the one adopted by Annandale, Banks, and Czerny. Banks has further modified it by using strong silver wire sutures to close the ring, leaving them to heal into the wound; a mode of operating found free from inconvenience, and more effectual than any other. The operation for inguinal hernia is thus performed. The incision should be commenced one inch above the external ring, and carried down to the lower limit of the sac. Before beginning to clear the sac out it must be thoroughly exposed, as any attempt to pull it out of its coverings without so doing is likely to be followed by suppuration. In old inguinal hernia some careful dissection may be required to separate the sac from the tunica vaginalis and from the cord. If the sac can be completely emptied, it is next drawn out and ligatured with carbolized silk or catgut close to the ring. The stump is then pushed into the inguinal canal and the pillars of the external ring, which must be cleanly exposed, are then brought together with strong silver wire, leaving only just enough room for the passage of the cord. Should there be adherent omentum, the sac must be opened and the mass ligatured, in separate pieces if large, and cut off. In cases of congenital hernia the same operation may be performed, but the sac must be cut across, and the lower part closed with sutures, so as to leave a tunica vaginalis. The whole operation should be performed with the strictest antiseptic precautions as the safety of the patient depends in great measure upon this.

A similar operation is practicable in other forms of hernia. In umbilical

hernia the ring may be sutured in the same way as in an inguinal but in a femoral this is impossible, and removal of the sac with ligature of its neck is all that can be done.

The results of this operation, so far as the life is concerned, are very good; but in a considerable number of cases the patient has not been able to dispense with the use of a truss. In many of these, however, the hernia which could not be retained in the abdomen before the operation was easily kept up after it. There is no doubt that such an operation cannot be devoid of a certain degree of danger. It should therefore not be undertaken in any case in which the hernia can be easily controlled by a truss. When this is not the case it probably gives the patient a good chance of relief, or possibly of cure, as any other method. In irreducible hernia it is the only available mode of operating should interference be considered advisable. In cases of strangulated hernia, when operative interference becomes necessary, many surgeons advise that the operation should always be completed by removing the sac and closing the ring, unless some special circumstance, such as the exhausted state of the patient or his great age renders it inadvisable.

The statistical results published by Banks are the most extensive at present before the profession. He has operated on the following hernia, uncomplicated by strangulation: 1 ventral, 1 umbilical, 2 inguinal, with undescended testicle, 11 inguinal, and 6 femoral. Only one of these died, apparently from causes unconnected with the operation. He also completed the operation for strangulated hernia by closing the ring in 6 inguinal and 3 femoral hernia, only one of which terminated fatally. All the survivors were either cured or materially benefited by the operation.

IRREDUCIBLE HERNIA.

IRREDUCIBLE HERNIA are usually of old date, and of large size. They generally contain a considerable quantity of thickened omentum, as well as intestine and mesentery. In many instances, a rupture of this kind is partly reducible, the greater portion remaining unreduced. It is usually the gut which slips up, and the omentum that cannot be returned.

Causes of Irreducibility.—The irreducibility of a rupture may be dependent on either its *shape*, on the existence of *adhesions*, or on its very *nature*. If the sac become the seat of an hour-glass contraction, or its neck become elongated and narrowed, the hernial contents may continue permanently protruding. So also, the expanded condition of the lower part of the omentum, and the narrowing of its neck, may prevent a return of the rupture. The existence of adhesions, either between the sac and its contents, or between protruded intestine and omentum, will commonly render a hernia irreducible; and most frequently these are associated with changes in the shape of the sac or of the omentum. Hernia of the caecum and bladder can never be returned, on account of the anatomical conditions, to which reference has already been made.

Symptoms.—An irreducible hernia is usually a source of great inconvenience; it has a tendency to increase if left to itself, until at last it may contain, as in some extreme cases it has been found to do, the greater portion of the abdominal viscera, forming an enormous tumor, inconvenient by its size and weight, in which the penis and scrotum are buried. Even when the irreducible hernia is of small size, it gives rise to a sensation of weakness in the part, with dragging pains, and is very frequently accompanied by colicky sensations and dyspeptic derangements. The patient also, in these circumstances, is in a state of considerable danger lest the rupture become strangulated by violent efforts, or injured and inflamed by blows.

Treatment. For the above reasons it is necessary not only to protect the rupture of this kind from external violence, but to endeavor to prevent its increase in size. This may best be done by letting the patient wear a truss with a large concave pad, which supports and protects it, provided the rupture be not of too great a size for the application of such an instrument. If its magnitude be very considerable, it must be supported by means of a suspensory bandage. Bransby Cooper has recommended that an attempt should be made to convert the irreducible into a reducible hernia by keeping the patient in bed for several weeks, on low diet, with the constant application of ice to the tumor. If it contains much omentum, and the patient is fat, the diet may be regulated accordingly. All food containing saccharine sugar, except a small quantity of bread, and all alcoholic drinks are to be forbidden. The patient must be fed on a small quantity of lean meat and green vegetables. At the same time a dose of blue pill and a small quantity of iodoide of potassium to promote absorption of the fat. The scrotum of the hernia be inguinal, must be raised on a pillow, and the foot of the bed must also be elevated. Taxis may be attempted daily.

By this plan I have seen very large irreducible hernia returned in a few weeks. If the patient be young and otherwise healthy, the question of performing the operation for radical cure by opening the hernia, dissecting through the adhesions, removing the sac and sewing up the ring must be considered. Such an operation, however, should not be rashly undertaken if the hernia be large and the patient fat.

Inflamed Irreducible Hernia.—The occurrence of inflammation in an irreducible hernia is a serious complication, and one that sometimes terminates very closely. When this complication occurs, the part becomes red, tender, and painful; there is not much tension in the tumor, which is seldom increased beyond its usual magnitude; there is a good deal of pain and symptoms of peritonitis spreading from the vicinity of the hernia to the rest of the abdomen. In some cases there is vomiting; but it is not constant, and never feculent, occurring generally early in the disease, and consisting principally of the contents of the stomach; being apparently an effort of nature to get rid of an indigestible meal. If there be constipation, as sometimes happens in all cases of peritonitis, it is not complete, flatus occasionally passing *per anum*, together with a small quantity of fluid feces. It is of importance in these cases to observe that the inflammation commences in the body of the sac, and extends into those parts of the abdomen that are contiguous to its neck; the gastric and intestinal derangements being secondary to this consideration.

The *Treatment* of an inflamed irreducible hernia must be directed to the peritonitis which attends it. The application of leeches over the tumor and its neck, and the administration of opium or hypodermic injection of morphia if the vomiting continues, followed by hot fomentation, with an antiphlogistic regimen and rest, will usually speedily subdue all signs of inflammation.

Incarcerated Hernia.—An irreducible hernia occasionally becomes obstructed, then constituting the condition termed *incarcerated hernia*. This condition occurs principally in old people, from the accumulation of indigestible matters, such as cherry-stones or the remains of a large piece of cabbage or spinach, in an angle of the gut. In these cases there is constipation, with eructation, and perhaps occasional vomiting. There may be some degree of pain, weight, or uneasiness about the tumor; but there is no tension in it or in its neck, and the symptoms altogether are of a chronic and subacute character.

The *Treatment* of such a case as this should consist in the administration of a good purgative injection; the compound colocynth enema is the best, thrown up as high as possible by means of a long tube. Ice may then be applied to the tumor for about half an hour; and the taxis, as will afterwards be described, may be used under chloroform. The ice may be omitted in those cases in which, on handling the tumor, gurgling can readily be felt; but the taxis should always be used, as by it the incarcerated gut may be partially emptied of its contents; or if any additional protrusion should have slipped down, this may be returned. After these means have been employed, an active purgative, such as a full dose of castor oil or a calomel and colocynth pill may be administered. Should there be any signs of inflammation, purgatives must be avoided, and the case treated as already described.

STRANGULATED HERNIA.

A hernia is said to be **Strangulated** when a portion of gut or omentum that is protruded is so tightly constricted that it cannot be returned into the abdomen; having its functions arrested, and, if not relieved, speedily running into gangrene. This condition may occur at all periods of life, being met with in infants a few days old, and in centenarians. It commonly arises from a sudden violent effort, by which a fresh portion of intestine is forcibly protruded into a previously existing hernia, which it distends to such a degree as to produce strangulation. But, though old hernias are more subject to this condition than recent ones, it may occur at the very first formation of a hernial swelling, the gut becoming strangled as it is protruded. There are therefore two distinct kinds of strangulation. One may be said to be of a passive kind, occurring chiefly in elderly people, the subjects of old and perhaps irreducible hernia; which, in consequence of some accidental circumstance, become distended by the descent of a larger portion of intestine than usual, and this, undergoing constriction and compression at the neck of the sac, gradually becomes strangulated. The other kind of strangulation is most frequent in younger individuals; in it the symptoms are more active, the bowel becoming protruded in consequence of violent exertion, and undergoing rapid strangulation, the tension of the parts not having been lessened by the previous long existence of an irreducible hernia.

MECHANISM OF STRANGULATION. Strangulation has been attributed either to a spasmodic action of the walls of the aperture through which the hernia protrudes, or to changes taking place in the protruded parts, subsequent to and occasioned by their constriction by the tissues external to them. The strangulation cannot, I think, ever be regarded with justice as of spasmodic character; the aperture in the abdominal wall, through which the hernia escapes, being tendinous or fibrous, and certainly not in any way contractile, though the action of the abdominal muscles may undoubtedly increase the tension of its sides. The continued and permanent character of the strangulation also, when once it has taken place, would discountenance this opinion; these forms of hernia, indeed, as the ventral, which occur in purely muscular structures, are very rarely strangulated, and, when they are so, the constriction is generally occasioned by the formation of dense adventitious bands upon or within the sac, and not by any muscular agency.

Strangulation is characterized by congestion of the protruded parts, induced by the constriction to which they are subjected; the mechanism being as follows. A knuckle of intestine, or piece of omentum, is suddenly protruded during an effort of some kind. This immediately becomes compressed by the sides of the narrow aperture through which it has escaped; the return of its venous blood is consequently interfered with, and swelling

and oedema rapidly ensue, culminating in stagnation of the blood in it. If the constriction be excessively tight, the walls of the ring being very firm and sharp, the part that is so strangulated may be deprived of its supply in the course of a few hours. If the strangulation be less severe so that the circulation is not entirely arrested, the changes characteristic of inflammation speedily supervene. In proportion as the congestion augments the return of the protruded parts is necessarily rendered more difficult by the increase of their swelling.

SEAT OF STRICTURE.—The stricture is very commonly situated outside the neck of the sac, in the tendinous or ligamentous structures surrounding and not unfrequently in the altered and thickened subserous areolar tissue. In other cases, and indeed with great frequency, it is met with in the neck of the sac itself (Fig. 785), which is narrowed, elongated, and tubular, and is

Fig. 785.—Stricture in the Neck of the Sac, laid open.

the stricture will be seen to be nipped or marked by a deep sulcus occasioned partly by the pressure to which it has been subjected, and partly by the swelling of the congested tissues beyond it. The changes that take place in the protruded intestine rapidly increase in proportion to the duration of the strangulation. The tightness of the stricture and the acuteness of the strangulation have, however, even more to do with these changes than its duration. I have seen the bowel so tightly nipped that, though the strangulation had existed only eight hours when the operation was performed, the vitality was lost in the part constricted (Fig. 791); and in other cases I have known the part to recover, although strangulation had lasted for five or six days.

The first change that takes place in the protruded parts in the case of a strangulated hernia is their *congestion*. This is purely mechanical, and arises from the fact that at first the pressure is seldom sufficient to arrest the arterial flow, while it seriously impedes that through the veins. As a consequence of this the gut gradually swells, and at last the arterial flow is arrested. The gut becomes at first of a claret, marone, or purplish-brown color, sometimes ecchymosed on the surface, with thickening and suffering of the coats owing to effusion into their substance. At the same time the arteries become distended with fluid poured out from the over-distended vessels, so that the circulation is completely arrested. The vessels of any omentum that may be present in the sac will be similarly distended. The interference with the circulation necessarily leads to a progressive diminution of vitality, which speedily terminates in gangrene of the strangulated gut. The phenomena of

inflammation cannot manifest themselves after the circulation is arrested. In fact, in all cases of severe and rapid strangulation they are entirely wanting, the surface of the gut being free from lymph, and the fluid in the sac perfectly clear though darkly stained with blood. In the cases of slow strangulation, on the other hand, in which the gut is so loosely held that circulation continues, although all passage of feces is arrested, the signs of inflammation are commonly met with. In these cases the bowel is dark in color, though not so dark as in more acute strangulation, and is coated here and there with flakes of lymph, which give it a rough and villous look; the omentum has a somewhat rosy tinge, and there is usually a good deal of pale reddish fluid containing flakes of lymph in the sac. It is theoretically possible that in some cases the strangulation may be so complete and sudden that the arterial and venous flow would be simultaneously arrested. In such a case the gut would be pale and the sac free from fluid. Such a condition, if it does occur, is of infinite rarity. When *gangrene* occurs, the bowel loses its lustre and polish, becoming of an ashy-gray, or dull black color, soft and somewhat lacerable, so that its coats readily separate from one another; the serous membrane especially peeling off. The omentum is dark purplish, or of a kind of dull yellowish-gray; and there is usually a considerable quantity of dark turbid serum in the sac, the whole contents of which are more or less offensive. Most usually, when gangrene occurs in a strangulated rupture, inflammation of the sac and its coverings takes place, accompanied, after a time, by a reddish-blue or congested appearance and some tenderness on pressure; and if the part be left unreduced, eventually by emphysematous crackling. If the case be left without being relieved, gangrene of the skin will at last take place; the sac giving way, and the fecal matters being discharged through the softened and disintegrated tissues. In such circumstances as these—which, however, are very rarely met with at the present day—the patient usually eventually dies of exhaustion from vomiting. In exceptional cases peritonitis may be set up by ulceration and perforation of the gut immediately above the seat of stricture, but in the great majority no effusion of feculent matter takes place as the portion of bowel immediately within the stricture becomes adherent to the wall of the abdomen and the neighboring coils of intestine, and thus fecal extravasation is prevented. It does not follow that there is always external evidence of the occurrence of gangrene within the sac; and the bowel is frequently nipped to such an extent as to prevent its regaining its vitality, without any unusual condition being presented until the sac is actually laid open and the intestine examined.

The fluid contained in the hernial sac undergoes changes in appearance and character, corresponding to those which take place in the strangled gut. In earlier and slighter cases it continues clear and but moderately abundant. Sometimes the quantity increases greatly and rapidly, but more commonly the chief alteration that takes place is in its character. It becomes reddish or brown in color from transuded blood. Sometimes even pure blood is found in the sac, and I have seen the protruded intestine invested with a layer of conglutium. If gangrene of the gut take place, the fluid becomes turbid, dark, and offensive. Suppuration in the sac is very rare. I have only once met with it in a woman, 32 years of age, three months pregnant, who was suffering from an acutely strangulated femoral hernia of sixty hours duration. In that case, the taxis had been freely used. Fluctuation could be felt deeply, there was diffused doughy infiltration of the groin, and on opening the sac it was found filled with dark thick pus—about half an ounce; at the bottom of which lay a small deeply congested but not gangrenous knuckle of intestine, which was replaced after the division of a very slight stricture. The patient recovered.

Inflammation of the Gut after relief of Strangulation occurs in a large proportion of cases. It has been already pointed out in the chapter on Inflammation (vol. i. p. 181), that the arrest of circulation through a part of the living body produces different effects according to the length of time that it is kept up. If the arrest is complete and of sufficient duration, gangrene sets in, such blood as the vessels contain coagulates, and on relief of the strangulation the blood is unable to enter the dead tissues. If the arrest of the circulation has been maintained for a length of time sufficient to impair the vitality of the part considerably but not to kill it, on the relief of strangulation all the phenomena of inflammation manifest themselves. The vessels become engorged with blood, abundant exudation takes place causing great swelling by which the feeble circulation may be again arrested and gangrene may set in. In other cases the inflammation may fall short of this, but may, in the case of the intestine, be sufficient to suspend the functions of the affected part so that, although the strangulation is relieved, the obstruction to the passage of feces remains for some days, or even till death results. If the arrest of circulation has been less complete or of shorter duration, the relief of strangulation is followed by temporary hyperemia, which soon subsides. It is not uncommon in fatal cases to find the coil of intestine free from gangrene, but swollen, covered with a thick layer of inflammatory exudate, fixing it to the neighboring coils, and evidently incapable of performing its functions. This inflammation after reduction is a fact of great importance as it shows the necessity of giving the gut rest, as far as possible, after the strangulation has been relieved, by the avoidance of purgatives or irritant food.

It was formerly assumed that in all cases of prolonged strangulation a general peritonitis sets in. This assumption is not borne out by the results of the post-mortem examination of cases dying of unrelieved strangulation. In such cases, as a rule, local peritonitis is found at the neck of the sac, but the membrane generally is free from any signs of inflammation. Should inflammation occur it is always slight, and seems to be secondary to local inflammation of the mucous membrane of the intestine above the stricture, which in too many cases is the result of the injudicious administration of purgatives.

SYMPTOMS.—The signs and symptoms of strangulation are of two kinds: 1. The local ones, affecting the Tumor; and, 2. The general ones, influencing the Constitution.

1. **Local Signs.**—The tumor, if the hernia be an old one, will be found to be increased in size; or it may have appeared for the first time. At the moment of strangulation it will generally be found to be hard, tense and rounded, more particularly if it be an enterocoele. When, however, the hernia is to a great measure omental, it is not unfrequently soft and doughy, though strangulated. It seldom increases in size after strangulation has occurred, as no fresh protrusion can take place below the stricture, but I have known it to be greatly augmented in bulk after the strangulation had existed for some hours, by the effusion of serum into the sac. If the hernia have previously been reducible, it can no longer be put back, and there is no impulse in it nor increase in its size on coughing, the stricture preventing the transmission of the shock to the contents of the tumor; and in this way, as pointed out by Luke, the situation of the constriction may sometimes be ascertained by observing at what point the impulse ceases. In most cases there is considerable local tenderness.

2. **Constitutional Symptoms.**—So soon as the strangulation has occurred, intestinal obstruction takes place, and the patient becomes uneasy and restless. If the constriction be of an active character, he will be seized with

acute pain in the part, which speedily extends to the contiguous portion of the abdomen. The first thing that happens when intestine is strangulated, whether a large coil be constricted, or a small portion only of the diameter of the gut be nipped, is an arrest of the peristaltic movement of the part implicated; and the occurrence of obstruction to the onward course of the intestinal contents is followed by constipation, vomiting, and colicky pains. The constipation is always complete, neither feces nor flatus passing through; the bowels may sometimes act once after the strangulation has occurred from that portion which lies below the seat of constriction, but they cannot, of course, empty themselves thoroughly, nor from above the strangled part.

Vomiting usually sets in early, and is often very severe and continuous, with much retching and straining; at first the contents of the stomach are ejected, with some bilious matters, but afterwards the vomiting becomes feculent or stercoraceous. The cause of feculent vomiting has usually been supposed to be an inverted peristaltic action of the intestines. Brinton, however, opposed this time-honored view, maintaining that the peristaltic action continues direct and causes a peripheral downward current as far as the obstruction, from which point a central upward current returns the contents of the intestine towards the stomach. The quantity brought up is often very large in amount, and consists not only of the normal contents of the intestine, but of an abundant secretion from the congested and irritated mucous membrane above the obstruction. It is greatly increased in quantity should the patient have taken a purgative. In cases of prolonged obstruction it is sometimes mixed with black shreds of altered blood, indicating intense congestion of the mucous membrane. The vomiting is attended by colicky and dragging pains about the navel. These symptoms are more severe in their character when the strangulation is acute, than when it is passive. They occur equally in the incomplete and the complete forms of the disease; indeed, it not unfrequently happens that the hernial tumor may be so small as to have escaped observation, the occurrence of the above-mentioned symptoms being the first indication of the probable nature of the mischief. Hence, it is well always to examine for hernia when called to a patient suddenly seized with constipation, vomiting, and colicky pains, even if told that no tumor exists.

After the strangulation has existed for some time, the abdomen becomes distended and tympanitic with much pain and distress. The pulse becomes small and rapid, and perhaps intermittent; the tongue is dry and speedily becomes brown; the countenance is pale, anxious, and dragged. The extremities become cold, congested, and clammy, and the temperature falls below normal. When gangrene of the rupture takes place, hiccup usually comes on, with sudden cessation of pain in the tumor, and intermittent pulse, cold sweats, pallor, anxiety, rapid sinking of the vital powers, usually with slight delirium; and death speedily occurs.

Modifications of Symptoms.—The symptoms just described are those which are usually met with in strangulated hernia. They may, however, be modified in some important respects.

1. There may be little or no tension in a strangulated hernia, the tumor continuing soft and lax; this is especially the case when the hernia contains omentum, and in congenital hernia when strangulated. It may occur also in the case of double hernia on the same side, in consequence of the outer sac being empty, or merely filled with serum, and the posterior one being protruded against this and strangulated, but its tension being masked by the lax state of the outer one.

2. Vomiting sometimes does not take place from first to last, there being at most a little retching; at other times the patient vomits once or twice, and

then there is no recurrence of this symptom so long as he remains quiet and keeps the stomach empty; but, on moving or taking nourishment of any kind, even fluids, it comes on again, and thus the Surgeon may detect as a symptom, should it be necessary in a diagnostic point of view.

3. Extensive peritonitis, with copious effusion of a puriform liquid can occur without any pain, and with but little tenderness and no elevation of temperature; the anxiety of countenance and sharpness of pulse being the only symptoms that lead to a suspicion of its existence.

4. Death may result from exhaustion consequent on vomiting, without any sign of gangrene in the constricted portion of intestine.

Diagnosis.—The diagnosis of strangulated hernia requires to be made from the following conditions:

1. **Obstructed Irreducible Hernia.**—In this there are no acute symptoms, and the rupture will generally be found to be a large one of old standing. It may become somewhat tense and swollen, but it is not tender to the touch, and always presents a certain degree of impulse on coughing. There may be constipation; but there is no vomiting, or, if there be any, it is simply mucous and bilious, consisting of the contents of the stomach. The speedy restoration of the intestinal action, by the treatment already indicated as proper in these cases, will remove any doubt as to the nature of the affection.

2. **Inflamed Irreducible Hernia.**—Here there are great tenderness and pain in the tumor, with pyrexia, and some general peritonitis, but there is no vomiting; or, if the patient have vomited once or twice, he does not continue to do so with the same degree of violence, or in the same quantity as he would if it were the result of strangulation. Again, the constipation is not absolute and entire, but flatus and liquid feces with usually pass.

3. **General Peritonitis conjoined with Hernia.**—Here the diagnosis is often extremely difficult, especially if the hernia be an irreducible one. In these cases, however, it may be observed that the peritonitis is most intense at a distance from the sac; that there will be little or no vomiting, or if there be, that it is simply of mucus and the contents of the stomach, and that the constipation is by no means obstinate or insurmountable by ordinary means.

4. In **Double Hernia**, one tumor may be strangulated and the other not, though irreducible. In these circumstances, it may at first be a little difficult to determine which one is the seat of constriction. This, however, may be ascertained by observing greater tension and tenderness about the neck of the strangulated than of the unconstricted hernia.

5. The coexistence of **Early Pregnancy**, or a threatened **Miscarriage**, may obscure the diagnosis, the Surgeon possibly being in doubt whether the vomiting is dependent on the state of the uterus or on the strangulation of the hernia. Here it may be stated generally that the vomiting of pregnancy never becomes stercoraceous; that constipation is not complete, flatus and feces passing; and that the local signs of strangulation are usually unmarked.

Besides these various conditions of hernia, which may be confounded with strangulation, there are other tumors which may be mistaken for this disease; but these we shall have to consider when speaking of the appearances of hernia.

TREATMENT.—The treatment of strangulated hernia is one of the most important subjects in surgery. The object to be accomplished is the removal of the constriction from the strangled hernial tumor. This is effected either by the Reduction of its Contents by Taxis; or by the Division of the Stricture.

Taxis.—The reduction of the hernia is effected by the employment of the taxis, by which is meant the various manual procedures employed in putting the rupture back. The taxis, when properly performed, is seldom attended by any serious consequences to the patient. I have never seen it followed by death; and out of 293 cases of hernia reported by Luke, as having been reduced by taxis in the London Hospital, none died. In the Reports of University College Hospital one fatal case is recorded in which death from ulceration and perforation of the gut at the seat of stricture followed reduction by taxis. It is not unfrequently followed, however, by a rather sharp attack of peritonitis, which might probably, in some instances, prove fatal; in one instance, I have seen it followed by very abundant hemorrhage from the bowel, probably owing to the rupture of some of the congested vessels of the strangled portion of the gut. In using the taxis, great care should in all cases be employed, and no undue force should be had recourse to. No good can ever be effected by violence; the resistance of the ring cannot be overcome by forcible pressure; and a vast deal of harm may be done by squeezing against it the tender and inflamed gut, causing this to overlap, and thus to be bruised, or even, perhaps, torn. The taxis should not be prolonged beyond half an hour; if it be properly employed for this time, the hernia, if reducible, will probably go back. If it be applied, as it often and very improperly is, for a lengthened period, and by several Surgeons in succession, the protruded part becomes ecchymosed, irritated, and disposed to inflammation; and the chances of recovery after a subsequent operation are much lessened. When the parts are much inflamed, the taxis should be employed with great caution, and, if it have been fairly and fully used by another Surgeon, it is better not to repeat it. When gangrene has occurred, the taxis should never be employed, as the putting back of the mortified gut into the abdomen would be followed by extravasation of feces and fatal peritonitis.

In using the taxis, it should be borne in mind that there are two obstacles to overcome—the resistance of the parts around the ring, and the bulk of the tumor. The first may be somewhat lessened by relaxing the abdominal muscles, and consequently diminishing the tension exercised upon the tendinous apertures and fasciæ of the groin. In order to effect this, the patient should be placed in a proper position, the body being bent forwards, the thigh adducted and semiflexed upon the abdomen; the Surgeon may then, by employing steady pressure on the tumor, endeavor to squeeze out some of the flatus from the strangled portion of intestine, and thus to effect its reduction. In doing this, the neck of the sac should be attended by the fingers of the left hand, whilst, with the right spread over the tumor, the Surgeon endeavors to push it backwards, using a kind of kneading motion, and sometimes in the first instance drawing it slightly downwards, so as to disengage it from the neck of the sac. The direction of the pressure is important—it should always be in the line of the descent of the tumor. These means may be employed as soon as the patient is seen by the Surgeon, when by steadily carrying on the taxis for a few minutes, he will perhaps hear and feel a gurgling in the tumor, which will be followed by its immediate reduction. If the patient be thin, and the outline of the aperture through which the hernia escapes tolerably defined, the protrusion may be reduced, after failure of the taxis in the ordinary way, by passing the tip of the finger or the nail under the edge of the ring, and pulling this firmly and forcibly on one side, so as to steady and at the same time dilate it, pressure being kept up on the tumor with the other hand. This manœuvre can be practised with more facility and success in femoral hernia, where the upper edge of the saphenous opening is sharply defined, but may also successfully

be had recourse to in inguinal and umbilical protrusions. In some cases reduction appears to have been facilitated by placing the patient on his side, and shoulders, and raising the body in the vertical position whilst the taxis was being employed. Should, however, reduction not ensue, it will be advisable to have recourse at once to further means, the object of which is relaxing the muscles and lessening the bulk of the tumor, to enable the hernia to be reduced.

Auxiliary Measures.—The means to be employed must be modified according to the condition of the strangulation, whether it be of the active or the passive kind. If it be acute, the patient may be put into a hot bath where he may remain for twenty minutes or half an hour or until he is faint; and, whilst he is in the bath in this condition, the taxis should be employed. If it do not succeed, he should be taken out, wrapped up in blankets, and be put fully under the influence of an anæsthetic. Flatus at the present time usually given, but in some cases it fails to produce perfect muscular relaxation, and chloroform may then be substituted. Whilst the patient is fully anæsthetized, taxis may be tried once again. Should this fail, operation must be immediately proceeded with. No good can possibly come of delay in these cases, and repeated attempts at taxis should be fully avoided. If the hernia do not admit of reduction in the early stage of the strangulation, it will necessarily be much less likely to do so, when the parts, squeezed and bruised much by manipulation, will have had their congested condition greatly increased.

When the strangulation is of a passive character, supervening gradually in an old hernia, especially of inguinal or umbilical, and occurring in the young or elderly people, other measures may, in exceptional cases, be adopted with the view of lessening the bulk of the tumor, which, rather than the tension of the parts, offers the chief object to reduction. In such circumstances, especially when the tumor is large and not very tense, it is well to disagree with the hot bath, which has sometimes a tendency to increase any congestion that may already exist in the brain; I have in more than one case seen a strangulated rupture enlarge considerably after the employment of the hot bath. In such cases, more time may safely be spent in attempts at reduction than in very acutely strangulated hernia. It is a useful practice to commence the treatment by the administration of a large enema, which, by emptying the lower bowel, will alter the relations of the abdominal contents, and may materially facilitate the reduction of the tumor. The best enema is one of glyster and castor oil, with some spirits of turpentine added to it; it should be injected through a full sized tube, passed high up into the gut, and with a moderate degree of force. In administering it, care must be taken that no injury be done to the bowel. It would scarcely be necessary to give such a caution as this, were it not that I was summoned, some years ago, by two very excellent practitioners, to see a woman with strangulated femoral hernia, to whom an enema of about two quarts of tepid water had been administered; and as this had not returned, and did not appear to have gone up the bowel, they suspected that it must have passed out of the rectum into the surrounding areolar tissue. As the patient, however, did not seem to be suffering from this cause, and as the symptoms of strangulation were urgent, I operated on the hernia. Death suddenly occurred, apparently from exhaustion, in about eight hours; and, on examining the body, it was found that the rectum had been perforated, and the fluid injected into the meso-rectum, separating the gut from the sacrum, whence it had extended into the general subperitoneal areolar tissue, which contained a quantity of the liquid; some of the water appeared to have entered the peritoneal cavity also.

In the large hernie of old people, more particularly the umbilical, in which there is a good deal of flatus, after the enema has been administered, a bladder of ice may be applied for three or four hours with excellent effect. Chloroform may then be given, and the taxis employed under its influence. Of late years, indeed, I have been in most cases in the habit of trusting almost solely to chloroform as a relaxing agent, and have often dispensed with the use of even the warm bath. If, however, this can be conveniently used without too much delay, it should be employed. After this, I put the patient at once under chloroform, and then try taxis for a period not exceeding half an hour; if this fail, the operation should be done without making any further attempts at reduction, which are not only useless, but injurious by bruising the protruded parts.

After taxis has been fairly employed for a sufficient time, and has not succeeded in reducing the hernia, the operation must be proceeded with. There are few Surgeons who will not at once acknowledge the truth of the remark of the late Hey, of Leeds—that he often regretted performing this operation too late, but never having done it too early. It is true that cases are occasionally recorded, in which, after four or five days of treatment, the hernia has gone up; but it is very rare to meet with such cases in practice; and, in all probability, in delaying the operation in the hope of finding one such case, the lives of dozens of patients would be sacrificed. Luke has shown, as the result of the experience at the London Hospital, that the ratio of mortality increases greatly in proportion to the length of time during which the strangulation is allowed to continue. Of 69 cases of strangulated hernia operated upon within the 48 hours of strangulation, 12 died, or 1 in 5.7; whilst of 38 cases operated on after more than 48 hours had elapsed, 15 died, or 1 in 2.5. Indeed, one chief reason of the greater mortality from operations for hernia in hospital than in private practice, probably arises from the fact that much valuable time is frequently consumed before assistance is sought, or in fruitless efforts to reduce the swelling before the patient's admission. Not only is time lost in this way, but the bowel is often bruised and injuriously squeezed, so that the inflammation already existing in it is considerably increased. Moreover, at the present time the improved methods of treating wounds, especially those implicating the peritoneum, have so far diminished the dangers of the operation that the great reason for hesitation has been removed. The mortality in operations for strangulated hernia performed within twenty-four hours of the descent of the gut, with antiseptic precautions, or even with common attention to cleanliness, is so small, that it may be said to be almost inconsiderable.

Persistence of Symptoms after Reduction. After the reduction of the hernia, the symptoms of strangulation may continue unabated. This untoward occurrence may arise from five distinct conditions: 1. The hernia may have been reduced in mass (*vide* Chapter LXII.). 2. An internal strangulation has existed within the sac, the taxis having overcome the external stricture, but failing to influence that within. 3. The gut may have been so severely nipped or strangulated for so long a time, that, as soon as the constriction of the vessels is relieved, the phenomena of acute inflammation manifest themselves, with complete arrest of peristaltic movement. This condition, as before stated, may end in gangrene. 4. The sac may be of an hour-glass shape, lying partly within the abdomen and partly outside, and in the apparent reduction the gut may have been merely squeezed from the outer part of the sac into that lying within the cavity of the abdomen. 5. A second hernia may exist in a state of strangulation, which has escaped detection.

The diagnosis of these several conditions may possibly be made by atten-

tion to the following circumstances. In the *reduction in mass* the tumor is slipped up without any gurgle; the canal is very open, and no trace of it can be felt in it, but a rounded tumor, possibly at the upper part, is remaining. In the case of *internal adhesion* there will have been no gurgling, the canal is still filled by the sac; the abdominal apertures are less patent, naturally patent and distinct. In the case of *extreme nipping* and consequent inflammation and paralysis of a portion of the gut, gurgling will have been felt and heard in effecting the taxis, which does not happen in either of the other conditions, and the symptoms of intestinal obstruction will not be so complete. The vomiting will lose its stercoraceous character, and probably some flatus will pass. An *hour glass sac* is met with only in oil inguinal hernia, and appears to arise from a partial reduction in mass. Four cases of this kind have occurred in University College Hospital in the last seven years. In each apparent reduction was easily effected, with slight pain or The protrusion readily reappeared, and was easily put back again. The nature of the case was recognized only after operation performed for persistence of symptoms in three cases, and after death in the fourth. In the case of the *existence of a second hernia* in a state of strangulation, the cause of the continuance of the symptoms may be ascertained by careful examination of the abdominal walls. It is especially the coexistence of a small femoral with a large umbilical or inguinal hernia that is apt to be overlooked. This I have seen happen in a very fat person. A man was taken into University College Hospital with strangulated inguinal hernia. It was reduced by the house-surgeon, but the symptoms persisted, and the patient died unrelieved, there being no indication for operation. After death a small piece, half a knuckle, of intestine was found strangulated in the canal of the same side. The patient being extremely fat, this strangulation was not detected, and could not be recognized during life. The body of the groin should be very carefully examined in all these cases.

The **Treatment** of these different conditions is full of difficulty and anxiety to the Surgeon. As a general rule, I think that the proper practice in all cases when the symptoms of strangulation, especially stercoraceous vomiting, continue *unrelieved and undiminished in severity* for some hours after the apparent reduction of the hernia, is to cut down upon the tumor, expose the sac, and, if that be found still strictured, divide the constriction in the way which will shortly be described. Should the hernia not have been reduced "in mass," it might possibly be found that a small knuckle of intestine is still gripped at the inner and deeper ring; but should that not be the case, it will, I think, be safer not to push any exploration into the abdominal cavity with the view of discovering the possible existence of unrelieved internal strangulation, the presence of which would be a right justification, and, if existing, could scarcely admit of discovery. The safer and wiser plan under such circumstances appears to be, to leave the wound open, with a light dressing over it, and to give the patient the chance of the formation of an artificial anus on the sloughing of the strangulated or badly nipped knuckle of intestine; a result that I have more than once witnessed, about the fourth or fifth day, the patient ultimately recovering.

In some cases, where the nipping of the strangulated intestine has been severe, yet not sufficient to arrest permanently the peristaltic action, or to destroy its vitality, constipation and retching, with nausea, may continue, and the tumor, if the hernia have been small and deeply seated, more particularly if femoral, may continue to be felt, though less tense than when consisting simply of the thickened and inflamed sac, with serous fluid in it. In these circumstances, we must be careful not to operate. I have, on two or three occasions, seen an empty sac operated on to the annoyance of the

Surgeon and danger of the patient. The mistake may be avoided by observing that the symptoms gradually lessen in severity by waiting, and that the tympanitis subsides, the abdomen becoming flat and supple.

The length of time during which the congested condition of the bowel will continue after a strangulated portion of intestine has been reduced, is very considerable. In a case of strangulated femoral hernia which was some time ago under my care, reduction was effected, but, strangulation recurring at the end of twelve days, an operation became necessary; this was performed, and the patient died on the eighth day after it, or the twenty-first from the first strangulation. On examination, the small intestine was found congested in two distinct portions, each of which was about eight inches in length; several feet of healthy gut intervening between them. One of these congested portions lay opposite the wound, and was evidently the intestine that was last strangulated. The other was altogether away from the seat of operation, but was equally darkly congested, being almost of a black color, and was clearly that portion which had been constricted some time previously; and which, although twenty days had elapsed, had not as yet recovered itself. When a second strangulated hernia exists it, of course, must either be reduced by the taxis, or the operation practised on it.

OPERATION FOR STRANGULATED HERNIA.

All operations for hernia should be performed with efficient antiseptic precautions. The Surgeon and his assistants must first carefully clean their hands (p. 263, vol. i.), and the sponges and instruments must be disinfected as already described (p. 66, vol. i.). The skin of the patient for some distance around the seat of the incision must be also cleaned and disinfected. The carbolic spray, if at hand, may be used, as experience has abundantly proved that in an operation for hernia it never does any harm, and in the opinion of many excellent Surgeons it is an additional security against septic peritonitis; especially as in operations for hernia it is impossible to clean out the cavity should any blood or fluid from the sac find admission to it. If the spray be not at hand, the wound may be occasionally irrigated with carbolic lotion (1 in 40), or other antiseptic solution, care being taken that the fluid does not pass into the peritoneal cavity; a basin of carbolic acid lotion should be at hand, into which the Surgeon should dip his hands before introducing the finger into the abdominal cavity. Should a coil of intestine be unavoidably exposed for any length of time, it may be covered with a piece of linen rag soaked in a warm 1 in 40 solution of carbolic acid. If the patient be much collapsed, the extremities must be covered with warm blankets, and no more of the body exposed than is necessary.

The operation for strangulated hernia may be performed in two ways; either by opening the sac, exposing its contents, and dividing the stricture, wherever it is situated, *from within*; or it may be done by dividing the stricture *outside*, without opening the sac. In either case the great object of the operation, the division of the stricture by the knife, is the same; but the mode in which it is effected is different. We shall first describe the operation in which the sac is opened; afterwards that in which it is not; and then briefly compare the two procedures.

OPERATION IN WHICH THE SAC IS OPENED. Exposure of the Sac.—The patient having been brought to the edge of the bed, or placed on a table of convenient height, the bladder is emptied, and the parts that are the seat of operation are shaved. The dissection of the hernial coverings in layers anatomically arranged, is never done at an operation. The Surgeon dissects, or rather cuts, down to the sac, then turns aside the coverings as a whole,

and divides the stricture. He proceeds as follows: An incision of sufficient length is made over the neck of the sac; this may be best done by passing up a fold of skin, pushing the scalpel through its base with the back of the instrument turned towards the hernia, and then cutting upwards (Fig. 786). A linear incision is thus made, which may be extended at either end if necessary; the dissection is then carried through the superficial fascia and fat with the scalpel and forceps. If any small artery spouts freely, it had better be tied at once, lest the bleeding obstruct the view of the part in the subsequent steps of the operation. As the Surgeon approaches the sac, care

Division of the skin.

Fig. 787. Operation for Hernia,
Division of Subserous Areolar Tissue.

caution is required, particularly if the subserous areolar tissue be dense, opaque, and laminated. The Surgeon must pinch this up with the forceps, make a small incision into it, introduce a director, and lay it open upward or on the finger (Fig. 787). If it be thin and not opaque, so as to admit a view of the subjacent parts, he may dissect it through with the unsupported hand. In this way he proceeds until the sac is reached, which is usually known by its rounded and tense appearance, its filamentous character, and by the arborescent arrangement of vessels upon its surface. In some cases the Surgeon thinks that he has reached the sac, when in reality he has come upon a deep layer of condensed areolar tissue in close contact with it; here the absence of all appearance of vessels, the dull and opaque character of the tissue and its more solid feel, together with the absence of the peculiar tension that is characteristic of the sac, will enable him to recognize the state of things. In other cases, it may happen that the sac is so thin, and the superficial structures are so little condensed, that the Surgeon lays it open before the earlier incisions, before he thinks he has reached it. In these circumstances a portion of the intestine protruding might be mistaken for the sac. This dangerous error may be avoided by observing the peculiarly smooth and highly polished appearance presented by the dark and congested gut, the absence of arborescent vessels, and the non-existence of any adhesion between its deeper portions and the tissues upon which it lies. If the sac be prematurely opened, the escape of fluid will indicate this, and if contents protrude, the granular appearance and peculiar feel of this tissue will at once cause its recognition.

Opening the Sac.—The sac, having been exposed, must be carefully opened; this should be done towards its anterior aspect; and, if it be a small one, at its lower part. It may best be done, if the sac be not very

tense, by seizing a portion of it between the finger and thumb, and thus feeling that no intestine is included; a small portion of it is then pinched up by the forceps, and an opening is made into it by cutting upon their points with the edge of the scalpel laid horizontally. If the sac be very tense, it cannot be pinched up in this way, and then it may best be opened by introducing the point of a fine hook very cautiously into its substance, raising up a portion of it in this way, and then making an aperture into it. There is little risk of wounding the gut in doing this; for the tension of the sac arises from the effusion of fluid into it, which will be interposed between it and the gut. In these cases, the fluid sometimes squirts out in a full jet, and occasionally in a very considerable quantity. I have seen at least a pint of slightly bloody serum escape on opening the sac of an old inguinal hernia which had become strangulated. Most frequently, however, there is not more than from half an ounce to an ounce; and sometimes the quantity is considerably less than this. Sir James Paget very wisely attaches great importance to the character and appearance of the fluid in a hernial sac; if this fluid be clear and transparent, of a yellow tint like serum, it is a good sign, as probably no great amount

Fig. 788. — Broad and Narrow Director on which the Sac may be Divided.

of congestion has taken place. If reddened by extravasation of blood, it is an evidence of increased congestion; and the deeper the discoloration, the browner, the more muddy the fluid, the greater probably has been the change induced in the strangled parts by the congestion or inflammation resulting from the stricture. In some instances scarcely any fluid exists; and then it becomes necessary to proceed with extreme caution in opening the sac, as the gut or omentum is applied closely to its inner wall. In such cases as these, the sac is not unfrequently sufficiently translucent to enable the Surgeon to see its contents through it: and he should then open it opposite to the omentum, or to any small mass of fat which he may observe shining through it. The opening, when once made into the sac, may be extended by the introduction of a broad director (Fig. 788), upon which it is to be slit up to a sufficient extent to allow the examination of its contents.

Division of the Stricture.—The next point in the operation is the division of the stricture; and this requires considerable care, lest injury be done to the neighboring parts of importance, or the gut be wounded. Vessels and structures in the vicinity of the stricture are avoided by dividing it in a proper

Fig. 789. — Hernia-knife.

direction, in accordance with ordinary anatomical considerations, which will be described when we come to speak of the special forms of rupture. All injury to the intestine is prevented by introducing the index finger of the left hand up to the seat of stricture, insinuating the finger-nail underneath it, and dividing the constriction by means of a hernia-knife, having a very limited cutting edge (Fig. 789). If a director be used to guide the knife, the intestine will be in considerable danger, as the instrument may be slid under that portion of it which lies beneath the stricture; or the tense gut, curling over

the side of the groove, may come into contact with the edge of the knife. These accidents are prevented by using the finger as a director, and passing the hernia-knife (which should not have quite so long a probe-point as is usually made) along the palmar surface of the finger upon its flat side (as represented in Fig. 700); the finger serves to keep the bowel out of the way and detects any part that may be interposed between the edge of the knife and the stricture.

During the division of the stricture, the protruding portions of intestine must be protected from the knife. The operator may spread his left hand

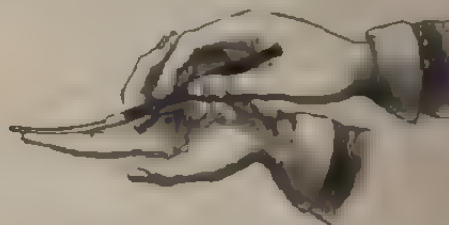

Fig. 700.—Mode of using the Hernia-knife

over them in such a way that they cannot be touched by the edge of the instrument: or they may be protected by an attentive and careful assistant.

In some cases the stricture is so tight that it is at first almost impossible to get the edge of the nail underneath it. The Surgeon will, however, generally succeed in doing so, by directing his assistant to draw down the coat of intestine, so as to loosen it, as it were, from underneath the stricture; he will then usually succeed in passing his finger up in the middle of the coat, where the mesentery lies. So soon as the blunt end of the hernia-knife has been passed under the stricture, its sharp edge must be turned up, and the stricture divided in a proper direction, to a very limited extent, from one-eighth to a quarter of an inch.

Reduction.—The intestine and omentum, having been examined, must be dealt with according to the condition in which they are found; as will be described at pp. 769-772, vol. ii. If these structures be sufficiently relaxed to admit of reduction, the intestine should first of all be replaced. This must be done by pushing it back with as much gentleness as possible, and must be by using the index fingers. When it has slipped up into the abdomen the omentum must be returned in the same way. In reducing the hernia protrusion, after the sac has been laid open, care should be taken that the margins of this are firmly held down by means of a pair of forceps, so that together with its contents, be returned *en masse*, the stricture being incised. After reduction, the Surgeon should pass his finger up into the canal through which the hernia has descended, and feel that all is clear.

Treatment of the Sac.—There is no necessity to close the opening in the sac by sutures. It unites readily under the pressure of the dressing. If the patient be young and healthy, and not too exhausted by previous illness, the operation may be completed by ligature of the neck of the sac, with strong catgut or silk, removal of the body of the sac, and an inguinal or umbilical hernia) suture of the abdominal opening. For more experience is required before it can be definitely stated how much this exceeds added to the danger of the operation. Those who have adopted it are highly of it and advise it in all cases in which no exceptional circumstances render it inadmissible. It should never be undertaken except in conjunction with efficient antiseptic treatment during and after the operation.

Treatment of the Wound.—After the operation is completed, whether the sac be removed or not, the wound must be brought together with sutures and a small drainage-tube inserted at the lower angle; it is then dressed, on ordinary principles, with some form of antiseptic dressing. Carbolic gauze, iodoform-wool, salicylic wool, or any other efficient antiseptic material may be used. It must surround the wound for some distance, and a pad of the dressing should be placed over the abdominal opening to prevent the protrusion of the hernia during a fit of coughing or a muscular effort. The dressing must be secured by a bandage, over which a single turn of elastic webbing may be applied, passing over the abdominal opening to act as a truss. Care must be taken, that although the dressing is firmly applied undue pressure is not exerted, lest it interfere with drainage and prevent the union of the wound. This is particularly necessary if carbolic gauze be used, as the pad is apt to cake into a solid mass, especially if the material be not of the best quality. In the absence of other dressings a pad of lint soaked in carbolic oil (1 in 10), or simple dry lint or cotton-wool may be used. Water dressing should always be avoided. In most cases the wound heals by the first intention. Should suppuration occur the stitches must be removed and a light antiseptic dressing be applied, lest the pus, not finding a ready outlet, may either be diffused between the muscular planes of the abdominal wall, occasioning sloughing or the formation of an abscess, or return into the peritoneal cavity, exciting inflammation of it,—a result which I have more than once seen occur.

After-treatment.—The patient should be kept quiet in bed; a dry hot flannel laid over the abdomen, and the leg on the affected side bent over a pillow. From 30 to 40m of laudanum may then be given, or $\frac{1}{4}$ to $\frac{1}{2}$ gr. of morphia hypodermically. If the strangulation has been of very short duration—under 24 hours—and the gut but little congested, the patient may be left without further medical treatment until the bowels act by themselves, unless this be delayed for three or four days, when a castor-oil and gruel enema may be given. In all cases in which the strangulation was of longer duration and more severe the bowels must be kept confined by small doses of opium till the fourth day at least. The opium may then be discontinued if there is no abdominal tenderness or other bad symptom, and the bowels allowed to act naturally. If they do not act before the end of a week, and the patient is well in other respects, an enema may be given. It is of very great importance not to administer any purgatives in these cases. If the mechanical obstruction has been removed, the bowels will be sure to recover their proper functions; though, in consequence of the gut having been severely constricted and almost wounded by the pressure of the stricture, it may require to be left quiet for a few days before it can recover its peristaltic action. The administration of purgatives, by still further irritating it, will increase the risk of inflammation in it, and will probably do much harm. The patient, of course, must be kept upon the simplest and most un irritating diet—indeed, he should be allowed only barley-water and ice for the first day or two, and afterwards some beef-tea; but no solid food must be given till the bowels have acted, and all risk of peritonitis has passed.

The result of the operation for strangulated hernia is greatly influenced by the age of the patient; the result being very much more favorable in the earlier than in the later periods of life. Of 15 consecutive cases operated on at University College Hospital, of which 8 recovered and 7 died, the average age of the fatal cases was 23 years greater than that of the successful ones. Obesity, also, has a very unfavorable effect. The depth of the wound in fat people adds to the difficulty of drainage, and the discharges,

it allowed to decompose, readily soak into the subperitoneal cellular tissue and give rise to diffuse cellulitis with sloughing.

ACCIDENTS AND MODIFICATIONS OF THE OPERATION.—The operation having been thus described, we have next to consider in detail certain accidents attending it, or modifications which may be required; such as Peritonitis, Acute Enteritis, the Management of the Intestine according to its conditions, the Management of Adhesions and of the Omentum, Wounds of the Intestine and of Arteries, Sloughing of the Sac, Artificial Anus, and Fecal Fistula.

Peritonitis after Operation.—The great danger to be apprehended after operations for hernia is the supervention of *diffuse peritonitis*. This very rarely exists at the time of the operation. In a considerable proportion of cases it arises from the introduction of septic matter into the cavity of the abdomen from the wound either at the time of the operation or at a later period should septic suppuration take place. In other cases it is dependent upon the condition of the gut at the time it is reduced. Even if it is actually gangrenous it may become rapidly surrounded by a firm inflammatory exudation and diffuse inflammation may thus be prevented. More commonly this fails, the inflammation extends more widely, the quantity of the exudation becomes so great that the healthy part of the peritoneum cannot absorb it (*vide p. 828, vol. i.*); septic changes then take place in the accumulated fluid; the irritating products are diffused widely and general peritonitis results. When the gut is gangrenous, and probably if it is never acutely inflamed as the result of so long strangulation, the surrounding inflammation of the peritoneum may assume a septic form, the infection taking place from within the gut. The first cause can be obviated by the use of antiseptics during the operation, but it is evident that these can have no influence when the source of infection comes from within the gut. The symptoms of peritonitis may assume two distinct forms, being active and acute or passive and latent.

Acute Peritonitis is commonly met with in strong and robust people otherwise healthy, who are the subjects of the operation. It presents the primary symptoms of acute idiopathic inflammation of the peritoneum. There is tenderness of a diffused character, with lancinating pains. The patient lies on his back, with his knees drawn up, has an anxious countenance, a quick hard pulse, a dry tongue, and much inflammatory fever, the respiration is principally thoracic, and tympanitis soon comes on. The bowels are usually constipated, though sometimes irritated. Vomiting usually forms a marked symptom. The *Treatment* of this form is best conducted by the administration of opium. A pill containing gr. j of opium may be given every fourth or sixth hour. If the patient is young and strong, gr. j of calomel should be added, and leeches, followed by hot fomentations, applied to the abdomen. The patient must be confined to barley-water, milk, and ice. When the inflammatory action is subdued, the constipation which is occasioned by it will be relieved without the necessity of administering any purgative. The tympanitis may best be removed by turpentine enemata, and any local tenderness by the application of blisters.

Latent or Passive Peritonitis occurs chiefly in old people, or in weak subjects, and is especially apt to follow upon inflammation of the operated and its consequent suppuration. In other cases it follows the reduction of inflamed or gangrenous gut. More commonly it is the consequence of the extension of unhealthy inflammation of septic or infective origin from the wound to the peritoneum. This form of inflammation is very apt to occur in overcrowded or unhealthy hospitals, and is prevented by the same means hygienic and local, as pyæmia, septicæmia, and the allied diseases. It

usually proves rapidly fatal, the patient being poisoned by absorption of the products of the unhealthy process; dying, in fact, of acute septic poisoning. In hospital patients especially, in whom all disease is apt to assume a low character, this inflammation is peculiarly liable to occur. In some instances, it sets in without the appearance of any marked local symptoms of inflammation, such as pain or uneasiness in the abdomen; but, two or three days after the operation, the patient becomes depressed, with a quick and weak pulse, an anxious countenance, a tumid and tympanitic abdomen, and rapid sinking of strength. In the majority of cases, however, some of the ordinary local signs of peritonitis are present. After death, the abdominal cavity will be found to contain a quantity of turbid serous fluid mixed with flakes of lymph; in many instances in such quantity as to give it a puriform appearance, and not unfrequently matting together the coils of intestine. In the *Treatment*, it is necessary to support the patient, and in some instances even to administer stimulants, such as ammonia, the brandy-and-egg mixture, etc. Depleting measures of all kinds are quite inadmissible: and, indeed, the remedy that offers the most prospect of benefit to the patient is opium in full doses, one grain being given every third or fourth hour until some effect is produced upon the constitution. At the same time, turpentine enemata may be administered, with the view of removing the tympanitis, which is a source of much distress to the patient.

Localized Peritonitis is of common occurrence. It is not characterized by any very evident symptoms beyond pain and tenderness at some point of the abdomen near the seat of the hernia. It is most commonly due to the condition of the gut when reduced, and is often conservative in character. Thus in a case in University College Hospital, in which the patient died six days after the operation from bronchitis and emphysema, the part of the intestine which had been nipped was found to be firmly adherent to the surrounding coils by recent inflammatory exudation. Opposite the seat of stricture was a small slough, about half an inch in diameter, affecting the whole thickness of the coats. It was already partly separated, and had the patient not died from other causes, would probably have been thrown off into the intestine, without fecal extravasation, owing to the firmness of the surrounding adhesions. The presence of the signs of local peritonitis are of importance only as indicating the necessity of avoiding purgatives or even enemata, until they have passed off. The patient must be kept slightly under the influence of opium to maintain rest of the inflamed bowel till all tenderness has disappeared.

Acute Catarrhal Inflammation of the mucous membrane of the intestines, or acute enteritis, occasionally follows the reduction of a hernia, and may prove fatal. In this condition there is profuse diarrhoea, commencing very soon after reduction. The stools are dark-colored from admixture of blood. At the same time there may be vomiting, the vomited matter also containing black shreds of altered blood. It is never stercoraceous. Unless relief be obtained, collapse soon sets in, the temperature becomes subnormal, the extremities become cold, and death soon follows.

The *Treatment* consists in the administration of morphia in repeated small doses, with the subnitrate of bismuth. No solid food must be allowed. Milk and soda-water, or barley-water, or carefully prepared chicken-broth may be given. Beef-tea is apt to increase the diarrhoea. Brandy is frequently of service, both as a stimulant and in arresting the diarrhoea.

Management of Congested Intestine.—The condition in which the contents of the sac are found in a case of hernia, determines greatly the course which the Surgeon should pursue after division of the stricture. Most frequently the intestine is deeply congested, being of a reddish-purple, a claret,

or chocolate color. This congested state must not be confounded with the gangrene of the part—a mistake which might happen if the surgeon content himself with judging of the condition of the bowel by its color. However dark this may be, the gut cannot be said to be gangrenous as long as it is polished and firm, free from putrescent odor, and without a greenish tinge. In cases in which there is much doubt as to whether its vitality is retained or not, it has been proposed to scurify its surface lightly with the point of a lancet. If blood flow from the punctures, this may be taken as a proof of the continuance of the vitality of the part. Such a procedure as this, however, is certainly attended by some degree of danger, and can seldom be required.

When the intestine is merely congested, however deeply, the rule is that it should be returned into the cavity of the abdomen in the hope of its ultimately recovering. This it will generally do if it have not been too much handled after the sac has been opened, but in some cases it will die a few days after it has been reduced, and, the feces being discharged through the wound, a fecal fistula will be formed; this may happen as late as the eighth or tenth day after the operation.

Management of Tightly Constricted Intestine.—When the intestine has been very tightly nipped by a sharp-edged structure, so that a deep scar or depression is left upon it, it seldom recovers, whether the whole of the coil of gut have been thus affected, or only a small portion of its diameter. It is remarkable how very quickly changes which are incompatible with life may ensue in a portion of gut that has been very tightly strangled. I have known a coil of intestine, that had been but eight hours strangled, and before the operation was performed, so tightly constricted as not to retain its vitality after reduction (Fig. 791). In such cases the patient usually

Fig. 791.—Gangrene of Intestine from Strangulation.

dies of peritonitis in the course of a few days without the bowels having assumed all peristaltic motion having necessarily been annihilated at the injured point. On examination after death, the constricted intestine will be found to present all the appearances of gangrene, being of a black or ash-gray color, and having any flocculi of lymph deposited upon its surface, though these may be so abundant in the neighboring parts. From the very unfavorable result of those cases in which there has been tight nipping of the protruded loop, a very cautious prognosis should be given, and, in reducing the gut after division of the structure, care should be taken not to push it far back into the abdomen, but to leave it near the inner ring, so

that, in the event of its ultimately giving way, there may be less need of feculent extravasation into the peritoneal cavity. In those cases in which the nipping has been very severe, the sulcus being distinctly marked in the intestine excessively dark and congested, though not actually gangrenous it would, I think, be better, after dividing the structure, to leave the gut on the side the ring than to return it; the reduction of intestine in this state is almost invariably followed by fatal peritonitis.

It is important to observe that it is not always possible to tell certainly whether the gut is past recovery or not, for intestine which has been severely

nipped may not be able to recover its vitality, and will fall into a state of gangrene after being reduced, and may not, at the time of its exposure, present the characters of putrescence; there is no fitor, no green or pulpy appearance, no loss of polish, no separation of peritoneum; it is simply of a dark purple or maroon color, and that it has been tightly nipped is evident from the sulcus upon it. There are no signs of gangrene, simply because sufficient time has not elapsed for putrefaction to set in. As, when a pile or navus has been tied, though vitality be extinct in the part, which is swollen and purple, some time must elapse before signs of putrescence manifest themselves, so it may be with a strictured gut which has lost its vitality.

Management of Gangrenous Intestine.—When the intestine is actually gangrenous, the integuments covering the tumor will be infiltrated, brawny, and dusky congested, and the structures immediately overlying the sac matted together; the sac will contain fetid, dark-colored serum or pus; and the softened, lacerable, or pulpy look of the protruded part, its loss of lustre, and peculiar greenish-black or dark-gray color, will cause the nature of the mischief to be readily recognized. In the majority of cases there will be much constitutional depression, and clammy skin, tympanitic abdomen, and brown or black tongue; but in some instances I have known all these symptoms to be absent, and the condition of the patient to present no very unfavorable state. Some difference of opinion exists as to the proper line of practice to be adopted in such cases. Travers and Lawrence seem to think that the division of the stricture is unnecessary, or may even be injurious; while Dupuytren, A. Cooper, and Key (with whom I concur) advise that it should be done; that the stricture should be divided in the usual way; that a free incision should then be made into the protruded portion of bowel, which must be left unreduced, so as to allow the escape of feces; and the wound left open and covered by a poultice. In this way, an artificial anus will necessarily be formed, through which the feculent matter finds exit. The gut in the vicinity of the stricture is retained *in situ* by masses of plastic exudation, which prevent the peritoneal cavity from being opened. If the intestine should already have given way before the operation is performed, the stricture must be divided, and the part then left unreduced, care being taken to interfere as little as possible with any adhesions or connections lying inside the neck of the sac; though I fully agree with Key, in thinking that the danger of disturbing them has been exaggerated.

When a small portion of the bowel only is gangrenous, the better plan is to return it just beyond the mouth of the sac, without laying it open; but it should not be pushed any distance into the cavity of the abdomen; the pressure of the surrounding parts will prevent extravasation. When the slough separates, it will probably be discharged into the cavity of the intestine; and the aperture resulting will be closed by the adhesions that extend between its margin and the abdominal wall.

During the last few years, the operation of removing the gangrenous portion of the gut and uniting the intestine by suture, originally performed by Dieffenbach, in 1836, has been revived and repeatedly performed by Billroth, Czerny, Juillard, Madelung, R. Parker, and others. Juillard, in 1882, published 44 cases, collected from various sources, in which this operation had been performed; of these, 23 died. These results contrast unfavorably with those of the same operation performed for the relief of an artificial anus or fecal fistula, of which Juillard records 23 cases with 8 deaths. He therefore recommends that in all cases the gut should first be treated as above described, and the attempt to unite the ends delayed for two or three weeks. By this time the patient, if he survive, will have gained strength; the fecal accumulation in the upper part of the gut will have been relieved, and the

operation will altogether be performed under more favorable circumstances. If the attempt to remove the gangrenous gut be made at the time of the operation for relief of strangulation, the condition of the surrounding parts is in many cases most unfavorable, diffuse inflammation often extending for many inches around the sac. Under such circumstances the removal of the gangrenous gut would evidently be out of the question. The operation will be described subsequently with removal of portions of the gut for other causes.

Management of Adhesions.—This varies according to the condition of the bowel, and the nature and situation of the bands. As has just been remarked, if gangrene be present, especial care must be taken not to disturb any connections that have been formed about the neck of the sac, and which constitute the most effectual barrier against feculent extravasation. When the adhesions are recent, consisting merely of plastic matter, in whatever situation they exist, they may readily be broken down with the finger or the handle of the scalpel, and the parts then returned. When of old standing and dense, they must be dealt with according to their connections. Most frequently these adhesions occur in the shape of thickened bands, situated within and stretching across the neck of the sac. In other cases, they may be found either as filamentous bands, or as broad attachments connecting the sac with its contents, and perhaps tying these together. When of a narrow and constricted form, and more particularly when seated in the neck of the sac, or stretching like bridles across its interior, they may readily be divided by a probe-pointed bistoury, or the hernia-knife. If they consist of broad attachments, they may be dissected away, by a little careful manipulation, from the parts in the inside of the sac; though, if the adhesions be very extensive and of old standing, it may sometimes be more prudent to dissect away that portion of the sac which is in connection with them, or even to leave them untouched, and the adherent intestine or omentum unreduced rather than to endeavor to separate them. They may, however, attach themselves in such situations that it becomes necessary to divide them; thus I have, in a case of congenital hernia, found it necessary to dissect away some very extensive and widely spread adhesions that had formed between the omentum and the testicle, and indeed had almost completely enveloped that organ.

Internal Adhesions between the omentum and intestine or mesentery occasionally exist, consisting usually of rather firm bands stretching across from one part to the other, sometimes connected with the inner wall of the sac, but in other cases confined to its contents. As these bands may constitute the real stricture, continuing to strangle the gut after the division of the structures outside and in the neck of the sac, they must necessarily be divided. This operation requires great care, lest the neighboring intestine be wounded. It is best done by passing a director underneath, and cutting the bands through with a probe-pointed bistoury; or if this cannot be done on account of their connections, they must be seized with forceps, and carefully dissected off the gut. In a case of large inguinal hernia, containing both gut and omentum, on which I operated some years ago, I found, after dividing the stricture, and taking hold of the omentum in order to push back the intestine, that this could not be reduced. On searching for the cause of difficulty, and drawing the mass well down, I found high up, in the part corresponding to the neck of the sac, a narrow band, like a piece of whipcord, stretching across from the omentum to the mesentery and firmly tying down the gut. On dissecting this carefully through, the constricted portion of intestine subjacent to it sprang up to its full diameter, and was then very readily reduced.

Management of Omentum.—The omentum may require to be treated in one of three ways: 1. It may be returned; 2. It may be left in the sac; 3. It may be cut off. The method of treatment must vary according to the state in which the omentum is found. If it be small in quantity, healthy in character though congested, and apparently recently protruded, not having undergone those changes that occur in it when it has been a long time in a hernial sac, it should be reduced after the intestine has been put back.

If, however, its mass be very large, if it be hypertrophied, indurated, or otherwise altered in structure, or if it be closely adherent to the sac, at the same time that it is congested, Surgeons are agreed that it should not be returned into the abdominal cavity; as inflammation of it, *Epiploitis*, will probably set in and terminate fatally with effusion into the peritoneal sac. So also, if the omentum be in large quantity, and have become inflamed in the sac, it should not be returned; as the inflammation in it is very apt to run on to a kind of sloughy condition of the whole mass. If gangrenous, it should certainly not be reduced. When simply hypertrophied and adherent to the sac, but without evidence of inflammation, it may be left in the sac; but, in many of the cases of hypertrophied, and in all cases of inflamed or gangrenous omentum, the best practice consists in cutting off the mass, as recommended by Sir A. Cooper and Lawrence. If it be left in the sac, inflammation or sloughing of it will occur, and the patient can derive no corresponding advantage to the danger he will consequently run. *Excision* of the mass may be best done by enclosing the neck in a ligature and then cutting it off below this. The ligature may be of carbolized catgut or fine carbolized silk. If the mass be large it is better to divide it into several pieces, and to tie each separately. The ligatures are then cut short and allowed to retract with the stump of the omentum into the abdomen. If the omentum has suffered much from the strangulation, it must be drawn well down, so that the ligatures may be applied to a healthy part. If carbolized catgut or silk be not at hand, a strong double ligature of whipcord or silk must be passed through the neck and tied securely on each side, the mass below then being cut off. As a ligature of this kind might become a source of irritation if it were drawn into the peritoneal cavity, it must not be cut short, and its ends may be secured to a piece of plaster on the forepart of the abdomen, to prevent retraction of the stump of the omentum. I have frequently employed this plan with excellent effect. The constricted stump of omentum sloughs away in a few days, and separates with the ligature. When this practice is adopted, the wound should not be closed, and must be lightly dressed. The quantity of omentum that is cut off varies considerably; the mass removed usually weighs from four to six ounces, but in some instances it may amount to a pound or more.

Sacs or Apertures are occasionally formed in the omentum, in which a knuckle of intestine may become enveloped, or by the margins of which it may be strangulated. These envelopes of omentum around the gut, which have been especially described by Sir P. Hewett, may occur in all kinds of hernia, at least in the inguinal, the femoral, and the umbilical, and sometimes acquire a large size, completely shutting in the gut. They appear to be formed, in some cases at least, by the adhesion of the opposite edges of floating layers of omentum around a piece of intestine, which thus becomes included. It is of importance to bear in mind the possibility of their existence, and in all cases to unravel the omentum before removing it, lest it contain a knuckle of intestine, which might be wounded in the operation.

Cysts, usually containing pellucid serous fluid, straw-colored or reddened, but sometimes filled with blood, are occasionally met with in the omentum. They appear to be formed in the same way as the sacs containing intestine

just described, except that they are enclosed on all sides, their contents being merely exudations from the peritoneal lining of the cyst. They are globular, elastic, and closely resemble in form a knuckle of intestine, occasioning not a little embarrassment to the Surgeon; by a careful incision and unravelling, however, of the omentum, their true nature will be made out; their fluid contents may then be discharged, and the cyst is dealt with according to the rules already given.

Wounds of the Intestine may accidentally occur at two periods of the operation; either from the Surgeon cutting too freely down upon the sac and opening this before he is aware of what he is about; or else, at the time of the division of the stricture, from a portion of the gut which lies beneath getting into the way of the edge of the knife, and being nicked by it. The first kind of accident can happen only from a certain degree of carelessness, but it is not always so easy to avoid wounding the gut, when the stricture is so tight that the finger-nail cannot be slipped under it as a guide to the finger-knife. In cases of this kind, a very narrow director must be used, and this is a most dangerous instrument, as, in passing it deeply out from under the tight stricture, a small portion of the gut may curl up over the edge into the groove, and thus become notched by the knife as this is sliding it. This accident has happened to the best and most careful Surgeons. Lawrence relates two cases that occurred to him; and Sir A. Cooper, Chas. Jobert, and Liston, have all met with it. It may be known to have occurred by the bubbling up of a small quantity of flatus and liquid from the bottom of the incision. The *Treatment* of a wound of the gut must depend upon its size. When it is very small, resembling a puncture rather than a cut, the practice recommended by Sir A. Cooper should be adopted, viz. to seize the margins of the incision with a pair of forceps, and to tie a thread tightly around them, the ends of which should then be cut off, and the gut returned into the abdominal cavity. Such a proceeding as this should appear to give rise to much, if to any, increase of danger. In a case that occurred to me many years ago at the Hospital, in which, owing to the excessive tightness of the stricture, a very narrow director only could be passed under it, the gut immediately above it was notched and opened in a kind of punctured wound; this was tied up in the way mentioned, and yet the death of the patient, which took place on the fourth day after the operation from gangrene of the strangulated portion of bowel, the silk upon was found to be completely enveloped in a mass of firm plastic exudation. If the wound be of larger size, it must be closed by Lambert's suture in the manner described in the chapter on Wounds of the Intestine, p. 562, &c. The gut must be very carefully cleaned with some antiseptic solution, and being returned.

Wound of one of the Arteries in the neighborhood of the sac may occur during the division of the stricture, either in consequence of some accident in the distribution of the vessel, or from the Surgeon dividing the parts in a wrong direction. This accident usually happens to the epigastric or the obturator artery; and Lawrence has collected fourteen recorded cases in which it occurred. The result in these has been very various, in some the patients have died; in others, after much loss of blood, and consequent faintness, the bleeding ceased spontaneously. The proper *Treatment* will certainly consist in cutting down upon and securing the bleeding vessel. In the event of the Surgeon operating on a case of hernia, without having been able previously to satisfy himself as to its precise character, or if from any cause, in dividing the stricture, he have reason to dread the proximity of an artery, he may safely and readily divide the constriction with a knife, and would not easily cut an artery; and he will find, if he blunt the edge of the

hernia-knife by drawing it over the back of the scalpel, that it will still be keen enough to relieve the strangulation, whilst it will push before it any artery that may happen to be in the way.

Sloughing of the Sac is of rare occurrence, and, when it happens, is commonly attended by fatal results; it is not, however, necessarily so. It has twice happened in my practice; and in both cases the patient recovered. In an old woman on whom I operated for femoral hernia of very large size, the sac sloughed away, exposing nearly the whole of Scarpa's triangle with almost as much distinctness as if it had been dissected; but, although in much danger for a time from an acute attack of peritonitis, she ultimately recovered.

Artificial Anus and Fecal Fistula.—When an aperture exists in the bowel by which the whole of the intestinal contents escape externally, the condition is denominated an *artificial anus*. When but a small portion so escapes, the greater part finding its way through the natural anus, a *fecal fistula* is said to exist. The quantity of feculent discharge necessarily depends upon the extent of the destruction of the intestinal coats; and its character on the part of the gut that is injured. The escape takes place involuntarily, and is usually continuous.

This condition may occur in several ways. Thus the gut may be accidentally wounded during the operation, and the feces may afterwards continue to be discharged through the aperture so made; or it may have been gangrenous, and have given way into the sac before the operation; or the Surgeon may have intentionally laid open a gangrenous portion of intestine, so as to facilitate the escape of the feces. In some cases in which the bowel has been severely nipped, and is dark and congested, though it have not actually fallen into a state of gangrene, it may not be able to recover itself after its return into the abdominal cavity, but will give way in the course of three, four, six, or even ten days after the operation. In these cases, a small quantity of feculent matter is first observed in the dressings; and gradually a greater discharge appears, until at last the fistulous opening is completely established. In such cases, it is of importance to observe that, although the bowel gives way within the peritoneal cavity, the feces do not become extravasated into this, but escape externally. This important circumstance is owing to the fact of the portion of the bowel that is nipped losing its peristaltic action, and consequently remaining where it is put back; whilst the parts in the neighborhood inflame, throw out a coagulable exudation, and become consolidated to each other and to the parietal peritoneum, so as to include the gangrenous portion of the gut, and completely to circumscribe it. It is consequently of great importance, in cases of this kind, not in any way to disturb the adhesions that have formed between the sides of the aperture in the gut and the neck of the sac.

The *Pathology of Artificial Anus* is commonly as follows: The edges of the aperture in the gut become firmly adherent to the abdominal wall; and whether the whole or a portion only of the calibre of the intestine be destroyed, the apertures of the upper and lower end, though at first lying almost in a continuous line, soon unite at a more or less acute angle. These are at first similar in size, and present no material differences in shape or appearance: as the disease becomes more chronic, they gradually alter in their characters; the lower aperture, being no longer used for the transmission of feces, gradually becomes narrower, until at last it may be almost completely obliterated; whilst the upper portion of intestine becomes dilated in consequence of there being usually some slight obstruction to the outward passage of the feces. The mesenteric portion, opposite the aperture, becomes drawn out into a kind of prolongation or spur, the full importance of which was first

pointed out by Dupuytren. This spur-like process projects between the two apertures, and, being deflected by the passage of the feces, has at last a tendency to act as a kind of valve, and thus to occlude the orifice into the upper portion of the gut. The integuments in the neighborhood of such an aperture as this usually become irritated, inflamed, and excoriated, from the constant passage of the feces over them. In some cases, the mucous membrane along the edges becomes everted, and pouting; and, in others, a true prolapse of the gut takes place, large portions protruding. An artificial anus thus formed in this way never undergoes spontaneous cure. Besides this variety is the ordinary form of artificial anus, we must, I think, recognize at least two other varieties, both of which I have met in practice. In one of these, the angle formed by the gut is adherent to the upper extremity of the sac which has been returned, and thus lies at some distance from the external orifice, so that the fecal matter traverses a long canal before it reaches the external aperture. In the other variety the angle of the gut is fixed at a higher point within the abdomen, and the feces find their way out through a channel bounded by agglutinated coils of intestine and layers of lymph. In both of these forms, there is a considerable distance between the external opening and the aperture in the gut. Thus, then, there are three forms of artificial anus, differing from one another according to the situation of the angle of the gut in relation to the external opening and to its connections.

When a *Fecal Fistula* has formed, the condition of the parts is somewhat different. The aperture in the intestine consists of merely a small perforation in its coats, unattended by any considerable loss of substance, through which a quantity of thin feculent matter exudes, giving rise to a good deal of irritation of neighboring structures. In some cases, there are several apertures communicating with the gut, and extending through the skin. *Fistulous* openings of this kind not unfrequently undergo spontaneous cure after existing for a few weeks or months.

Treatment.—If the aperture be merely a small one, with a narrow fistula leading into the gut, the chief inconvenience suffered by the patient then arises from the irritation of the skin around the opening by the continued moisture of the feculent matter. In such cases the skin should be protected by means of zinc ointment or eucalyptus oil and vaseline spread on lint, and the patient should wear a pad to restrain the discharge. By the pressure of this pad the aperture may sometimes be made to close. In other cases, the occasional application of the galvanic cautery or of a red-hot wire will induce contraction of its edges; and in other instances, again, a plastic operation of some kind may be required. But I confess I have not usually seen much advantage result from such operations, which are often followed by erysipelas. As the existence of an artificial anus, by interfering with nutrition, constantly gives rise to considerable emaciation, it becomes necessary to support the patient's strength by a sufficient quantity of good and nourishing food. This is of greater consequence the higher the fistula is, as the interference with the earlier stages of the digestive process, and the loss of nutritive material, by the discharge of the chyme, is proportionately great. Spontaneous cure will occasionally take place, even though a perfect artificial anus exist. In a case under my care at the Hospital, a whole knuckle of intestine was gangrenous, and sloughed away, leaving an artificial anus, which discharged the greater part of the intestinal contents, but gradually contracted and closed without any local application or treatment beyond attention to cleanliness.

If the aperture become a permanent artificial anus, surgical means must be adopted in order, if possible, to effect a cure. Many plans have been suggested for effecting this object, the two most important being Dupuytren's operation and suture of the gut, with or without removal of a portion.

In Dupuytren's operation two important indications have to be fulfilled: the first is to diminish or destroy the projecting valvular or spur-like process, and thus to reestablish the continuity of the canal; and, after this has been done, the external wound may be closed, by paring its edges, and bringing them together with harelip pins.

The first object is best accomplished by Dupuytren's *enterotome* (Fig. 792); this consists of an instrument something like a pair of scissors, with blunt but serrated blades, which may be brought together by acting upon a screw that

Fig. 792.—Dupuytren's Enterotome.

Fig. 793.—Enterotome Applied.

traverses its handle. One blade of the instrument (*a*) is passed into the upper, the other *b*, into the lower portion of the intestine; they are then approximated slowly, and fixed by means of the screw in such a way as to compress on each side the spur-like process (Fig. 793). Very gradually, day by day, this screw is tightened so as to induce sloughing of this projection, and cohesion of its serous surfaces. As this process goes on, the irritation caused by the instrument will occasion inflammatory exudation in the angle formed by the intestine, so that the peritoneum and mesentery become consolidated, and all opening into the peritoneal cavity is avoided. Should the spur-like process be accidentally cut through before the lymph is thrown out in sufficient quantity, the peritoneum would be opened, and death would probably ensue; hence the necessity for caution in this procedure. So soon as the blades of the instrument have come into contact, and the spur-like process has consequently sloughed away, the great obstacle to the closure of the artificial anus will be removed; and the continuity of the canal being thus reestablished, the lips of the external opening may be pared and brought together by harelip pins and sutures. In some cases, from the length of time that has elapsed—many years, possibly—the fistula continues permanently patent, and no treatment is available for its closure. Its existence is not incompatible with good general health. I have had two cases under my constant observation, in one of which, that of a woman about fifty years of age, the whole of the intestinal contents have been discharged for four years through an aperture of the umbilicus, in consequence of the sloughing away of a large coil of intestine in an umbilical hernia; the other being that of a lady more than eighty, who has for upwards of thirty years had a fecal fistula in the right groin, consequent on an operation for femoral hernia.

In the second method of operating adopted by Dittel, Billroth, Czerny, and many other continental Surgeons, the gut is freely exposed and dissected

away from its adhesions to the abdominal wall. This must be done with antiseptic precautions. The bowels must have been thoroughly washed before the operation is commenced. The external opening must be carefully cleaned with some efficient antiseptic, and unhealthy granulation tissue must be scraped away with a sharp spoon. The orifice of the gut must also be cleansed, and a small piece of sponge, which has been properly disinfected by carbolic lotion, may be pushed into the upper orifice to prevent the escape of any fecal matter. The opening through which the gut protrudes must then be enlarged by an incision carried in the most convenient plane, and the gut dissected away and drawn out. If the opening is small, and only, and very small, it may be closed by sutures; if large, the whole abdominal portion of the gut is cut away. The details of this operation are described later on, as they are identical with those practised in the removal of portions of intestine for other causes. As before stated, the death rate in the published cases in which this operation has been performed is one in four; so it must not be lightly undertaken. If the patient suffers merely from a fecal fistula, which can be easily controlled by a pad, it would evidently be unjustifiable to submit him to the risk of such an operation. If, however, the patient is otherwise in good health, but suffering great inconvenience from the artificial anus, and other means have failed, the operation is at least a fair prospect of relief and may be undertaken.

OPERATION WITHOUT OPENING THE SAC.—The possibility of removing the stricture in strangulated hernia without laying the sac open, naturally suggested itself when it was known that in many cases the stricture was seated in the tendinous and areolar tissues outside the neck of the sac; so that, when these were divided, the protrusion was readily reduced. The operation was performed by Petit as long ago as 1718, but was seldom practised until it was revived of late years by Aston Key and Luke. The great advantage sought to be gained by this operation is that, as the peritoneum is not interfered with, nor its cavity opened, the risk from peritonitis is proportionately lessened. The wound made by the operation being almost superficial, and the sac not opened, its risk has been compared to that of a taxis, with the addition of that which would result from a superficial laceration. This argument would be conclusive in favor of the operation without opening the sac, if it could be shown that, in all cases of strangulation, peritonitis is occasioned by interfering with the peritoneal cavity; it can, however, be admitted, even by the keenest advocates of Petit's operation, that this is not the case. It has before been pointed out that, in a considerable proportion of cases, the inflammation of the peritoneum starts from an injured portion of gut, and is not the consequence of septic processes originating from the wound, or of septic matter introduced by the fingers of the Surgeon. The former causes will come into play whether the sac be opened or not, and the latter are so far controlled by the modern improvements in the treatment of wounds, that a wound of the peritoneum is now robbed of most of its dangers.

There can be no doubt, from the experience of former times, that an opening into the cavity of the abdomen made without antiseptic precautions is attended by some danger of setting up peritonitis or aggravating any that may exist at the time. It is equally certain that, with no precautions at all, may occasionally fail in preventing sepsis in a wound seated so near to genital organs, as the dressings may accidentally be soiled with urine or displaced by the movements of the patient. The arguments, therefore, in favor of Petit's operation, founded on its reducing the risk of peritonitis, cannot be said to be completely invalidated by the general use of antiseptics.

There are, however, two objections that may be urged against Petit's

operation with more justice than that it does not prevent the occurrence of peritonitis. The first is, that, if the intestine be not seen, it may sometimes be returned in a gangrenous condition; and, the second, that the gut may possibly be returned still strangled by bands of adhesion, or by inclusion in an omental aperture. With regard to the first objection, it may be stated that if the intestine be in a gangrenous state, there will usually be some evidence of this, either in the change that has taken place in the general symptoms of the patient, or in the condition of the sac and its coverings, which will enable the Surgeon to guess at the condition of the enclosed parts, and will, of course, induce him to expose them fully and examine them thoroughly. This objection, however, cannot apply to those cases in which the strangulation has existed only for a time that would be insufficient to allow the occurrence of gangrene, and does not, therefore, oppose the performance of Petit's operation in recent cases of strangulation. With regard to the occurrence of internal strangulation, it is excessively rare, and when it does occur, it still more rarely happens, whether the strangulation be effected by bands of adhesion or by an aperture in the omentum, that the parts can be returned without opening the sac, adhesions usually existing also between this structure and its contents. But the best answer to the objections against the operation without opening the sac, are the results that have followed this practice. Luke, who has had great experience on this subject, states that he has operated in 84 cases of hernia. In 25 of these the sac was opened; in 59 the sac remained unopened. Of the 25 in which it was opened, 8 died; whilst, of the 59 in which Petit's operation was performed, only 7 died. If to Luke's cases we add those reported by N. Ward, we shall find 36 deaths in 153 cases of Petit's operation. That the ordinary operation, indeed, of opening the sac is an exceedingly fatal one, is well known to all hospital Surgeons, and is fully proved by surgical statistics. Of 77 operations for hernia, reported by Sir A. Cooper, 36 proved fatal; and of 545 cases recorded in the journals, and collected by Turner, 260 are reported to have died. The result, therefore, of Luke's operations is very favorable, when contrasted with those in which the sac was opened, but it must not be assumed that the entire difference is due to the sac not being opened, for every serious complication of hernia, such as gangrene of the gut, prolonged strangulation, reduction in mass, etc., necessitates the opening of the sac.

The operation without opening the sac may be practised in all forms of hernia, but is much more readily done in some varieties of the disease than in others. It is especially applicable in cases of femoral hernia, in which the stricture is commonly outside the sac, as will be mentioned when speaking of that form of the disease. Of 31 cases of femoral hernia, operated on by Luke, the sac required opening in 7 only. In inguinal hernia it is not so easy to perform Petit's operation; indeed, in the majority of cases the Surgeon will fail to remove the stricture in this way. This is owing to the constriction being usually seated in the neck of the sac, as is especially observable in congenital hernia. Of 29 inguinal herniæ operated on by Luke, the sac required opening in 13 instances.

For the various reasons that have been mentioned, I am decidedly of opinion that this operation should always be attempted, in preference to the ordinary one of opening the sac, in those cases in which the hernia, not having been long strangulated, presents no sign of the occurrence of gangrene in it, and more especially when it is femoral or umbilical. Even if the Surgeon fail in completing Petit's operation, in consequence of the existence of a stricture in the neck of the sack, or the constriction of this part, no harm can have resulted; for the sac, after being exposed, may at any time be

opened in the ordinary way, and the operation completed by dividing the stricture from within.

When the hernia is of large size and irreducible, it is of especial importance to avoid opening the sac. If it be opened, the contents will adhere, and fatal peritonitis commonly ensues. In these cases, as Luke has pointed out, it rarely happens that the old inherent parts are seriously strangled, but the whole mischief seems to be occasioned and the injury to be received by the new protrusion that has taken place, and that gives rise to the tension; and if this can be liberated and reduced, the Surgeon has done all that need be accomplished. The evidence of the reduction of the tumor protrusion, although the old adherent and irreducible hernia be left, is usually sufficiently obvious; the portion of gut returning with a slight gurgle, with considerable diminution in the general tension of the tumor.

Operation.—With regard to the mode of performing Petit's operation little need be said here, as it is precisely identical with the steps of the other operation up to the period of the exposure of the sac, except that, when it is not intended to open this, the incision should be placed more directly over its neck. The stricture, if situated outside the sac, will then be found either in some of the tendinous structures surrounding it, or else in the subserous areolar tissue lying upon it. After the division of the constricting bands in this situation, by means of a probe-pointed knife carried underneath them, or by dissecting down upon them, an attempt at taxis may be made by compressing the tumor in the usual way, at the same time that the neck is stretched by the fingers of the left hand. If the contents can be reduced, the incision in the superficial structures is brought together and dressed as already described (p. 767). Should peritonitis come on, as the result of the strangulation, it must be treated in the usual way. If after the Surgeon has fairly divided all the structures outside the sac he still finds that the return of the hernia is prevented by some constriction at the neck, it will be necessary to lay this open and divide the constriction in the usual way.

Reduction in Mass.—The reduction of the hernia in mass consists in the return of the sac and its contents into the abdomen still in a state of strangulation. When it is said that the parts are returned into the abdomen, it must not be understood that they are pushed back into its cavity, but that the external protrusion is caused to disappear by being pushed into the subserous areolar tissue behind and underneath the parietal peritoneum between it and the abdominal muscles. This remarkable accident, which was first described by the French Surgeons of the last century, received but little notice from practitioners in this country until attention was drawn to it by Luke, by whom its pathology has been carefully studied. Birkett, who has also investigated this condition with much care, is of opinion that the sac is not torn from its connections in the scrotum or canal, and pushed back, but that it is ruptured, usually at its posterior part at its neck, and that the contents of the sac are forced through this rent into the subperitoneal tissue; whilst the mouth of the sac, still constricting the hernia, and thus keeping it in a state of strangulation, is pushed back from the interior of the abdomen. It appears to me that both explanations are correct, and that we must admit two forms of reduction in mass; the sac being pushed back intact in a state of strangulation, in one form, as described by Luke; whilst in the other, as observed by Birkett, the sac is ruptured, and the hernia, strangulated by the displaced mouth of the sac, is forced out through the rent.

Cause.—The reduction in mass has been far more frequently observed in cases of inguinal than in those of any of the other varieties of hernia. It has been met with in femoral hernia, but very rarely, and, so far as I know,

not in any other form of the disease. This comparative frequency of its occurrence in inguinal hernie is doubtless due to their large size, and loose areolar connections. The accident has more often occurred from the patient's own efforts at reducing strangulated hernia, than from those of the Surgeon. It is a remarkable fact that, in most of the instances in which it has occurred, only a very slight degree of force appears to have been employed in the reduction of the tumor; and the accident would seem to have resulted from the adhesions between the sac and the neighboring parts being much weaker than natural, so that a moderate degree of force caused the whole to slip through the canal. It may, however, occur from the Surgeon's efforts, if these be too forcible or long continued.

Symptoms.—The symptoms indicative of this accident are constitutional and local. The constitutional symptoms consist in a continuance of those that are indicative of the existence of strangulation, notwithstanding the disappearance of the tumor. The vomiting and constipation persisting, the patient speedily becomes much depressed in strength, being seized with hiccup and prostration of all vital power; signs of gangrene then evince themselves within the sac; and death ensues.

An examination of the parts in hernia will usually enable the Surgeon to recognize the nature of the accident; he will ascertain that a tumor had previously existed, and will learn from a description of its general characters, and the symptoms occasioned by it, that it was in all probability a strangulated rupture. He will then find, on examining the part, that there is a total absence of all that fulness which is occasioned by the presence of the sac, even after its contents only have been reduced; the sac, in such cases, always giving rise to a feeling of fulness and roundness in the part. He will, on the contrary, find that the abdominal ring is peculiarly and very distinctly open; it is much larger than usual, and somewhat rounded. On pushing the finger into the canal, this will be found quite empty; but in some cases, on deep pressure with the finger, especially when the patient stands up or coughs, a rounded tumor may be indistinctly felt behind the ordinary seat of the hernia. In many cases, however, the most careful manual examination will fail to detect any prominence of this kind.

Treatment.—If, after careful examination of such a case as this, in which the symptoms of strangulation continue, the Surgeon learn by the previous history that a tumor has existed, but that it has suddenly gone up; and further, if he find that the seat of the supposed hernia presents the negative evidence that has just been described, it will then be necessary for him to push his inquiries a step further by an exploratory incision. Such an incision as this may first be used as a simple means of diagnosis, and, as it does not penetrate the peritoneal cavity, there is no danger attending it; and if the hernia be found, it will serve the purpose of the ordinary incision required in the operation, and may be used for the relief of the strangulation. The first incision should be made so as to expose the abdominal ring; if this be found peculiarly round and open, it would increase the probability of the existence of the condition sought for. The inguinal canal must next be laid open, and the parts contained within it carefully examined. If no appearance of hernial sac be found, but the cord be distinctly and clearly seen, still further presumptive evidence will be afforded of the reduction having been effected in mass; for, if the hernia have been put back in the usual way, the sac will necessarily be left in the canal, and will preserve its usual relations to the cord. This supposition will be strengthened almost to a certainty if it be found that the "condensed cellular capsule immediately investing the sac," as it is termed by Luke—in other words, the condensed and laminated subserous areolar tissue—has been left in the canal. An

opening made into this will, as that Surgeon observes, allow the finger to be brought into contact with the hernial tumor itself. Should, however, no condensed areolar tissue not be found, it must not be considered that a hernia is present, inasmuch as this investment may have been absent. The finger should then be passed into the internal ring, where it probably be found open, and should be carried from side to side, the finger if present, will be detected lying externally to the peritoneum behind the abdominal wall. When found, it must be brought down into the cavity, enlarging the ring; it must then be opened, its contents examined, and the stricture in its neck divided. The intestine that has been so strangled must be dealt with in accordance with the rules already laid down. If the tumor cannot be readily brought down so as to admit of an examination of its contents, the patient should be desired to make some propulsive efforts so as to cause it to protrude. If it still do not come down it must be opened, and the stricture cautiously divided within the abdomen with a rhinotomy bistoury.

Treatment of Strangulated Hernia by Aspiration.—This operation, in which it is attempted to render a strangulated hernia reducible by withdrawing its gaseous and fluid contents by means of the pneumatic aspirator, was introduced into practice by Dieulafoy, and is thus performed: An aspirator of the form represented in Fig. 93, page 254, vol. i., is to be preferred, and the needle must not exceed $\frac{3}{8}$ inch in diameter. The aspirator having been proved to be in working order, and the needle clear, a vacuum is made by withdrawing the piston. A few drops of water may be left in the bottom of the cylinder, so that gas may be recognized as soon as it enters. The needle is now introduced into that part of the tumor, where, from resistance or percussion, or elastic feel, the gut is supposed to lie, and as soon as it is covered the vacuum is turned on. The needle must now be exerted and steadily pushed onwards. If there be fluid in the sac this will rise into the syringe, and as soon as it ceases to flow, the needle must be again cautiously pushed onwards, until, from the appearance of gas or fecal matter in the syringe, it is known that the gut is reached. The needle must be held steadily and pushed in one direction only, as any lateral movement would tend to scratch or tear the gut. The gas may be sufficient in quantity to fill the vacuum, and if this occur, the cock must be turned the other way, emptied, and a fresh vacuum made. If one puncture fails to draw out the bulk of the tumor, the needle must be withdrawn and inserted at a new spot, and this may be repeated two or three times. If the needle becomes plugged, it is better to abandon the operation at once, as further attempts would probably meet with no better success. After the operation has been formed. Aspiration has been performed sufficiently often to show that needles of the proper size be used carefully, it is almost, if not altogether, innocuous. Dieulafoy records 27 cases, 20 of which were successful, reduction of the gut by taxis following the operation. In the remainder, 7 were harmless, and of these 3 died and 4 recovered, after the ordinary operation for hernia. Other Surgeons have not succeeded in obtaining satisfactory results. At University College Hospital aspiration has been performed 11 times. In 1 case only was it followed by reduction; in 1 the fluid was drawn out only was withdrawn, yet the impulse returned and the patient required the ordinary operation was performed in 3 cases successfully. In the last two days after the operation the punctures could not be found at the post-mortem examination. In the remaining case the patient was in a very bad state at the time, and died a few minutes after the operation. At the post-mortem

no gas or fluid could be squeezed from the punctures in the gut. It seems, therefore, that the danger of fecal extravasation is very small, although it is said to have occurred. The operation may fairly be tried in suitable cases, especially when the hernia is very large and resonant on percussion, and only recently strangulated. It would be unwise to attempt it when from the duration of the strangulation inflammation or gangrene of the gut might be suspected.

CHAPTER LXII.

SPECIAL HERNIÆ.

INGUINAL HERNIA.

By **Inguinal Hernia** is meant that protrusion which occupies the whole or a portion of the inguinal canal, and when fully formed, passes out of the external abdominal ring into the scrotum. Many varieties of this hernia are recognized by Surgeons. Thus it is said to be *Complete*, when it passes out of the external ring; *Incomplete*, or *Interstital*, so long as it is contained within the canal; *Oblique*, when it occupies the whole course of the canal; *Direct*, when it passes forwards through a limited extent of it; *Congenital*, when it descends through an unobliterated processus vaginalis and lies in the sac of the tunica vaginalis; and *Encysted*, or *Infantile*, when it lies behind this. Inguinal herniæ constitute the commonest species of rupture, and would be much more frequent than they are, were it not for the obliquity of the canal, and the manner in which its sides are applied to one another, and closely overlap the spermatic cord. They occur with most readiness in those cases in which the canal is short and the apertures wide. Although these herniæ are commonly incomplete in their early stages, it is seldom that they come under the observation of the Surgeon until the protrusion has passed beyond the abdominal ring.

OBLIQUE INGUINAL HERNIA, often called *Ex'ternal*, on account of its relation to the epigastric artery, passes through the whole length of the canal, from one ring to the other; and usually protrudes through the external one, constituting one of the forms of **Scrotal Hernia**.

Coverings.—As it passes along the canal, it necessarily receives the same investments that the spermatic cord does; although these are often greatly modified by being elongated, hypertrophied, and otherwise altered in appearance. If we regard the inguinal canal as consisting of a series of protrusions of the different layers of the abdominal parietes, the outermost being the skin, and the innermost the fascia transversalis, with the peritoneum applied to this, it is easy to understand how the hernia in its descent has these prolongations drawn over it, thus becoming successively invested with the same coverings as the spermatic cord. Thus it first pushes before it that portion of the peritoneum which lies in a fossa just external to the epigastric vessels; it next receives an investment from the subperitoneal fat, which, uniting with the fascia transversalis, constitutes the *fascia propria* of the sac; as it passes under the internal oblique, it receives some of the fibres of this

muscle, in the shape of the cremasteric fascia; and, lastly, when it reaches the external abdominal ring, which it greatly distends and renders tense, and open, it becomes covered by the intercolumnar fascia receiving as a partial investment around its neck from some of the expanded and thinned fibrous bands that lie near the ring, and which are always most dense upon its outer side.

Relations.—The relations of the spermatic cord and testes, and of the epigastric artery, to an inguinal hernia, are of great importance. The spermatic cord will almost invariably be found to be situated behind or rather underneath the oblique inguinal hernia; and the testis will be found there at its lower and back part, where it may always be distinctly felt. In some cases the elements of the spermatic cord become separated, the vas deferens lying on one side, and the spermatic vessels on the other. In other cases, an instance of which there is in a preparation in the University College Museum, the hernia lies behind the cord and has the testis in front. In other cases, again, it may happen that the elements of the cord are accurately spread out on the forepart of the hernial tumor. The epigastric artery has the same relations to the oblique inguinal hernia that it has to the spermatic cord, lying to the inner side of and behind its neck. The present large and old inguinal hernia has, however, a tendency to modify somewhat the relations of this vessel. By distending the rings, and dragging the posterior wall downwards and inwards, they shorten the canal, and cause a great deflection of the artery from its natural course, which is changed from an oblique direction to one curved downwards and inwards, under the outer edge of the rectus muscle.

DIRECT INGUINAL HERNIA.—This does not pass out like the oblique through the internal abdominal ring, but pushes forwards through a triangular space, which is bounded by the epigastric artery on the outer side, the edge of the rectus on the inner, and the crural arch at its base; through this the hernial tumor protrudes, pushing before it or rupturing the posterior wall of the inguinal canal.

Coverings.—These vary according to the length of the canal that the hernia traverses, and the portion of the posterior wall through which it protrudes. In fact, there are at least two distinct forms of direct inguinal hernia, which differ according as they are situated internal or external to the obliterated hypogastric artery. One, the most common variety, is situated internal to the cord like remains of this vessel, between it and the outer edge of the rectus. The other, which is of less frequent occurrence, is situated outside this vessel, between it and the epigastric artery.

In that form of direct inguinal hernia, which lies internal to the hypogastric artery, the protrusion takes place through that part of the posterior wall of the inguinal canal which is situated almost behind and opposite to the external ring. In this situation, the investments successively received by the hernia are, first, the peritoneum, the subperitoneal fat, and the fascia transversalis; it then comes into contact with the compound tendons of the external oblique and transversalis muscles, which it may either rupture or, before it, thinned out and expanded. Most frequently these are ruptured, constituting a partial investment to the protrusion, which is most evident in the innermost part of the sac, that which is nearest the mesial line. As the hernia passes through the external abdominal ring, it receives from it the intercolumnar fascia and fibres, and lastly is invested by the common fascia and integuments.

In the rare form of direct inguinal hernia which lies external to the hypogastric artery, the protrusion may pass under the lower ledge of the internal oblique muscle, and then receive a partial investment of cremasteric fascia, and

cially on its iliac side, as it comes into relation with the internal oblique. This form of direct inguinal hernia, therefore, receives very nearly the same covering that the oblique does, though its investment by the cremaster is not so perfect. It does not come into relation with the conjoined tendons.

Relations.—In the direct inguinal hernia, the *spermatic cord* lies to the outer side of the sac; and its elements are never separated from one another, as occasionally happens in the oblique. The *epigastric artery* also is on the outer side, but usually arches very distinctly over the neck of the sac, sometimes, indeed, completely encircling the upper as well as the outer margin (Fig. 794).

INCOMPLETE OR INTERSTITIAL HERNIA is usually of the oblique kind; but Lawrence has observed that it may be of the direct variety. It often escapes notice, but may not unfrequently be observed on the opposite side to an ordinary inguinal hernia.

Double Inguinal Herniæ, on opposite sides, are of very common occurrence, and they may be of the same, or assume different forms. In some instances, the two forms may be observed on the same side (Fig. 795).

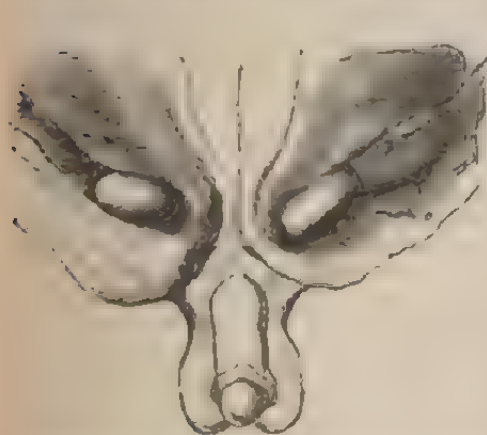

Fig. 794. —Double Direct Inguinal Hernia, Neck of Sac crossed by Epigastric Artery.

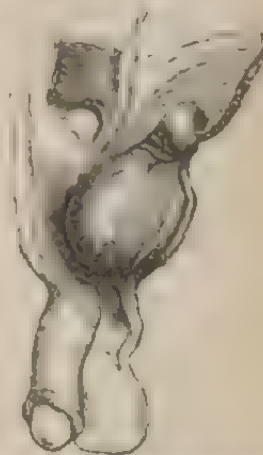

Fig. 795. Double Inguinal Hernia on the same side; Oblique above, Direct below; separated by Epigastric Vessels.

In females, inguinal herniæ are much less frequent than in males. They may occur at all ages, but seldom come under the notice of the Surgeon except at advanced periods of life. They have the same relations as in the male, except that the round ligament is substituted for the spermatic cord.

Signs.—The signs of inguinal hernia vary somewhat according to its character, whether interstitial, complete or serotal, oblique or direct. In the *interstitial hernia*, a degree of fulness will be perceived in the canal when the patient stands or coughs; and, on pressing the finger on the internal ring, or passing it up into the external ring, and directing the patient to cough, a distinct impulse, together with tumor, may be felt. In the ordinary *oblique inguinal hernia*, a tumor of an oblong or oval shape, oblique in its direction, taking the course of the canal downwards and forwards, will be felt protruding through the external abdominal ring, and presenting all the usual signs of a hernia. So long as it is confined to the neighborhood of the

pubes, it is of moderate size; but, when once it enters the scrotum, where it meets with less resistance, it may gradually enlarge until it attains an enormous bulk. The testicle, however, may always be felt tolerably distinct at its posterior interior part. In women, this form of hernia descends into the labium, but never attains the same magnitude as in man. When of large size, these ruptures usually contain both intestine and omentum, and frequently a portion of the ileum, though the various other viscera, such as the cecum, bladder, etc., have been found in them. In the *direct inguinal hernia*, the symptoms closely resemble those of the oblique, except that the tumor is more rounded, and usually not so large, the neck is wider and situated near the root of the penis, with the cord on its outer side.

Roser directs attention to the important fact that the oblique or external inguinal hernia is most common in young males, whilst the internal or direct inguinal hernia is almost confined to elderly men. This appears to be owing to the imperfect closure of the fascicular process of the peritoneum being the common cause of the first, and absorption of fat of the scrotal form.

The different forms of inguinal hernia are not unfrequently complicated with various other affections; either with different kinds of rupture, or with diseases of the cord or testis, such as hydrocele of the cord or of the tunica vaginalis, or varicocele. These various complications necessarily make the diagnosis somewhat more obscure, but with care and practice it may generally easily be made out.

Diagnosis.—The diagnosis of inguinal hernia is usually readily effected, the characters and position of the tumor enabling the Surgeon to determine its true nature. In most cases it is useless to endeavor to ascertain whether the hernia is oblique or direct; all old oblique hernia having a tendency to drag the inner ring downwards and inwards, approximating it and bringing it nearly opposite to the outer one, shortening and destroying the diameter of the canal. Hence the direction of the neck and of the axis of the tumor in these cases so nearly resembles what is met with in the direct form of hernia, that the Surgeon should not attempt to undertake an operation more particularly the division of the stricture, on any imaginary doubts. Some forms of femoral hernia may occasionally be confounded with the inguinal, the distinguishing points between these two forms of the disease will be considered in the section on femoral hernia.

The diagnosis of inguinal hernia from other diseases in this vicinity can be considered under the two conditions in which the rupture is located, 1, *in the canal*, and, 2, *in the scrotum*.

1. Whilst still lying *in the canal*, inguinal hernia requires to be diagnosed from the following conditions: a. *Abscess*, descending from the interior of the abdomen or pelvis through the canal, and passing out through the abdominal ring. The diagnosis may here be effected by recognizing the fluctuating feel of the abscess, which, though reducible on pressure, does not present the same characters and the gurgling sensation of a hernia. b. *Encysted Hydrocele of the Cord*. In the *encysted hydrocele* there is a small oval swelling situated on the cord, which can be apparently reduced and pushed up into the canal, and descends again on coughing or straining; it may be distinguished from hernia by being always at the same spot, by not being reducible into the cavity of the abdomen, by the absence of a gurgle, and by its very defined outline. If the testicle be drawn down, the *encysted hydrocele* becomes fixed and is no longer reducible even into the canal. In the *diffused hydrocele* of the cord, the absence of a distinct impulse on coughing, the impossibility of returning the swelling completely

within the abdominal cavity, and of feeling the cord in a free and natural state in hernia, will prevent the diseases from being confounded with each other. *c. Hematocoele of the Cord.* Here the soft and fluctuating nature of the swelling, the ecchymosis, the impossibility of complete reduction, and the absence of gurgling, will indicate its true nature. *d. Fatty or other Tumors* occasionally form on the cord; but the circumscribed character and limited size of these swellings, the absence of impulse on coughing, and of reducibility into the cavity of the abdomen, and their becoming fixed when the testicle is drawn down so as to put the cord on the stretch, will point out that they are not hernia. *e. Lodgement of the Testis in the Inguinal Canal* will give rise to a tumor, which closely resembles incomplete inguinal hernia; and if it should happen to become inflamed in this situation, the difficulty of the diagnosis from strangulated hernia may be very considerable. In the ordinary undescended testis, the absence of that organ in the scrotum on the affected side, the peculiar sickening pain occasioned by the pressure of the tumor, the absence of gurgling, and of all possibility of reduction, will enable the diagnosis to be effected. *f. Inflamed Undescended Testis.* From this it is not always at once easy to effect the diagnosis of incomplete inguinal hernia in a state of strangulation, with which, indeed, it may be complicated. This point in diagnosis will be more fully treated of in speaking of congenital hernia. In the meanwhile, it may be stated that the absence of *persistent* and *continuous* vomiting and constipation, the feel of the tumor, hard below, elastic above, and the peculiar pain when it is compressed, will enable the Surgeon to recognize the true nature of the tumor as being a retained and inflamed testis.

2. When the hernia has descended *into the scrotum*, it may be confounded with: *a. Hydrocele of the Tunica Vaginalis.* In this disease there is an oval or pyriform tumor, usually translucent, unchangeable in size or shape by pressure, and having the cord clear and distinct above it, with an absence of impulse on coughing, or of gurgling in attempts at reduction. The patient will usually have noticed in hydrocele that the swelling first appeared at the bottom of the scrotum, while in hernia it descended from above. In cases of congenital hydrocele in children, in which there is still an opening communicating with the peritoneal cavity, the tumor may be diminished in size by steady pressure, but gradually returns, fluctuates, and is translucent. In these cases its translucency, and the gradual manner in which the sac is emptied and is refilled, very different from the sudden slip up and protrusion of a hernia, enable the Surgeon to establish the diagnosis. In infants, however, it must be remembered that a hernia is often translucent, as it seldom contains omentum, and the contents of the gut may be chiefly gas. It not unfrequently happens that *hernia is complicated with hydrocele of the tunica vaginalis.* In these cases the two separate tumors can usually be distinguished, there being some degree of constriction, or of consolidation, between them. The hydrocele will present its ordinary characters of translucency, irreducibility, and circumscribed outline, and is commonly placed anterior to the hernia, which lies towards the back of the scrotum, and may be distinguished by its reducibility and impulse on coughing. It sometimes happens, as in a case which once fell under my observation, that a *hydrocele of the cord is associated with one of the tunica vaginalis and a hernia*; in such circumstances, the diagnosis requires a little care, but may be effected readily enough by separately determining the characters of the different swellings. *b. Varicocele.* Here the diagnosis may be effected in the way pointed out by Sir A. Cooper. The patient should be placed in the recumbent position, and the swelling reduced; the Surgeon then presses upon the external ring with his fingers, taking care to cover the whole of it, and desires the patient

to stand up. If it be a hernia, the tumor cannot descend; but if it be a varicocele, it will speedily reappear *whenever the pressure is being kept up*, the blood being conveyed into it through the spermatic arteries. *c. Tumor of the Testis.* These may be distinguished from hernia by their solid and rounded shape, by the absence of all impulse on coughing, and especially by the cord being felt free and clear above them, and the inguinal canal unoccupied. *d. Hematocoele of the Tunica Vaginalis.* Here the cause is the swelling, its oval shape, opacity, solid feel, the absence of impulse on coughing, and the defined characters of the cord, will enable the Surgeon to make a diagnosis.

Treatment.—When inguinal hernia is reducible, the rupture must be kept up by a well-made truss, the pad of which, of an oval shape, should press not only upon the external ring, but upon the whole length of the canal. It is in this form of hernia that the various operations for the radical cure are most applicable. When it is irreducible, and of large size, nothing can be done beyond supporting it in a bag-truss.

Operation.—When the hernia is strangulated, if the taxis powers employed in the direction of the canal have failed, the operation must be performed in the following way: The bladder having been emptied, the pubes shaved, the patient should be brought to the edge of the bed, and the Surgeon standing between his legs, and having the skin covering the external ring well pinched up, divides the fold in the usual way, by an incision two inches in length, commencing about half an inch above the external abdominal ring. Should any spouting vessel, as the external pudic, be divided in this incision, it had better be ligatured. The Surgeon then proceeds with the section through the subcutaneous structures. He will in many cases find the superficial fascia considerably thickened, particularly if the patient have long worn a truss. He divides this structure in the middle of the external incision, and then exposes the intercolumnar fascia, which will also generally be found thickened, and incorporated with the superficial fascia. In many cases, the intercolumnar fibres will be found condensed into a thick and broad fillet, which limits the further extension of the cord, and produces an evident constriction upon the neck of a large inguinal hernia. An opening should be carefully made into this fascia a good director passed under the edge of the ring, and this slit up. In some cases, though but very rarely, it will now be found that the hernia may be reduced, its strangulation depending on the constriction of the margins of the aperture; most commonly, however, the stricture is situated deeper than this. The cremasteric fascia, which is generally considerably thickened, is now exposed, when its fibres will be found to form a kind of reticulated mesh over the hernial tumor. This structure must be carefully divided upon a needle, when the transversalis fascia and subserous areolar tissue, or *laminæ serosa*, will be laid bare. This structure is usually thickened and vascular, and sometimes unfrequently the stricture appears to be situated in it, or in a kind of denser ring formed by the incorporation of it with the meshes of the cremaster. If it be found, after the division of these fasciæ, that the hernia can be reduced, it would of course be unnecessary to lay open the sac, and the patient's chance of recovery will be considerably enhanced, more particularly if the operation be performed for an old scrotal hernia of large size, by not doing so. If, however, as will happen in the majority of instances in inguinal hernia, it be found that the stricture is in the neck of the sac itself, occasioned by a condensation, constriction, and puckering of it, the sac must be carefully opened at its anterior part, the finger introduced, and the stricture divided from within, by pressing the finger on under it, and cautiously sliding the hernia-knife along this. It is an estab-

lished rule in surgery, that this division should be effected in a direction immediately upwards, so that it may lie parallel with the epigastric vessels, whether it be situated upon the inner or outer side of these. It is true that, if the Surgeon could be sure that he had to do with an oblique inguinal hernia, he might safely divide the stricture outwards; or, if he were certain that the protrusion was of the direct kind, he might make the section inwards; but, as it commonly happens that he cannot determine with absolute certainty upon which variety of hernia he is operating, he adopts the safer plan recommended by Sir A. Cooper and Sir W. Lawrence, of cutting upwards from the middle of the ring parallel to the epigastric vessels. After the hernia has been reduced the ring may be closed in proper cases, as already described (p. 750).

The *Seat of Stricture* in inguinal hernia will thus be seen to differ in different cases; and in some instances it exists in two situations. I think it most commonly occurs in the neck of the sac, owing to contraction and elongation of it, with condensation of the subserous areolar tissue lying immediately upon it. In other cases, though much more rarely, it seems to be formed by a thickening of the transversalis fascia in the inner ring, but altogether outside the sac. Occasionally it is met with in some part of the canal, at the lower edge of the internal oblique, but much more frequently at the external abdominal ring. In many cases there is very tight constriction in this situation, as well as in the deeper portions of the canal, or at the inner ring; hence, after the division of any stricture at the external abdominal ring, the deeper portions of the canal should always be carefully examined before any attempt is made to put the hernia back.

The operation for an *Incomplete Inguinal Hernia* requires to be conducted in the same way as that which has just been described, except that the incision need not be quite so long, and should not extend beyond the external ring. After this has been laid open, and the tendon of the external oblique slit up, a flat director must be passed under the lower edge of the internal oblique, which must be carefully divided; should the stricture not be relieved in this way, and the sac required to be laid open, the deep section must be made in the same way and in the same direction as has already been described.

In *Inguinal Herniæ*, containing either the *Cæcum*, the *Sigmoid Flexure* of the Colon, or the *Urinary Bladder*, the protruded viscera are only partially covered by peritoneum; hence, in operating upon such herniæ, when strangulated, care must be taken that the contents be not wounded, which is apt to occur if the Surgeon divide the parts without due caution, not suspecting himself to have reached the neighborhood of the viscera, but believing that he has met with a sac which does not exist. As the protruded parts are generally adherent in these cases, the Surgeon must content himself with leaving them unreduced after the division of the stricture; in such circumstances, it has happened that the protrusion is ultimately drawn back into the abdomen by some natural action of the parts.

Operations for strangulated inguinal hernia are required during a greater range of ages than those for any other kind of protrusion. I have operated successfully for congenital hernia in infants less than six weeks old, and for ordinary oblique inguinal hernia at seven weeks and at four months of age; and the operation has been done on centenarians. When small and recent, the protrusion usually consists of intestine only; when large, it commonly contains omentum as well. The treatment of these contents, and the after-management of the case, must be conducted in accordance with the rules laid down at p. 767 *et seq.*, vol. ii.

HERNIA IN THE TUNICA VAGINALIS: CONGENITAL HERNIA—In this case the hernia descends by the unobliterated *processus vaginalis* in the peritoneum inside the tunica vaginalis, which constitutes its sac. It is always oblique, and takes the course of the spermatic cord, most commonly descending into the scrotum, but sometimes lying within the canal, out of which perhaps the testis has imperfectly passed. This hernia differs from an ordinary oblique hernia in the absence of a peritoneal sac of new formation, the protruded parts lying in the tunica vaginalis in contact with the testis (Fig. 796). The great peculiarity, indeed, of this hernia consists in its descending along the canal left open by the descent of the testis. In the

Fig. 796.—Congenital Hernia.

fetus the testis originally lies below the kidney, and, as it descends in the later months of intrauterine life into the inguinal canal and scrotum, it pulls down a prolongation of the peritoneum, exactly resembling a hernial sac. In addition to this defective closure of the vagina, recess of the peritoneum, there is another anatomical condition which tends to the formation of congenital inguinal hernia—viz., an abnormally long mesentery. This, unlike the open peritoneal process, is not necessary to the formation of the hernia, but when existing it is a material factor in its production, and is attended by this serious inconvenience, that it is an obstacle to the radical cure of the hernia by the closure of the open funicular process of peritoneum by the pressure of a truss.

That prolongation of the peritoneum which is carried down around the testis in its descent, and is divided into two portions, the funicular and the testicular. The funicular is that which corresponds to the cord, extending from the internal ring to the scrotum; the testicular is that which becomes the tunica vaginalis. A congenital hernia occurs in consequence of the funicular prolongation not becoming, as in the normal condition, converted into a filamentous fibro-cellular tissue, but remaining pervious, and thus serving as a medium of communication between the general cavity of the peritoneum and the tunica vaginalis; and along the open channel thus left the congenital hernia descends. Hernia in the tunica vaginalis, though usually called "congenital," is rarely so in reality; the tendency is congenital, but the disease is not. Not unfrequently happens, it is true, that these hernia show themselves early in life, in infants a few weeks or months old; though even at these ages the funicular prolongation of the peritoneum may be so completely converted that the hernia which occurs is of an ordinary oblique character. Not infrequently, however, the hernia does not take place until a considerably later period of life than this, and may suddenly happen in the adult. Velpeau relates instances in which it occurred for the first time between the ages of eighteen and twenty-five. I have operated in a case on a man twenty-five years of age, in whom this kind of hernia occurred for the first time when he was twelve years old; and some years ago in a case at the Hospital, on a man about fifty, in whom, on the most careful inquiry, it appeared that the protrusion had not shown itself until he was about thirty years of age. The explanation of these cases is, that the funicular process is only partially closed or contracted, and that, under a sudden effort, the septum is broken through, and thus a knuckle of gut falls into the tunica vaginalis.

Signs and Diagnosis.—The signs of hernia in the tunica vaginalis closely resemble those of the ordinary oblique; most commonly, however, if scrotal, the tumor is much rounded, and the neck feels narrow and constricted. The testis, also, cannot be felt distinct and separate from the tumor, but is surrounded by, and, as it were, buried in the substance of the hernia, through which it may sometimes be felt at the lower and back part of the scrotum. In an ordinary inguinal hernia, the tensor the sac the more clearly is the testicle seen and felt outside it. In a congenital hernia, if the sac is tense the testicle cannot be felt at all. On inquiry, also, it will usually be found either that the hernia has existed in childhood, or that the testis is still in the canal, or has descended later than usual. A hernia of the tunica vaginalis may be associated with a congenital hydrocele. In these cases, after the fluid has been returned into the peritoneal cavity by directing the patient to lie on his back, and raising the scrotum, the portion of protruded gut may be felt and recognized by its gurgle and upward slip when reduced. This hernia may be associated with the testis, either undescended or lying at the external abdominal ring. In the first case, the hernia is, of course, incomplete; in the second, it is scrotal. When incomplete, the diagnosis may be made by feeling a soft swelling with the ordinary hernial signs above the small and hardened testis.

When symptoms of strangulated hernia occur in a person in whom the *testes have not descended* into the scrotum, very great difficulty may be experienced in effecting an exact diagnosis. In such cases as these, an oblong or rounded tumor, tense and painful, will be found to occupy the inguinal canal, not passing beyond the external ring, with some abdominal tenderness, and possibly nausea and constipation. The question here arises as to the nature of this tumor. Is it simply an inflamed undescended testis; or is it an undescended testis, inflamed or not, as the case may be, having a knuckle or loop of strangulated intestine lying behind it?

When the tumor consists simply of an inflamed undescended testis, the pain will be of that peculiar character which is indicative of orchitis, and the constitutional symptoms of strangulation, however simulated for a time, will not be persistently present. The following case is a good illustration of this condition. A man aged about forty, said to be laboring under strangulated hernia, was sent up from the country for operation. On being called to him, I found the house-surgeon attempting the reduction of the tumor in the hot bath; but as soon as I felt the swelling, I was convinced, from its hard, solid, and irregular feel, that it was not a hernia. On inquiring into the history of the case, it appeared that the patient had for the last two days suffered from occasional vomiting, and had been constipated; that the tumor in the groin had not appeared suddenly, though it had enlarged with great rapidity; that it was exceedingly painful; and that he had always worn a truss for a supposed rupture on that side, until the last few weeks, when, in consequence of the instrument breaking he had discontinued it. On examining the groin, carefully, a tumor about as large as the fist was found in the right inguinal canal; it was tender to the touch, hard, and irregular at the upper and outer part, but somewhat soft and fluctuating below; when the finger was passed into the external ring, the outline of the tumor could be very distinctly felt in the canal. There was no impulse in it on coughing, but some abdominal tenderness on that side. The right testis was not in the scrotum. I ordered the man to be bled, the tumor to be leeches, and salines administered, under this treatment the case did well. When a knuckle of strangulated intestine lies behind and above the testis, still retained above the external ring, the symptoms of strangulation will be violent and persistent; and this, even though the tumor present but

little the feel or the ordinary character of a hernia. In fact, in such a case the Surgeon is guided by the character of the general symptoms and not by those of the local tumor. In a case of this kind to which I was called there could be felt behind and above an inflamed and swollen testis which lay at the external abdominal ring, a small, hard, round tumor at the upper portion of the canal. As symptoms of strangulation were present this was cut down upon, the anterior wall of the canal was incised, and the tunica vaginalis, much distended with fluid, was laid open, when a small knuckle of intestine was found lying at its upper part, very tightly constricted by the inner ring. But in other cases the diagnosis is not so easy, the whole tumor lying in the canal feels smooth, elastic, and uniform, so that no manual examination can enable the Surgeon to say with certainty whether the tumor is an inflamed testis surrounded by fluid in a distended tunica vaginalis, or whether there is a loop of intestine lying above an undescended testis. In such cases as these, however, the Surgeon is guided in the course he should adopt by the symptoms. If these indicate strangulation of intestine, and persist after a reasonable time has been consumed in the application of leeches and hot fomentations, he should, without further delay, cut down on the tumor and examine its nature. If it be hernia, at least, the internal ring will require division, the intestine must be reduced, and the testis put back in the canal.

Treatment.—The treatment of congenital hernia consists in the reduction of the tumor, and the application of a proper truss, the pad of which should compress the whole length of the inguinal canal. In children, a radical cure may be effected in this way; but, in order to accomplish this desirable result, the truss must be worn for several years. The application of a truss with an air-pad will in many instances be found especially useful, and it applies itself with greater exactness than an ordinary incompressible pad. In applying the truss, care must be taken not to compress the testis if it is descended. In order to avoid this, the lower end of the pad may be cut out so as to be concave, and thus press down the testis while it supports the hernia.

When strangulated, congenital hernia does not commonly admit of reduction, and thus necessarily renders an operation imperative. The procedure is more commonly required for this kind of hernia in adults than in children. The operation is the same as that for oblique inguinal hernia, but the parts concerned are usually thinner, the tunica vaginalis serving for a sac. Hence more caution than usual is required in these cases. The sac commonly contains a large quantity of fluid, usually clear, but often dark in color, and being, in fact, a hydrocele conjoined with the hernia. The stricture is always found in the neck of the sac, at which point it is often constricted by a sharp narrow ring; hence it is useless in these cases to endeavor to relieve the strangulation, without laying open the sac and dividing its neck from within. The stricture, in fact, appears to be formed by the imperfect contraction of that portion of the funicular prolongation of the peritoneum which normally becomes obliterated before birth, and establishes the communication between the two serous sacs of the tunica vaginalis and of the peritoneum. As the congenital hernia is always external to the epigastric vessels, the section of the stricture may be done with perfect safety in a direct upwards and outwards, though, if the Surgeon should have any doubt as to the exact nature of the case, it will be better to divide the stricture directly upwards. The reduction of the contents of the hernia may in the adult be prevented by adhesions in the neck of the sac, or between them and the testis. I have found both the gut and omentum closely incorporated with this organ, and requiring some nice dissection to separate them. In oper-

ating upon infants of a very tender age, much caution will necessarily be demanded, on account of the tenuity of the coverings, their tension, and the small size of the apertures. The narrow ring forming the stricture may often in these cases be ruptured by passing a director under it and stretching it, and the use of the knife is thus avoided. The testis, as well as the spermatic cord, the veins of which are excessively turgid, come into view, and will usually be found much congested, and of a black or bluish-black color.

A species of congenital hernia has been met with in the female, especially in children, in which the protrusion takes place into the canal of Nuck, which invests the round ligament. In one instance, I have seen a double inguinal hernia in a girl five years old. It is of extremely rare occurrence, and requires the same treatment as the corresponding disease in the male.

ENCYSTED HERNIA OF THE TUNICA VAGINALIS, OR INFANTILE HERNIA, as it has been somewhat absurdly termed, occurs in those cases in which the funicular portion of the tunica vaginalis is partly obstructed by a septum, or by being converted into filamentous tissue, but in such a way as to leave a pouch above, which is protruded down behind or into the tunica vaginalis, so that it lies behind this cavity (Fig. 797). There are no characters by which the encysted can be distinguished from the ordinary congenital hernia. If it should become strangulated, it must be borne in mind that during the operation the tunica vaginalis will first be opened; no hernia will be seen here, but the tumor lies behind this sac, and requires to be dissected into it through the double serous layer of which it is composed. The stricture will probably be in the neck, and requires to be divided in the usual way.

Fig. 797—Infantile Hernia.

FEMORAL HERNIA.

By **Femoral Hernia** is meant a protrusion that escapes under Poupart's ligament, and enters the sheath of the vessels internally to the femoral vein. This hernia passes down to the innermost compartment of the sheath, which is occupied by fat and lymphatics, and usually contains a gland or two. It passes first of all through the crural ring, where it has Gimbernat's ligament to its inner side; the septum which separates the femoral vein from the inner compartment of the sheath of the vessels, to its outer aspect; Poupart's ligament in front; and the bone behind (Fig. 798). After passing through the crural ring, it enters the crural canal, which extends for about half an inch down the thigh in front of the pectineus muscle, and is covered by the iliac prolongation of the fascia lata. As it approaches the lower corner of the saphenous opening where the canal terminates, it passes under the talariform process of the fascia lata, and out upon the thigh through the saphenous aperture; here it expands, becomes rounded, and has a tendency to turn upwards over Poupart's ligament (Fig. 799), lying in this way upon the iliac region, and sometimes even ascending to some distance upon the anterior abdominal wall. In the descent of the hernia through this course, it first of all pushes before it the peritoneal sac, and then receives an investment of the subserous areolar tissue—the **septum crurale**, a mass of dense areolar tissue, containing fat and lymphatics, occupying the crural ring. This septum often becomes incorporated and matted with the contiguous portion of the sheath, thus constituting the **fascia propria** of this hernia, which is commonly thickened, laminated, and of an opaque fatty structure,

like omentum. As the hernia continues to descend, it comes into contact with the cribriform fascia, which occupies the saphenous opening; and lastly, it pushes before it the integumental structures.

As the tumor descends through this course, it necessarily comes into

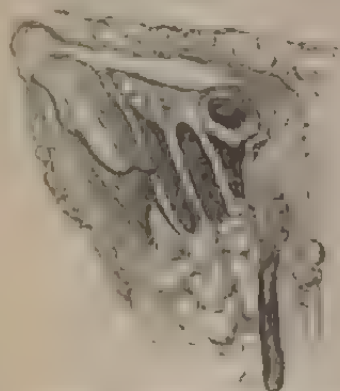

Fig. 799. — Femoral Hernia, tumor upwards.

Fig. 798.—1. Femoral Artery, 2. Femoral Vein, 3. Innermost Compartment of the Sheath of the Vessels, into which a small Hernia is protruding, 4. Saphena Vein.

tion with very important parts (Fig. 800). Thus it is separated from the femoral vein solely by the septum of the sheath of the vessels. It has the epigastric artery above and to its outer side, and the spermatic cord in the male, or the round ligament in the female, almost immediately adjacent

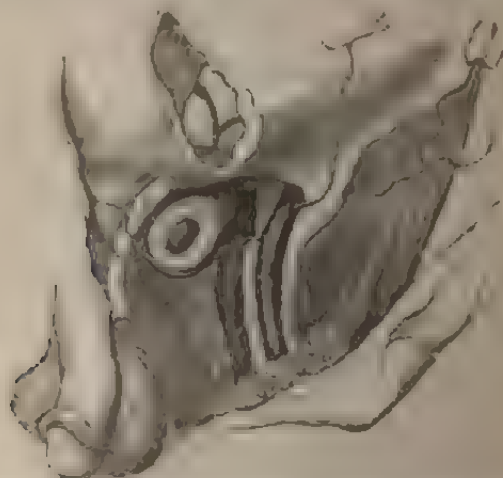

Fig. 800. 1. Femoral Hernia, 2. Femoral Vein, 3. Femoral Artery, giving off a branch to the Trunk of Epigastric and Obturator Arteries, and 4. Epigastric Artery, 5. Spermatic Cord.

The obturator artery, when arising in the normal manner from the internal iliac, does not come into relation with the neck of the sac; but when it takes its origin, as it not unfrequently does, from the external iliac, the epigastric, or the common femoral, it may have important relations to this part of the hernia. Most commonly, in these circumstances, it passes to the right of

outer side of the neck, but occasionally it winds round its inner or pubic side, coming into close relation with it; and then, as will immediately be mentioned, it may be in considerable danger during the operation. The combination, however, of this particular variety of the obturator artery and femoral hernia, is a very uncommon occurrence; because, in the first place, this internal distribution of the artery is rare; and when it does occur, as it usually passes directly over that portion of the crural ring through which the sac would protrude, it necessarily strengthens this, and so diminishes the chance of rupture.

Contents.—The contents of a femoral hernia are usually intestinal, and most commonly consist of a portion of the ilium. Occasionally omentum is contained within the sac, but seldom in large quantity. I have, however, several times had occasion to operate in cases of old femoral hernia, in which it became necessary to remove large portions of adherent omentum; in one, ten and a half ounces, and in another about seven. In each case there was a small knuckle of intestine strangulated behind the omentum. The ovaries, Fallopian tubes, etc., have been known to be strangulated in this variety of hernia.

Signs.—The signs of femoral hernia are usually well marked. They consist of a tolerably firm, tense, and unyielding tumor, of a rounded shape, situated in the groin, to the inner side of the femoral vessels, and to the outer side of the spine of the pubes, having its neck under Poupart's ligament, though, as it increases in size, its base is turned above that structure; sometimes, though rarely, it passes downwards upon the thigh. Its size varies considerably; most commonly it is not larger than a walnut or a pigeon's egg, and then is deeply seated in the angle between the body of the pubes and the femoral vessels; but occasionally it may attain a considerable bulk, as large as the fist or a French roll. When large, this hernia rises up above Poupart's ligament, and extends outwards in a direction parallel to it, so that it assumes an elongated shape; it is then usually somewhat doughy and soft, even when strangulated; very different from the excessively tense feel that it has when small.

In some rare cases the femoral hernia has been found lying external to the vessels, the mouth of the sac being between them and the iliac spine. In these circumstances strangulation cannot well occur, inasmuch as the mouth will be the widest part of the sac; but, as Hesselbach has observed, if the fascia iliaca be torn by the pressure of the tumor, the rupture may be strangled in the aperture thus formed. Should an operation ever be required in such circumstances, it must be borne in mind that the circumflex ilii artery may be in some danger.

As a femoral hernia passes out through the crural ring, it comes into very close relation to the femoral vein, being separated from the vessel merely by the septum, which divides the inner from the middle compartment of the femoral sheath. Were it not for this septum, as Röser has observed, the femoral vein would be compressed by the tense hernial tumor protruded between it and Gimbernat's ligament, and the inevitable consequence would be oedema of the whole lower extremity. As the hernia pushes down in the track of the crural canal, it can make no impression on the inner or on the posterior wall of the canal—both of which are unyielding; but, pushing the anterior wall upwards, it drags upon the septum on the other side of the neck of the sac, renders this tense, and thus saves the femoral vein from compression.

Diagnosis.—The diagnosis of femoral hernia is not always easy. When the hernia is large, and more particularly when it rises up above Poupart's ligament, which some hernie, even of very moderate size, are apt to do, it

might at first be mistaken for an inguinal rupture. The diagnosis, however, may usually be effected by ascertaining the relation that the neck of the tumor has to Poupart's ligament, the inguinal hernia being situated *above* the femoral *below* this cord. When, however, a small femoral hernia in a woman rises upwards, so as to be over Poupart's ligament, it resembles very closely an incomplete inguinal hernia; but its characters may be determined by the passage of the finger up the inguinal canal, which will be found to be free, and the hernia can be felt only through its posterior and inferior wall. In the female, the finger cannot be passed up the canal, but the inguinal hernia will descend into the labium, and may thus be recognized from the femoral, which lies in the upper and inner part of the thigh. In both cases the relations of the neck of the sac to the spinous process of the pubes, which can always be felt in the fattest subjects, are most important in a diagnostic point of view. In femoral hernia the spine is to the inner, in inguinal to the outer side of the protrusion; and, should a patient happen to be the subject of both inguinal and femoral hernia on the same side, the spine would be felt between the two. After reducing a femoral hernia, the finger can sometimes be pushed into the inferior aperture of the crural canal, whence the situation and sharp outline of the falciform process will determine the nature of the opening through which the protrusion has occurred.

The diseases occurring in the groin, with which femoral hernia may readily be confounded, are—1. *Enlarged Lymphatic Glands* in this situation. From these it may be distinguished by the absence of impulse in the parasternal tumor, and by the simultaneous enlargement of several glands. A small strangulated hernia may, however, coexist with these, being situated to, and covered in by them. When this is the case, and the local signs of hernia are obscure, whilst the symptoms of strangulation continue unrelieved, should be made into the part, and the dissection carefully carried through and underneath the glands, with the view of determining whether the hernia exist or not. 2. *A small Fatty Growth* has been met with in the crural canal, closely simulating a hernia. The want of impulse on coughing, together with the limited and doughy character of the tumor, will enable the surgeon to distinguish it from hernia. 3. *Pilon Abscess* may point nearly in the situation of femoral hernia; but generally it leaves the abdomen external to the vessels, while a hernia is internal. It may be further distinguished by a fluctuating feel, by its soft yet semi-elastic character, and by the growth history of the case. The impulse on coughing, which is very distinct in the abscess, is commonly more forcible and direct than that of a hernia, although the purulent collection may in many cases be squeezed back into the abdomen when the patient lies down, yet it returns without a gurgle and without that distinct slip which accompanies the reduction of a hernia. 4. *Varic of the Saphenous Vein* is in some danger of being confounded with hernia. It may, however, be distinguished from this by the impulse on coughing being less distinct than in hernia, and by the enlargement of the lower part of the vein being marked in the varic, but not existing in the rupture.

Femoral hernia most commonly occurs in women, and very seldom before the age of twenty; differing in both these respects from the inguinal rupture. Sir A. Cooper states that he had seen only three cases under the above age. It very seldom becomes strangulated at an early period of life, even when existing. I have had a girl of nineteen under my care with femoral hernia in whom strangulation had already occurred on four occasions, reduction, however, having been happily effected each time.

Treatment.—The treatment of femoral hernia, when it is reducible, must be conducted in the ordinary way by the application of a proper truss. A cure, however, is never, I believe, effected by the pressure of a pad, as some

times happens in inguinal hernia; owing probably to the rigidity and incompressibility of the tendinous and aponeurotic structures through which this rupture protrudes. It is often difficult to keep this form of hernia up by means of a truss. The best instrument for this purpose is the Moenmann truss, which I have found to succeed when all others have failed. When the hernia is irreducible, it should be supported by means of a truss with a concave pad.

When a femoral rupture is strangulated, reduction should be effected either by taxis or by operation as speedily as possible, gangrene ensuing more rapidly in this than in any other form of hernia. In attempting taxis, the structures in the groin should be well relaxed by flexing the thigh upon the abdomen, and adducting it, which relaxes the margin of the saphenous opening; if it do not succeed with the assistance of the means recommended at p. 760, vol. ii., the operation should be proceeded with at once. The operation for strangulated femoral hernia may be undertaken earlier and with a better prospect of success than that for any other form of rupture; this is owing to the stricture being so commonly seated outside the sac, that the operation usually admits of being completed without implicating the peritoneum. The advantage of this mode of procedure in femoral hernia has been fully pointed out by A. Key, Luke, and Gay, and is now very generally recognized in practice. Gay, more particularly, has pointed out that the stricture may commonly be divided without opening the sac, by making a very limited incision on the inner surface of the neck of the tumor; and he observes that the operation undertaken in this manner is little more than the taxis with the addition of a superficial incision. There is, however, this important difference between a hernia reduced by the ordinary simple taxis and one returned by Petit's operation, that the strangulation in the latter case has been far tighter, or the operation would not have been necessary, and the consequent injury to the protruded parts is much more severe.

The stricture in femoral hernia is often found to be occasioned by the pressure of the sharp edge of Gimbernat's ligament. Most Surgeons recommend that this should be divided, but some advise that the division should be made at the junction of Gimbernat's and Poupart's ligaments, dividing at the same time the fibres of the superior cornu of the falciform border of the saphenous opening which are attached to Gimbernat's ligament, and were first described by Hey, under the name of "the femoral ligament" (1803). Hey, subsequently (1814), dropped this designation, but these fibres are still sometimes called "Hey's ligament."

It is in this situation that both Lawrence and Hey recommended the incision to be made. In operating for femoral hernia, I have certainly most frequently found the stricture still to continue after the division of these ligamentous structures, and to be occasioned by the deep crural arch which forms in many cases a very distinct narrow and glistening band lying across the neck of the sac in the fascia propria of the hernia; and I agree with the opinion expressed by Sir A. Cooper, that the neck of the sheath is the common seat of strangulation in femoral hernia. The bands forming the deep crural arch are probably thickened in old hernia from the pressure of the truss and the contents of the sac. In order to expose them, it is commonly necessary to draw the neck of the sac well down, when they will be seen deeply to indent and constrict it.

The operation without opening the sac may most conveniently be performed when the tumor is small, by making an incision by transfixion along the inner side of its neck, and then dissecting through the superficial structures until the fascia propria is brought into view and carefully opened, and

the sac exposed. The point of the finger should then be carried to the inner side of this, well under the fascia propria. The finger nail or director may then be insinuated under the sharp edge of Gimbernat's ligament, and at the point of junction with Poupart's, may be divided upwards and inwards to the extent of a line or two by means of a hernia-knife. By this is done not only is the edge of Gimbernat's and Poupart's ligament divided, but also the condensed and compressed fascia propria lying between them, at the inner side of the crural arch. The reduction may now be attempted, as often effected; should any obstacle exist, the neck of the sac must be withdrawn down and exposed, and any transverse bands belonging to the septum crurale which may be situated upon it dissected through with the knife and forceps, or divided on a director. These bands are incorporated with the fascia propria; and when they are found, it is usually owing to the surgeon not having exposed the neck of the sac sufficiently before passing the nail or director under the stricture. It is owing to the incision being confined to the constriction occasioned by the superficial crural arch, and not including, as it ought to do, the subjacent condensed fascia propria, a point of very great practical importance. Sometimes this condensed and constricting portion of the fascia propria is so closely incorporated with the neck of the sac, that it cannot be divided without opening the latter. The operation performed in this way, without opening the sac, is certainly a very simple procedure; and adds little, if anything—nothing more, in fact than a simple incision through superficial structures—to the danger of the patient.

If it be thought desirable to **open the sac**, or if it be necessary to do so, in consequence of its incorporation with the fascia propria, the operation may be performed by a similar incision to that above described, slightly extended in length, but if the tumor be of considerable size some Surgeons prefer to expose it more freely by an Γ shaped incision, the vertical limb of which passes along the inner side of the sac and horizontal limb parallel to Poupart's ligament and immediately below it. In whichever way the first incision be made, the dissection must next be carried through the superficial fascia, and the cribriform fascia, when the fascia propria, septum crurale, and septum crurale fused together will be exposed; in some cases exposed if the hernia be a large one, this is thin, and requires to be carefully cut on a director. In many instances, however, it is so dense, laminated and changed in structure, as scarcely to be recognized for what it is. It often frequently happens that, after the superficial fascia has been divided, an oval, smooth, and firm body is exposed, which at first looks like the neck of the sac, or a lump of omentum; this is in reality the fascia propria thickened by the long-continued pressure of the truss, and congested, perhaps, with cysts containing bloody serum may occasionally be found in it, and the difficulty in the recognition of the structures is greatly increased. From the mobility of this mass, the facility of tracing its neck, and the roundness of its general outline, often cause it to be mistaken for sac or omentum, and may be distinguished from the first by the absence of the characteristic vessels upon its surface, and from the second by its more rounded, smooth, and uniform appearance. When the sac has been reached it must be carefully opened, there being usually very little if any fluid between it and its contents; the finger nail must then be passed under the sharp edge of the stricture, which should be divided in a direction upwards and inwards. The reason why this line of incision is universally chosen by Surgeons in this country at the present day, is, that it is the only direction in which the stricture can be divided without risk of inflicting serious injury upon neigh-

boring parts. If the section be made outwards, the femoral vein will be in danger; if upwards and outwards, the epigastric artery; if directly upwards, the spermatic cord; hence the only direction is either inwards, or upwards and inwards. If the cut be made inwards, the sharp edge of Gimbernat's ligament alone will be divided, and the crural arch not sufficiently liberated. But if the division be made upwards and inwards, the tension of the whole of the arch lessened; the only danger that can occur from the division of the stricture in this direction is the very remote one of the wound of the obturator artery, when it takes the anomalous course round the inside of the neck of the sac. Guthrie states that he has known some of the best Surgeons in London to lose patients by hemorrhage after the operation for femoral hernia. This accident, however, is of extremely rare occurrence, and might in a great measure be guarded against by slightly blunting the edge of the hernia knife before dividing the stricture, so that the tense fibrous bands constituting the constriction would yield, while the artery would probably escape, being pushed before the blunted edge. I have, however, more than once seen blood well up rather freely on the division of the stricture; but it has ceased spontaneously, and I have never known it to give any trouble. If the division of the stricture be limited to a line or two, there will be but little danger of wounding the vessel, even when it takes the abnormal course.

The best means of arresting the bleeding from a wound of an abnormal obturator can hardly be said to be certainly determined. A. E. Barker, to whom this accident happened in operating on a patient in University College Hospital, successfully arrested the hemorrhage by pressure, the patient dying from gangrene of the gut four days after. In a case recorded by A. H. Corley, of the Jervis Street Hospital, in Dublin, the bleeding was very free, but was easily controlled by passing the forefinger into the wound and grasping the abdominal wall between it and the thumb. A curved needle was accordingly passed in through the ring and out immediately above Poupart's ligament, and a twisted suture applied around it. The hemorrhage ceased, and did not recur. The patient died from other causes, and the post-mortem examination showed the obturator arising from the epigastric and cut opposite the neck of the sac. The two ends had retracted one inch apart, the distal having gone so far in the direction of the obturator foramen that any attempt to reach it would have been out of the question. The needle was found to have passed immediately in front of the proximal end, crossing the track of the artery, but not actually including it; yet the traction so exerted seems to have been enough to close the vessel, as it was obliterated by a clot. The distal end contained no clot. Bartley, in the *Annals of Anatomy and Surgery*, 1881, records a case in which he successfully ligatured the vessel after enlarging the wound sufficiently to bring it into view. The patient recovered. Barker, who collected the records of 16 cases of this accident, states that in 6 a ligature was applied. Probably the best means would always be to enlarge the wound up to Poupart's ligament, and attempt torsion or ligature. The artery might also be exposed by an incision above Poupart's ligament, like that for ligature of the external iliac by Cooper's method, if simple enlargement of the wound did not bring it into view. If these means fail, acupressure or pressure may be resorted to.

It will generally be found, that the intestine contained in the sac of a femoral hernia is dark-colored and tightly nipped; it requires to be treated in accordance with the general principles that guide us in the management of hernia.

UMBILICAL HERNIA.

By *umbilical hernia* or *exomphalus* is meant a protrusion through the umbilical aperture. It occurs either in children or in adults.

Umbilical Hernia in Children is sometimes *congenital*. At an early period of fetal life, a great part of the intestinal canal lies without the abdomen and is gradually drawn in as development advances. Congenital umbilical hernia or true exomphalus is the result of an imperfection in this process. In other cases a diverticulum from the ileum, due to an imperfect closure of the ductus vitello-intestinalis, may extend some distance up the cord from the navel. In either of these conditions it may happen that the protrusion is included in the ligature applied to the umbilical cord. If a large portion of intestine be strangulated in this way, a fatal result usually follows; but if it be merely a diverticulum, the stump of the cord may separate safely, the opening in the gut being obliterated. In other cases a *tea fistula* may form at the umbilicus.

Umbilical hernia occurs more frequently shortly after birth in consequence of the child straining and crying, forming the condition termed by some "starting of the navel." In this form the umbilical cicatrix yields to the natural depression being completely replaced by the projection of the tumor. It is readily recognized by a smooth, rounded, and tense tumor, starting forwards at the umbilicus, readily reducible on pressure. The treatment should consist in the application of a small pad, made of a piece of lint wrapped in a soft piece of lint and powdered with starch. This is secured in position by a circular piece of soap-plaster spread on an adhesive of the American rubber-plaster. An elastic belt with an air-pad is sometimes recommended, and may be applied to older children, but in infants it is useless, as the variation in size of the abdomen, according to the amount of flatus in the intestines is such that no bandage can be really efficient. In most commonly happens that, after pressure has in this way been kept up for some months, a radical cure results. These small hernie are never strangulated, and consequently never cause death; yet it is very rare to see a child of ten years of age, though in infants we meet with them by the score.

Umbilical Hernia in Adults most frequently occurs in women, especially those who have borne many children, or who are loaded with uterine tumors. It is by no means unlikely that a tendency to this disease is often established in childhood, but does not become developed until the abdominal muscles have been relaxed by the pressure of the gravid uterus. The hernia in adults does not, as a rule, stretch the umbilical cicatrix in the skin. It is usually clearly recognizable at the lower part of the tumor, the hernia cord commonly escaping through the upper part of the umbilical aperture.

Umbilical rupture generally attains a considerable bulk, and sometimes an enormous size; when large, it is commonly irregular or reticulated, sometimes appearing to be composed of several distinct tumors. It is usually partly doughy and partly tympanitic to the feel, has a distinct impulse on coughing, and is readily reducible; not unfrequently it happens, however, that a portion of the rupture continues irreducible, owing to the existence of adherent omentum. The coverings of an umbilical rupture are usually extremely thin, consisting merely of the peritoneum, a layer of superficial fascia which is often perforated at several points by circular openings through which the hernia protrudes, and the integuments which are exposed over the part and in which the umbilical cicatrix is usually clearly perceptible. The sac generally contains both intestine and omentum, but the stomach and other viscera have been included in it; and Murray

recorded a case in which the gravid uterus, at the eighth month of pregnancy, formed the contents of an umbilical hernia.

Treatment.—The treatment consists, if the hernia be reducible, in wearing a properly constructed truss; if irreducible, in applying a hollow cup-shaped pad supported by a bandage over the part. It not unfrequently happens that, in consequence of an indigestible or flatulent meal, an irreducible umbilical rupture in old persons becomes obstructed, the symptoms consisting of tension of the protrusion, with nausea and constipation. In these cases, much discrimination will be required to avoid contounding this passive condition of the tumor with acute strangulation of it. This may be done by attention to the rules laid down (p. 753, vol. ii.). By leeching, fomentations, and enemata, relief may usually be afforded. Should, however, the bowels not speedily act, and stercoraceous vomiting come on, the tumor continuing irreducible, it will be better to cut down upon it, and treat it as a strangulated hernia, dividing adhesions, and reducing the swelling; for, if it be left obstructed and unreduced, the whole tumor may run into a state of gangrenous inflammation, and then operative interference will be of little use. In such circumstances death usually results; but I have known the patient to survive the gangrene, the whole of a coil of intestine, the sac, and much mesentery and omentum sloughing away, and an incurable artificial anus resulting.

When an umbilical hernia becomes strangulated, as often happens in old irreducible tumors of this description, the symptoms are not usually very acute at first; but no time should be lost in effecting reduction, if possible, by taxis, as they speedily assume an active and urgent character. If taxis fail, a large umbilical hernia may sometimes be reduced by the application of the elastic bandage. This must be carefully applied round and over the tumor. The gentle and uniform pressure exerted by it may displace some flatus, and thus the contents of the hernia may gradually be emptied and the protrusion reduced. If this fail and the symptoms are not acute, small doses of opium may be given, and an ice bladder applied, and kept on for a few hours. Taxis may then be again employed, when reduction of some portion of the swelling will usually follow. Should this not succeed, the operation must be proceeded with without further delay, lest gangrene set in. If the symptoms are from the first acute, the same rules apply to umbilical as to other hernie, not to waste time with inefficient means, but to try taxis under an anæsthetic, and failing to reduce to operate immediately.

Operation.—The parts covering an umbilical hernia are usually very thin in places, so that much caution is required in making the early incisions. The stricture should, if possible, be divided without opening the sac. This may usually be accomplished by drawing the tumor well down, and then making an incision in it about two inches in length over the neck at its upper part in the mesial line. If the tumor overlap here, it may be more convenient to make the incision by the side of the umbilical cicatrix; but, as a general rule, the upper part is the best. After the division of the integumental structures, and often of a deep layer of fat, the end of the nail may be slipped under the edge of the sharp circular aperture through which the protrusion has occurred, and, the stricture being divided away from the sac, and, if possible, in the mesial line, reduction may be readily and safely accomplished. Should the strangulation not be thus relieved, the sac must be opened, and any stricture divided from within.

The operation for umbilical hernia was formerly extremely fatal if the sac was opened, especially when the protrusion was of great size. Death usually took place from septic peritonitis. The well-known danger of the operation formerly produced considerable hesitation on the part of the Surgeon, and

perhaps tempted him to lose time over inefficient means, and this may have been another cause of the excessive mortality. The risk is now greatly diminished by the use of antiseptics, and if the operation be performed early the death-rate is not greater in umbilical than in other forms of hernia. Sometimes, after the external division of the stricture, it will be found that there is an internal strangulation in the hernia, the gut having slipped through an aperture in the omentum; if so, the edge of this sharply-pointed opening may require division. Sir A. Cooper mentions an umbilical tumor forming two tumors, having a communication between them, and Scott relates a case in which the tumor resembled a figure of 8, a dense fibrous band binding down the middle of the sac. In such cases as these, which are by no means uncommon, central constriction may require to be done as well as the stricture at the neck of the sac. Adherent omentum, I think, better be left in the sac in cases of umbilical hernia, and gangrened intestine or omentum must be treated upon general principles. It is not often that strangulation of an umbilical hernia occurs during pregnancy, but, should it do so, the operation must be performed as usual; this operation does not complicate the case much, and instances are recorded by Sir A. Cooper, Sir W. Lawrence, and others, of its successful performance at this period. After division of the stricture and reduction of the parts, the wound must be closed by sutures, a drainage-tube being introduced and an antiseptic dressing put on, over which a broad flannel roller may be freely applied.

When the patient is not too fat, the operation may be completed by removal of the sac after ligaturing its neck, and an attempt may be made to close the ring by sutures. In very fat subjects the strain upon the sac would be so great that this would very probably fail. It should not be attempted in the absence of the means of carrying out efficient antiseptic treatment.

VENTRAL HERNIA.

By **Ventral Herniæ** are meant those protrusions of the intestine that exit through any part of the abdominal wall, except the inguinal, the femoral, or the umbilical apertures; they most commonly occur in the middle between the recti muscles, the linea alba appearing to have given way in this situation during parturition; and here they may attain an immense size. A case was once sent to me from the country, in which there was a large angular gap through the upper part of the abdominal wall, extending from the umbilicus to the ensiform cartilage, through which a protrusion had taken place that was nearly as large as an adult's head. These ruptures have also been met with in the linea semilunaris, and in the hypochondric and iliac regions; and Cloquet describes a case occurring in the lumbar region. When these herniæ form in the vicinity of the stomach, they are apt to occasion dyspeptic symptoms and much gastric irritation; but Lawrence is doubtless right in thinking that these symptoms do not arise from the implication of the stomach but simply from irritation of it. Intestinal protrusions have occasionally been met with as the result of a wound by which the anterior abdominal wall has been lacerated; indeed these, too, if ever, take place below the umbilicus, unless arising from a direct traumatic cause.

Treatment.—The treatment of ventral hernia must consist in supporting the tumor by means of a broad belt and properly constructed padding, should it become strangulated, which I believe very rarely happens, owing to the width of the neck of the sac, the operation must be performed in the same way as for umbilical rupture, care being taken to divide cautiously the

teguments, any aponeurotic investments, and the peritoneal sac if necessary; the stricture should always be divided upwards.

A rare kind of ventral rupture has been described by Guthrie, in which, after a blow, the abdominal wall has been absorbed or yielded to a considerable extent, forming a broad and expanded tumor, without any distinct neck or pedicle. Sometimes this tumor may attain an immense size, stretching perhaps down to the knees, and containing even the gravid uterus.

PELVIC HERNIA.

OBTURATOR HERNIA.—This rare form of hernia, in which the protrusion of intestine takes place through the thyroid foramen, was first noticed by Garengot, in the early part of the eighteenth century; and, since that time, about eighty cases have been recorded. Its existence has rarely been ascertained till after death; in fact, Lawrence seems to doubt the possibility of the recognition of the complaint during life, in consequence of the small size which the tumor attains, and its being covered in and compressed under the pectineus muscle. But several cases are on record in which it was recognized during life. It generally occurs in persons above the age of fifty; in consequence, according to Gurli, of the participation by the muscular structures passing through the thyroid foramen in the general wasting of tissue which occurs at that time of life. Pimbet, who has collected the records of all the published cases up to 1882, states that in 73, in which the sex was mentioned, 65 were women and 8 men.

Symptoms.—In obturator hernia, the intestine descends through the thyroid foramen; the neck of the sac thus lies behind the horizontal ramus of the pubes. The symptoms have in some cases sufficiently resembled those of strangulated femoral hernia to lead able Surgeons to suppose they had to deal with the latter affection. In addition, however, to the ordinary symptoms of strangulation, there are two special signs which may lead to the suspicion of the existence of this hernia, if not to its positive diagnosis. The first of these is a slight fulness and hardness in the upper part of the thigh to the inner side of the femoral vessels, often very indistinct, yet giving to the surface of the limb a different outline from that which is observed on the other side. The other is, pain extending down the inner side of the thigh towards the knee; or even, as in a case referred to by Birkett, as far as the great toe. This pain has been noticed in a large number of the recorded cases, and is due to the pressure of the hernia on the obturator nerve: it may also be increased by pressure with the hand over the thyroid foramen, and, according to Pimbet, by forced external rotation of the limb. It does not extend to the testis; but it may, as happened in a case which I have seen, affect the thigh to such an extent that the patient, to relieve it, flexes the limb on the abdomen. Roser has recommended, as a means of diagnosis, an examination of the interior of the pelvis, *per rectum* in the male, and *per vaginam* in the female. Most reliance, however, is to be placed on the symptoms which I have described.

Treatment.—Taxis has been employed in a few cases. In one instance, Roser reduced an obturator hernia in this way, the patient surviving; but, in another case under my care, death took place, a portion of the walls of the intestine remaining strangulated. Werner was successful in an instance in which, in addition to applying pressure externally, he introduced his hand into the vagina, and employed traction backwards and upwards. Welsch, of Herrenberg, reduced an obturator hernia by external pressure; the patient was apparently doing well, when, in a few days, an abscess appeared at the site of the hernia, and he died in seven weeks. At the

post-mortem examination, the end of the vermiform appendix was found projecting through the thyroid foramen, with its tip laid open by the efferent process.

In thirteen cases of which I can find records an operation was performed followed in four cases by recovery and in nine by death. The operations occurred in the practice of Obre, Bransby Cooper, and Lörinser, of Vienna, and the deaths in cases operated on by Heath, of Newcastle-on-Tyne; Natta, of Leicester; Heiberg and Zahrtmann, Arntz, of Rongkjobing, Uden and Wilms, of Berlin (two cases), and Sigmundi, of Vienna. In Obre's case, the patient was seized with symptoms of strangulation, but no tumor could be detected in any of the ordinary seats of hernia. "On uncovering the upper part of both thighs at the same time, the eye detected a slight degree of fulness in Scarpa's triangle on the right side; this triangle of the opposite limb was well marked with a hollow, or depression passing down its center, but this was lost on the affected side, and the whole contour of this part of the limb was visibly fuller than that of the corresponding one. There was no tumor or circumscribed swelling; but, on standing over the patient, and using firm pressure with the ends of the fingers over the neighborhood of the femoral artery, and a little below the saphenous opening, a distinct hardness could be felt (slight in its extent), giving an impression as if the sheath of the vessels were being pressed on." Taking the dangerous state of the patient into consideration, Obre acted in accordance with the best rules of surgery; and, thinking that there might be a hernia deeply strangulated in the femoral canal, he made an incision downwards in this situation, but was disappointed on finding, when the saphenous opening was exposed, that there was no intestine confined there. As, however, a hard structure could be felt deeply at the inner border of the opening, the fascia lata was exposed, and the pectineus muscle divided to the extent of about two inches, when a hernial sac of about the size of a pigeon's egg, and containing intestine, came into view. In this operation the saphenous vein gave some trouble lying in the course of the incision. The sac having been laid open, the stricture was divided upwards, during which part of the procedure the vein was accidentally cut, and required ligature; no other vessel was tied. The operation, which reflects the greatest credit on Obre's diagnostic skill and dexterity, was perfectly successful, the patient making an excellent recovery. In Bransby Cooper's case, the patient, a woman aged forty-nine, recovered from the operation, but died of bronchitis before leaving the hospital. In Lörinser's case, the existence of the hernia was detected by vaginal examination. On cutting down on the hernia (on the eleventh day of the symptoms) the intestine was found gangrenous. A fecal fistula resulted and subsequently closed; and the patient survived eleven months, dying of tuberculosis. In Sigmundi's case the patient died from dysentery some time after the operation. In another case operated on by Greenough, the patient died on the twentieth day of perforation of the intestine. It was K. J. Girdler operated on a case in University College Hospital by an incision in the middle line of the abdomen. The hernia was reduced with difficulty, but the patient who was extremely collapsed at the time, died about twenty-four hours after the operation.

Considering the results which have followed the operation for obturator hernia, I think, that when, in addition to the ordinary signs of strangulation, there are also present the altered contour of the limb (perhaps with distinct local swelling) and the pain which have been above described, these symptoms not only justify, but demand, that an exploratory incision be made through the structures overlying the obturator foramen so as to examine it. If a hernia be found there, it must be dealt with by the general

rules already laid down, according to the state of the intestine. The stricture must be divided directly downwards as the artery is most commonly above the sac.

Besides the obturator, various other pelvic hernie may take place, as into the perineum, the vagina, or through the sciatic notch. These various forms of rupture are of extreme rarity, and present many difficulties in their diagnosis.

PERINEAL HERNIA commonly occurs in the middle line, between the rectum and the bladder in men, or the rectum and vagina in women; but sometimes the protrusion has been known to take place by the side of the anus. Of these various forms of rupture, many instances have been collected, by Lawrence from different writers. The *Treatment* of such a hernia would consist in supporting the protrusion by means of a pad and bandage; as the mouth of the sac is very large, strangulation is not probable.

VAGINAL HERNIA has occasionally been met with; the tumor protruding through the posterior or upper wall of the vagina, and presenting the ordinary characters of this disease, such as impulse on coughing and reducibility. It must be kept up by means of a pessary.

PERINEAL HERNIA has been described by Sir A. Cooper as very closely resembling vaginal rupture. The situation of the tumor may cause it to be mistaken for an inguinal hernia; but from this it may be recognized by the upper part of the labium and the ring being completely free, whilst a tumor presenting the ordinary characters of a rupture is situated in the lower part of the labium, and forms a prominence along the side of the vagina.

SCIATIC HERNIA.—This rare form of hernia has been described by Sir A. Cooper as passing through the sciatic notch, where it lies between the lower border of the pyriform muscle and the spine of the ischium. It lies in close relation with the sciatic nerve, and with the internal iliac vessels. In the case related by Cooper, the obturator artery passed above, and the vein below the neck of the sac. From the depth at which such a hernia would be seated, and its small size, it would probably escape observation during life; but, if detected, it might readily be retained by means of proper bandages and a pad. Should operation ever be required, the deep incisions must be carefully conducted, on account of the great importance of the parts surrounding the sac.

DIAPHRAGMATIC HERNIA.

Congenital defect of the Diaphragm is occasionally met with.¹ It has consisted, in most of the recorded cases, of an aperture in this membrane, varying in diameter from an inch upwards; and amounting, in some rare instances, even to an entire absence of one or both wings of the diaphragm. Through these openings, the contents of the abdomen have been protruded; the stomach and small intestines being most frequently displaced, and the spleen and liver having been found in the chest in a tolerably large proportion of the cases. The hernia has been mostly observed in children at or soon after birth; but in several instances the subjects have lived to adult age, the hernia at last taking place apparently accidentally. In some of these latter cases, however, it may be a question whether the opening in the diaphragm was not the result of an accident, perhaps some time antecedent to the occurrence of the hernia. The opening has generally been found in the left side; sometimes, however, on the right.

¹ A most complete and interesting account of Congenital Diaphragmatic Hernia was published by Mr. Thomas Haller in the *Edinburgh Medical Journal*, for April, 1804.

Diaphragmatic hernia is sometimes obviously of traumatic origin, being the result of a wound or laceration of the diaphragm. It usually attains a large size, and commonly contains the stomach or the transverse colon and a portion of the omentum, which forms a tumor in the thoracic cavity, encroaching upon the lungs, and pushing the heart to one side. The hernia is not enclosed in a peritoneal sac, but has been found partially enclosed by the pleura. It occurs generally on the left side of the chest, but cases have been recorded by Percy and others where the injury of the diaphragm was on the right side. The following case is a very good instance of this rare affection.

A man, seventy-four years of age, was admitted into University College Hospital. About twelve months before, he had fallen into an area about six feet deep; he believed that he had injured his chest and head, as from that time he had suffered much from shortness of breath and occasional sensation of suffocation, had a hacking cough, and could not lie down without feeling some difficulty in breathing. At the time of the accident, he coughed up about three spoonfuls of blood. Ever since the accident, he suffered much from dyspeptic symptoms and constipation, though before he met with the injury he had experienced no inconvenience in this respect. About a month before admission, the difficulty in breathing increased; and four days before he came to the hospital, violent pain in the abdomen came on, and he ceased to act, although he took a variety of aperient medicines, and the enemata containing croton oil. On admission, the abdomen was much distended, tense, and tympanitic, with pain around the umbilicus; the tongue was coated with whitish-brown, moist fur; the pulse was small, quick and somewhat resisting; there was nausea, but no vomiting. The skin was cool and the countenance anxious; the bowels had not acted for seven days.

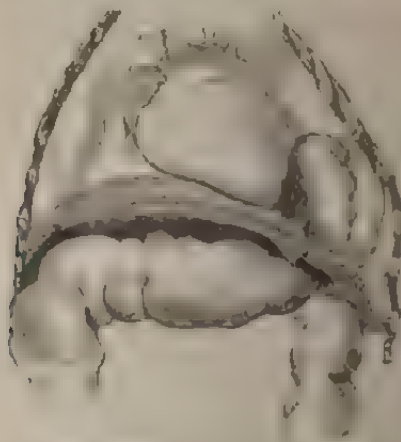

Fig. 801.—Diaphragmatic Hernia of Colon.

he had frequent desire to go to stool. He was ordered an aperient draught every third hour. As this had no effect he was directed to take calomel and chloridium pills, and to have turpentine enemata, which afforded him some relief, though they brought away no feces. The patient became more restless, the skin cold and flabby, the countenance more anxious, the breathing shorter, and the abdomen more tympanitic, and he died two days after admission, and nine from the commencement of the obstruction.

Examination of the Body twenty-four hours after death.—The abdomen was distended and tympanitic, and the peritoneal sac contained about six ounces of fluid, with here and there patches of recently effused lymph. The small intestines were not distended: the large were greatly distended with flatus, the cæcum extending into the cavity of the pelvis; the ascending and the transverse colon were much distended, and it was found that a large loop of the transverse and of the descending colon had passed through an opening in the cordiform tendon of the diaphragm into the pleural sac, and was there strangulated (Fig. 801). The colon below the stricture was contracted, and entirely empty. On opening the thorax, the loop of intestine, fourteen inches in length, of a pale slate-color, and distended with gas, was found in the left pleural sac. It reached as high as the fifth rib, touched the pericardium, and was overlapped by the free margin of the left lung. Where strangulated, it was of a darker color than elsewhere. The opening in the diaphragm, through which it had passed, admitted little more than the point of the forefinger, and had a thin tendinous margin. The tenth and eleventh ribs, on the left side, were found to have been fractured; the latter was united by bone, but the tenth rib, at the seat of fracture, had formed a false joint. Connected with this and with the intercostal space below it, was a firm adhesion about an inch broad and an inch and a half long, united by its other extremity to the protruded meso-colon and the diaphragm. The protruded meso-colon was firmly adherent to the upper surface of the diaphragm, close to the opening in it. The lungs were tolerably healthy. The right pleura contained three ounces, and the left eight ounces of serum.

CHAPTER LXIII.

INTESTINAL OBSTRUCTION.

Intestinal Obstructions may be of two distinct kinds, *Acute* and *Chronic*. These must not be confounded with one another, as they are usually dependent not only upon very different conditions, but require different lines of treatment for their relief.

Acute Intestinal Obstruction may arise from the following pathological conditions:

1. *Internal Strangulation.*—This may arise from a portion of gut slipping through an aperture in the mesentery or omentum, forming the so-called internal hernia. Or a portion of the intestine may be constricted by becoming entangled round a band passing from one part of the abdominal cavity to another. These bands may be entirely of new formation resulting from local peritonitis with the formation of adhesions which have become gradually stretched; whilst in other cases the strangulating band is composed of the vermiform appendix, or of a diverticulum from the ileum, the free end of which has become attached to some part of the abdominal wall.
2. A portion of gut may become twisted on itself, thus forming a valvulus, owing to the meso-colon or the mesentery being unusually long and allowing a half twist to take place, in consequence of which complete obstruction takes place. This occurs most commonly—in fact, almost exclusively—in the sigmoid

flexure and the descending colon. 3. In other instances, the symptoms of acute obstruction may arise in consequence of a stricture gradually closing, and then at last becoming suddenly occluded. 4. Foreign bodies obstructing the small intestine may cause the signs of acute obstruction. Amongst the most common of these, are large gall-stones which have found their way into the intestine by ulceration from the gall-bladder. 5. Severe and even fatal intestinal obstruction may occur as the result of inflammatory affections of the intestines without the existence of any mechanical lesion. It was formerly supposed that the same condition might arise simply from spasmodic contraction, but this is not supported by any sufficient evidence. 6. Acute obstruction frequently arises from invagination or intussusception, a part of

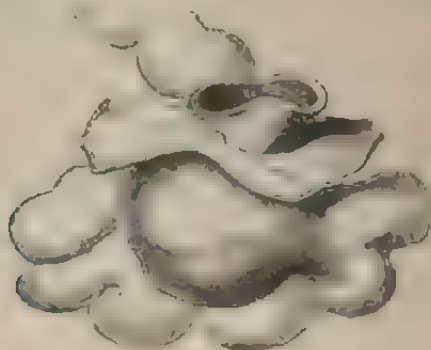

Fig. 502.—Intestinal Obstruction from Internal Hernia.

the intestine slipping into that below and being constricted by it; but, as this affection may assume either an acute or chronic form, and presents many peculiar features, it is best considered apart from other causes of obstruction.

The relative frequency of these forms of obstruction is well illustrated by the statistics published by Bryant, derived from the records of Guy's Hospital, and collected chiefly by the late Hilton Fagge. Of 124 cases of intestinal obstruction, 33 were acute, 76 chronic, and 15 were due to intussusception. Of the 33 acute cases, 1 was due to internal hernia, 7 to twists, and 25 to bands causing internal strangulation. Of the 25 bands, 14 were old adhesions, 6 were connected with diverticula from the ileum, 2 with the vermiform appendix, 2 with the neck of a hernial sac, and 1 with the pedicle of an ovarian tumor.

Symptoms.—The symptoms of acute intestinal obstruction, more especially when arising from a mechanical cause, such as the formation of an internal hernia, or volvulus, are always characterized by very marked vital depression. There is constipation from the very first; but this symptom is not the most prominent one, and those that result are evidently, as in an ordinary case of strangulated hernia, as much the consequence of the injury inflicted upon the intestine, as of the mere mechanical obstacle to the onward passage of the feces. At the moment of the occurrence of the strangulation, the patient is usually seized with a sudden feeling of something wrong having taken place in the abdomen; or, he is struck with intense pain at one point. This pain persists more or less throughout the case, and is sometimes violent and paroxysmal. There may be sudden syncope, though most usually the depression of vital power does not amount to this. Vomiting speedily occurs, at first of the contents of the stomach, but after a time of stereora-

ceous matter; sometimes it assumes this form almost from the very first. The abdomen becomes swollen and tender, the intestines being blown out with flatus, giving rise to immense tympanitic distention, rolling over one another, and occasioning loud rumbling and gurgling noises. If the abdominal walls be thin, the rolling of the intestines may be distinctly felt, and in many cases seen, through them; and may sometimes be observed to be continued up to one spot, where it ceases. At this point, an intumescence may sometimes be indistinctly felt corresponding to the seat of strangulation. If relief be not afforded, the sufferings of the patient become very severe, and his mental distress agonizing. The vomiting, perhaps, becomes less frequent, but the vital depression increases, and at last death results, usually about the sixth to the tenth day, though sometimes sooner, from exhaustion, peritonitis, or gangrene. The mind remains clear to the last, the patient's attention being intently and distressingly riveted upon the possibility of getting relief from the bowels.

CHRONIC INTESTINAL OBSTRUCTION.—This usually arises from one of five causes; viz., 1. The gradual obliteration of some portion of the colon in consequence of a malignant growth from its wall; 2. The compression of the gut by a tumor growing near it; 3. Chronic peritonitis, usually tubercular, but sometimes connected with diffused malignant growths in the peritoneum; 4. The obstruction of the large intestine by the accumulation of large masses of hardened feculent matter; 5. Intussusception may assume a chronic form, especially in the adult.

The relative frequency of these various causes is clearly shown in Bryant's statistics. Of 129 cases of obstruction, including intussusception, 76 were chronic; of these, 3 resulted from fecal impaction, 3 from pressure of tumors, 47 from stricture, and 23 from matting together of the intestinal coils from chronic peritonitis or cancer. Of the 47 strictures, 2 occurred in the small gut, and 45 in the large. To these 45 cases may be added 59 collected by Morris and Coupland. Of these 104 strictures of the great intestine, 78 occurred in the rectum and sigmoid flexure, 19 in the transverse colon or at one of the flexures, and 7 in the cæcum or ileo-colic valve.

The *Symptoms*, in the earlier stages of these cases, are commonly those that will be described as indicating stricture of the large intestine; but, when once complete obstruction has come on, the constipation becomes the most prominent symptom. In some instances, this will occur without any antecedent leading to the supposition of the existence of stricture. There may be comparatively little constitutional disturbance at first, but the bowels cannot be made to act, and any attempt at forcing their operation by the administration of purgatives gives rise to sickness and much distress. During the progress of the attack, eructations, retchings, and even vomiting, are of frequent occurrence, but it seldom happens that this is stercoreaceous till the very last; there may be much tympanites, with rumbling and gurgling of the intestines, but most frequently the abdomen fills slowly and gradually, and these symptoms do not occur till after some days have elapsed. The distress of the patient does not depend so much on the length of time that the obstruction has existed, as on the amount of tympanitic distention of the abdomen. The greater this is, the more urgent will be the symptoms. In many instances, life is prolonged for several weeks, for five or six, even after complete obstruction has set in; and in some cases a recovery may take place, even though a very considerable time have elapsed from the occurrence of the obstruction. In the case of a lady whom I attended many years ago with Mr. Powell, recovery took place, although there had been complete obstruction for upwards of five weeks; and I have seen other cases recover

in which from forty to forty-five days had elapsed before the obstruction was relieved.

INTUSSUSCEPTION, or the invagination of an upper into a lower part of the intestine is a common cause of intestinal obstruction, especially in children. It may occur in three situations—in the ileum, at the ileo-colic valve, or in the large intestine. Its most common seat is at the ileo-colic valve. Of the 124 cases of obstruction tabulated by Bryant, 13 were intussusceptions of these, 2 were rectal, 7 ileo-cæcal, and 6 in the small intestine. An intussusception, when examined after death, is found to be composed of three parts of intestine, one within the other. The outer tube or sheath is composed of the lower part of the intestine. It is thrown into numerous folds, which can readily be straightened out by slight traction, thus giving rise to apparent partial reduction of the invagination. The middle, or reflected tube, is turned inside out, so that its mucous membrane is in contact with that of the sheath. On making an incision through this, the inner, or entering tube is brought into view, the serous surface of which is in contact with that of the reflected tube. In the space between these will be found the mesentery belonging to the entering and reflected tubes. If the invagination has commenced at the ileo-colic valve, the vermiform appendix also will be found in this space. An intussusception increases entirely at the expense of the sheath, the line of reflection between the entering and reflected tubes remaining unchanged. The length of the part invaginated varies greatly. When limited to the small intestine it is usually short, not more than two or three inches in length; in the large gut as many feet may be involved. The inner and middle tubes show, as a rule, marked evidence of strangulation. They are intensely injected with blood and swollen, and the mesentery included in the space between is in a similar condition. It is this swelling that offers the great barrier to reduction. The strangulation is caused by the closely packed folds of the sheath at the point of reflection between it and the reflected tube. The fate of an unrelieved intussusception varies according to circumstances. If the strangulation is very slight, not being sufficient to cause gangrene of the inner and middle tube, while at the same time seriously or completely obstructs the passage of feces, death must necessarily occur sooner or later. If the constriction is sufficient to cause gangrene, adhesions may form between the upper part of the entering tube and the reflection between the sheath and the reflected tube, the gangrenous portion may then be cast off into the bowel, and complete recovery take place. Unfortunately the patient often perishes from exhaustion before this is accomplished.

The causes of intussusception are often uncertain. In children they are sometimes due to the irritation of worms or to the straining accompanying dysenteric diarrhoea. In adults the invagination not unfrequently commences at the seat of a tumor.

The symptoms of intussusception may be acute or chronic, according as the more or less tightly strangulated. In all cases the invasion is sudden, the patient feeling that something has gone wrong internally. If the case is acute, the signs of urgent intestinal strangulation are well marked, and are accompanied by tenesmus with the passage of a bloody mucus or gangrenous charge. Vomiting soon sets in, but does not become feculent for some time. In such cases the patient, especially if a young child, will die in the course of five days or a week from collapse. If older, he may recover from gangrene and separation of the included part of the intestine. Chronic cases occur more frequently in adults, but may be met with in children. In these the symptoms are more obscure. There is a sudden invasion, followed by paroxysmal pain, with some vomiting. The bowels may not be completely

obstructed, fecal matter escaping in small quantities, often mixed with blood, and this condition may last for some weeks, at last ending in complete obstruction. The abdominal distention is usually not great. The acute intussusception is usually situated in the ileum or at the ileo-colic valve in children; the chronic is commonly at the ileo-colic valve or in the colon in adults.

In all cases of intussusception there is a tumor at the seat of disease which can usually be felt through the abdominal walls. It is sausage-like in form, doughy to the feel, and becomes tense under manipulation from the peristaltic contraction of the gut composing it. It is tender, and the hardening during manipulation is accompanied by some griping pain. If the case be watched from the beginning, the tumor will be found to change its position as the invagination progresses; thus, when beginning at the ileo-colic valve, it will be first felt in the right iliac fossa, subsequently in the umbilical region, and often at last in the left iliac fossa. If the intussusception be ileo-caecal or of the great intestine, it often descends low enough to be felt by passing the finger up the rectum. In one case, related by Hutchinson, the intussusception was of such length that the inverted ileo-colic valve was extruded for some inches beyond the child's anus, and had been mistaken for and treated as a prolapsus. Such a condition is easily recognized by passing the finger beside the protruding gut into the rectum, which it is of course impossible to do in a case of prolapsus.

DIAGNOSIS. The diagnosis of the cause of the obstruction is of great importance; attention as to whether it assumes the acute or the chronic form, will throw some light upon the conditions that occasion it. It is often difficult to determine whether the obstruction is mechanical, or whether it depends upon some inflammatory affection of the intestine. The practice to be adopted in any particular case must at last be determined by a history of the symptoms, by a careful exploration of the abdomen and rectum, and by the light that can be thus thrown upon the question, as to whether the obstruction be dependent on causes that are removable or not by medical means. In many instances, the history of the case, the assemblage of strongly marked symptoms, and the result of abdominal and rectal exploration, enable the Surgeon to determine, without much difficulty, that the obstruction is dependent on causes that are not removable by any means short of operative interference. But, in other cases, no means that we possess enable us to arrive at a correct or even an approximate diagnosis. Cases are recorded that have ended fatally from obstruction in forty-eight hours, without sickness, fixed pain in the abdomen, or tympanites. These, however, are certainly exceptional, and do not bear upon the question as to the propriety of performing gastrotomy in those instances in which it can be satisfactorily determined that a mechanical obstacle, not removable by medical means, exists. That the diagnosis may so far be effected with tolerable certainty is evident, from the fact that, in all those cases of gastrotomy which have been of late years practised in this country, mechanical obstruction irremovable by any but operative interference had been diagnosed and was found.

In all cases of intestinal obstruction, certain conditions should first be excluded, which, though not generally included under the name, give rise to symptoms of a similar nature. These are lead colic, typhlitis, and general acute peritonitis. Lead colic may be in most cases recognized by the history, by the occurrence of previous attacks, and by the blue line on the gums. Typhlitis and perityphlitis may be recognized by the history of constipation, with gradually increasing pain in the right iliac fossa, followed by a somewhat sudden exacerbation when the peritoneum over the gut becomes impli-

cated. The obstruction is seldom complete, and vomiting does not form a marked symptom. There is fulness with acute tenderness over the tumor. In acute attacks there is usually a distinct elevation of temperature. In many cases there is a history of previous attacks. Acute peritonitis is recognized by the intense general tenderness, with distention of the abdomen and the peculiar vomiting without straining. The cases which most nearly resemble some form of acute intestinal obstruction are those arising from perforation of the vermiform appendix.

The first step in the diagnosis of any case of acute obstruction must always be a careful examination of the various abdominal and pelvic apertures for some of the more obscure forms of external hernia; for in cases of strangulated internal strangulation, it has occasionally turned out, after death, that a patient had been laboring under a small femoral, obturator, or scrotal hernia.

The points that will chiefly engage the Surgeon's attention in determining the nature of the obstruction are: 1. The previous history of the patient. 2. The mode of invasion. 3. The general condition of the patient. 4. The character of the pain. 5. The character of the vomiting. 6. The duration and degree of constipation. 7. The physical examination of the bowels. 8. Examination of the rectum. 9. The character and quantity of urine.

1. **The Previous History** often throws much light upon the nature of the disease. In cases of internal hernia or obstruction by bands or twists arising from intussusception, the patient has usually enjoyed good health up to the time of the obstruction, although in some cases there is a history of a previous attack of the same kind. If the other symptoms seem to point to strangulation by a band, diseases likely to cause local adhesions in the peritoneum such as typhoid fever, typhilitis, or ovaritis in the female may be required for. In chronic obstruction arising from gradual closure of a stricture there is a history of *gradually increasing difficulty* in obtaining relief from the bowels, with uneasiness and dyspepsia. Most commonly there have been periods of prolonged constipation followed by diarrhoea. These alternating periods of constipation and diarrhoea are very characteristic and should always raise a suspicion of stricture, most probably in the great intestine. In cases of obstruction of the small intestine from impaction of a gall-stone, there will be a history of *prolonged pain and discomfort in the region of the gall-bladder* during the time that the stone was making its way by ulceration into the intestine.

2. **Mode of Invasion.**—When the attack commences with *severe pain coming on so suddenly* that the patient can state the exact moment at which it seized him, or when this is quickly followed by the other signs of acute obstruction, and when up to the time of attack he was in good health, there is strong reason to believe that it is due to an internal hernia, a twist, or an acute intussusception. When the attack begins with *uneasiness, increasing a little at a few hours* until it becomes actual pain, followed at some interval by signs of obstruction it may be due to impaction of a foreign body such as a gall-stone, to inflammation of the small intestines, or to a sudden closure of an old stricture. When the symptoms begin *gradually*, with *uneasiness and constipation*, they may be due to any one of the chronic forms of obstruction.

3. **The General Condition of the Patient.**—*Early collapse* is a sign of the acute forms of obstruction, internal hernia, twist, or acute intussusception. The pulse is considerably quickened in all these. The temperature is variable, usually slightly elevated at first, but soon becoming normal. In the chronic forms collapse comes on slowly. In both acute and chronic

obstruction the tongue soon becomes furred and dry, and thirst is often a prominent symptom.

4. The Character of the Pain.—*Acute abdominal pain fixed in one spot with paroxysmal exacerbations* is met with in twists, or internal strangulations. In acute intussusception the pain is of the same character, but commonly less acute. In chronic intussusception the pain is *paroxysmal, but usually distinctly localized*. In chronic obstruction of the great intestine it is *diffused*, and there may be prolonged intervals of ease.

5. The Character of the Vomiting.—*Early severe vomiting speedily becoming stercoraceous*, is characteristic of acute obstruction of the small intestines. *Early vomiting, not stercoraceous* for from two to three days, is observed in twists of the great intestine, acute obstruction of an old stricture, in acute intussusception of the ilio-colic valve or colon, and in inflammatory affections of the small intestine. *Vomiting, slight at first, and not stercoraceous for a week or two*, is characteristic of chronic obstruction of the great intestine from chronic intussusception, stricture, etc. In chronic peritonitis, vomiting may be delayed for many weeks.

Vomiting, however, even when feculent, is not sufficient to determine the presence of complete mechanical obstruction of the bowels, for it may occur in cases apparently of inflammatory origin in which the obstruction is removable by medical means. Of this I have seen several instances—the feculent vomiting being very persistent, and the patient presenting all the other symptoms that are usually considered to be dependent on internal strangulation; but eventually recovering under the use of opium, and other medical means without the necessity of operative interference. It is, therefore, as necessary to bear in mind the occasional dependence of feculent vomiting on conditions that are removable by medical aid alone, as that it may be absent in cases in which the obstruction, whether seated in the small or in the large intestine, can be relieved only by surgical assistance.

6. The Duration and Degree of Constipation.—The duration of the constipation does not necessarily throw much light upon the cause. Indeed, if patients be naturally costive, constipation may last for a considerable number of days, or even weeks, without producing any very serious consequences. Most practitioners must have seen cases in which constipation has continued for three or four weeks, without destroying the patient. Johnson mentions a case, in which it lasted during forty-five days. In these cases, however, constipation has usually come on gradually, being, as it were, an aggravation of the patient's natural condition. It is the *character* rather than the mere duration of the constipation that is important. The sudden occurrence of irremovable obstruction, both of flatus and feces, in persons otherwise regular in their bowels, and the sense of its dependence on a fixed cause, are points of importance, as tending to show that it arises from an acute mechanical condition. In acute internal strangulation, the constipation is always sudden, and is accompanied or speedily followed by other symptoms indicating obstruction. In chronic obstructions the complete constipation is usually merely an aggravation of a previous condition. When the obstruction is in the small intestine, the patient feels no sense of desire to defecate. In obstruction low down this may be present, especially if it is due to fecal accumulation. In intussusception when the invaginated portion is in the colon, there is usually frequent straining and tenesmus. If the strangulation be complete and acute, nothing but a little blood-stained mucus will pass; if it be chronic, both flatus and feces may pass in small quantities with much straining.

7. The Physical Examination of the Belly. (*a*) *Inspection*.—The chief points to be observed are the distention of the abdomen, the form it has

assumed, the appearance of distended coils of intestine and peristaltic movements.

Distention of the Abdomen.—In acute obstruction distention quickly sets in and usually becomes very marked in a few days, often so great as to interfere with respiration and to form the most distressing symptom from which the patient suffers. In chronic obstruction from stricture of the great intestine it comes on gradually, and may at last become very great. In intestinal obstruction it is not very marked, especially in the chronic cases. In chronic peritonitis, or disease of the intestines, there is always some distention, but it never forms a prominent symptom.

The Form of the Abdomen.—When the obstruction is in the small intestine and acute, the distention is usually most marked in the epigastric, umbilical, and hypogastric regions, the flanks being less distended. In obstruction set down in the great gut the distended colon on each side fills out the flanks giving the abdomen a barrel-shape. In some cases of strangulated hernia or band or internal hernia, the abdomen may be irregularly distended, one region being more prominent than the rest. Too much importance must not be attached, however, to the form of the abdomen, as it is often deceptive. In women who have borne children, there is always great prominence in the umbilical and hypogastric region, whatever the cause of the distention may be.

Coils of intestine visible through the abdominal walls may be observed when the patient is thin, in all forms of obstruction in which there is much distention. The visibility is said to be most marked in obstruction from acute peritonitis. The distended coils of small intestines can be seen twisting and conger coils, and are often so large that they may be mistaken for transverse colon or sigmoid flexure, and thus lead to an error in diagnosis.

Peristalsis is often visible in the distended coils. This is said to be most marked when the obstruction is in the great intestine. When visible it must be taken as evidence that the distention is not due to paralysis of the gut as to acute peritonitis; but beyond this it is not of much value.

Percussion.—By percussion we try to ascertain the condition of the coils. In the normal condition the different notes given by the stomach, transverse small intestine, usually enable us to determine their positions, but in the distended abdomen the evidence thus obtained is often fallacious. The sound is always concealed by the distended intestines. If the small intestines are much distended, their note becomes indistinguishable from that of the large. Extreme superficial tympanitic resonance, uniform in note and extent of the liver-dullness, with a very pointed abdomen, indicates free gas in the peritoneal cavity either from actual or impending perforation. Hyper-resonance in each flank is usually a sign of distended colon. Dullness in the flanks disappearing on turning the patient on one side is usually evidence of fluid and may indicate that peritonitis is commencing. In a case in the College Hospital a few years ago, this sign was, however, found to be dependent on a loaded colon with a long meso-colon, which moved out of the flank when the patient was turned to the opposite side.

Manipulation.—By manipulation the degree of tension is estimated. It is of much diagnostic value in tubercular peritonitis, as the peculiar sensation may serve to show the nature of the disease. In intestinal obstruction the tumor already described may be felt, and in malignant disease of the colon the growth may be perceptible as a hard lump. In other cases distention usually conceals any tumor that may be present. Sometimes a tender spot may be recognized as the point at which pain is chiefly felt, and this may be of value in indicating the seat of obstruction.

8. **Examination of Rectum** should never be omitted; by it we ascertain the presence of strictures within reach of the finger, or tumors pressing on the rectum, and of fecal accumulations. In intussusception, we may feel the end of the invaginated intestine. Those whose hands are small enough to pass into the rectum, an uncommon condition in men, might possibly detect a malignant structure in the sigmoid flexure.

If the stricture be seated low down in the sigmoid flexure or at the upper part of the rectum, it may be recognized in some cases by a careful examination of the bowel with bougies.

Another method of examination often employed is the administration of the largest possible enema, with the view of ascertaining whether the obstruction is low down in the great gut. This is very fallacious, as the abdominal distention is often so great that even when the whole colon is free the patient cannot bear the injection of more than a few ounces of fluid.

9. **The Quantity of Urine.**—It is frequently stated that in obstruction high up the quantity of urine secreted is diminished, owing to the lessened extent of intestinal surface capable of absorbing liquids. That scanty urine is commonly met with in these cases is undoubted, but it is probably due to the fact that the patient vomits all the liquid he takes.

By attention to the foregoing points, there may be no great difficulty in coming to an accurate opinion as to whether the obstruction is in the large or small intestine. It may also be borne in mind that with the exception of twists of the colon and acute intussusception, all acute obstructions are seated in the small intestine, while the great majority of chronic are in the large. The earlier occurrence of feculent vomiting when the obstruction is in the small intestine, the greater tympanitic distention and bulging in the course of the cæcum and colon when it is seated in the large intestine, and the result of careful exploration of the rectum, will most commonly enable the Surgeon to decide this question with sufficient precision to guide him in the choice of an operation. Yet cases do occur in which, though the obstruction be seated in the large intestine, the symptoms are acute and evidently not dependent on chronic obstructive disease, vomiting is of early occurrence, the distention of the abdomen slight, and exploration by the rectum yields no result; and it is in cases of this description, presenting a train of symptoms of mixed and uncertain character, that the diagnosis of the precise seat of the obstruction cannot be made with sufficient precision to justify operation.

The most important point to determine in reference to the operative treatment of intestinal obstructions, is whether the seat of occlusion is so situated that relief can be given by "Amussat's operation," in which the colon is opened behind, and not through, the peritoneum. This can be done whenever the obstruction is below the lower end of the descending colon, by the ordinary operation on the left side, and in those rare cases in which it is seated in the transverse or ascending colon, by the same operation on the right side. If the obstruction is above this, it will be necessary to do Gastrotomy, or, as it is more correctly termed, Laparotomy, an operation by which the peritoneal cavity is opened, and the peril to the patient thus greatly increased.

In all doubtful cases it is better not to rush hastily to a conclusion. The patient should be carefully examined, all the points mentioned in the preceding pages being carefully considered. A list of all the causes of obstruction should then be made, and each considered in order. By thus eliminating the various causes one by one, a correct opinion will in most cases be arrived at.

TREATMENT. Treatment of Acute Obstruction. This must necessarily be in a great measure determined by the diagnosis that is made as to the cause. The treatment of intussusception presents so many special points that it will be better to consider it separately. If the general obscurity of the symptoms in these cases renders an exact diagnosis in the early stages almost impossible, it is generally expedient to try the effect of proper medical treatment, which will sometimes, even in apparently hopeless cases, afford relief. In former times it was the custom to administer purgatives in these cases, but it has long been recognized that they do nothing but harm; they increase the pain and vomiting, exhaust the patient, and can have no influence over any real intestinal obstruction. The only plan that appears to me of any value is the continued administration of opium, accompanied by hot fomentations to the abdomen. It was formerly the custom to add a small quantity of calomel to the opium, but further experience has shown that this is not necessary, and as it might possibly cause some irritation of the intestine it is better avoided. The opium may be given in the usual form; but in acute obstruction, if there is much vomiting this would be useless, and hypodermic injections of morphia then be administered. It may be given in such quantities as to relieve pain; usually about one grain of opium, or a quarter of a grain of morphia hypodermically every six to eight hours will be found sufficient. This treatment will in all cases be of considerable service, and in some, even the most hopeless and complicated cases, afford satisfactory results. In a very complicated case of intestinal obstruction which I attended with Garrod, this plan was eminently successful. A patient was admitted into the Hospital, having symptoms of internal strangulation; he had at the same time double inguinal hernia, and a second umbilical rupture, as well as the remains of a fatty tumor, which had been partially removed from the abdominal wall many years previously. There were peritonitis with tympanites, stercoraceous vomiting, and much abdominal depression; but, as there was no strangulation existing in any of the external hernia, and as there was no evidence as to the precise locality of the internal mischief, it was not thought advisable to have recourse to operation. The patient was accordingly treated with opium, when, on the tenth day the obstruction gave way and the bowels acted, the patient ultimately recovering.

H. O. Thomas, of Liverpool, who has paid considerable attention to the subject of intestinal obstruction, and advocates the exclusive use of opium in all forms of the affection, gives some valuable practical directions for the management of these cases. He insists that the drug must always be administered hypodermically, and in sufficient quantity to relieve all pain. The patient must of course be confined to the recumbent position. Food must be limited to the smallest possible amount, and must be exclusively liquid. Arrowroot or ground rice and cooked with water, with the addition of a little brandy or wine, is the food he chiefly recommends, mutton or chicken broth being occasionally allowed as a change. Milk he has never found to aggravate the symptoms. On small quantities of this food, and at intervals of two hours, a patient kept warm in bed and under the influence of opium may maintain life for many weeks without serious loss of strength. Should natural relief take place, the restricted diet and rest should be continued till all pain has passed away and the bowels have become regular. In cases of acute obstruction with severe vomiting, Thomas states that the patient experiences much relief from having the foot of the bed raised about ten inches on blocks, by which the act of vomiting is facilitated. He advises that the abdomen should be kept cool. If symptoms of collapse appear, he recommends the hypodermic injection of small doses of atropine.

Inversion of the Patient is an empirical method of treatment that has occasionally proved successful in the relief of cases of internal strangulation of an obscure character. It is applicable only to those cases in which the sudden invasion of the disease and the acuteness of the symptoms lead to a strong presumption of the presence of a twist or internal hernia. It is useless to attempt it if there is great abdominal distention. The operation is done as follows. The patient is anesthetized to complete muscular relaxation. He is then suspended by the flexed knees over the shoulders of a strong man. The small intestines will then be seen to gravitate towards the epigastrium, the pubic and iliac regions becoming hollow. The abdomen may now be gently manipulated, and the man who supports the patient may raise himself on his toes and come down sharply on his heels so as to give a slight concussion. In a case at University College Hospital, of extremely acute obstruction with violent stercoraceous vomiting, this treatment was immediately successful. As the patient was inverted there was a loud gurgle and a feeling like the reduction of a large hernia was perceived by the hand on the abdomen. I have seen a case of fatal obturator hernia—unrecognized during life—in which at the *post mortem* examination it seemed probable that inversion and shaking would have effected reduction and so saved the patient.

Enemata are useless and usually injurious in cases of acute obstruction.

The external application of belladonna has been recommended with the view of stimulating the peristaltic action of the intestine, but it does not seem to have been of any service.

Puncture of the Intestine by means of a trocar or the aspirator for the purpose of withdrawing flatus in cases of great distention has been frequently performed, sometimes with great relief to the patient. It may be safely done with a trocar, about a tenth or twelfth of an inch in diameter. This must be introduced at the most prominent resonant point. The trocar is then withdrawn and the canula left in for from five to ten minutes, the gas being allowed to blow off. It must not be moved about needlessly while it is in the gut. When no more gas escapes, the vacuum of the aspirator may be applied to it as it is withdrawn, to prevent any fecal matter falling into the peritoneal cavity. If the canula becomes choked with fecal matter, it should be withdrawn. The puncture is rarely followed by any escape of feces into the cavity of the abdomen. In some apparently hopeless cases relief of the obstruction has been known to follow the paracentesis of the intestine.

Operation for Acute Intestinal Obstruction.—When a patient is suffering from the symptoms of internal strangulation which resist medical treatment, and have not yielded to inversion—if it have been thought expedient to employ it—he will to a certainty die, unless relief can be afforded by operation; and two great questions will at last press themselves upon the Surgeon's attention: 1, whether it is advisable to have recourse to operative interference; and, 2, when it is proper to undertake it. The solution of these questions is fraught with difficulty, and must always be a matter of the most anxious consideration to the Surgeon. It is not only that he knows that, if the patient be left unrelieved, he must necessarily die; but that he is aware that the only means of relief, gastrotomy, is probably nearly as fatal as the disease for which it is undertaken. But the difficulties that present themselves in the solution of the question are much increased by the great obscurity in diagnosing the cause of the obstruction, for in many cases it is absolutely impossible to determine with certainty whether it arise from mechanical causes or not; and by the fact that apparently desperate cases occasionally recover without operation. If, however, by attention to any of

the points that have been pretty fully adverted to, it can be satisfactorily made out that there is an internal strangulation, and more especially if the intumescence occasioned by it can be felt, it will evidently be the duty of the Surgeon to give the patient his only chance by the division of the stricture. With regard to the time at which this should be done, the only general rule that can be laid down is probably the conclusion arrived at by B. Phillips: that operation is justifiable when three or four days have passed without any relief from ordinary means, constipation being complete, and vomiting of fecal matters continuing. The details of the operation will be described on a subsequent page.

Treatment of Intussusception.—There can be little doubt that spontaneous disentanglement occurs in many of the slighter cases of intussusception. In others **Inflation of the Obstructed Intestine** by the injection of air into the rectum has been recommended, and has occasionally been practised with success. In two instances I have successfully had recourse to it. One was the case of an infant, a few months old, seized with symptoms of intussusception, whom I attended with Cousins. The other patient was a young lady about ten years of age, to whom I was called into consultation with Sir T. Watson, Dr. Murphy, and Dr. West; inflation was performed on the fifth day after the setting in of symptoms of acute intestinal obstruction, apparently dependent on intussusception. The proceeding was followed by perfect success: the child felt "as if a bone broke" in the abdomen, the obstruction was removed, and motions followed in three hours, though all the previous treatment had been unavailing. For the convenient performance of this operation, I have had an apparatus constructed, consisting of a circular double-action bellows, with a long vulcanized India-rubber tube, furnished with a stop-cock and rectum-tubes of different sizes for children and adults. Should this not be at hand, a well-fitted stomach-pump will answer the purpose. In performing this operation too much force must not be used, as serious injury to the intestine has been known to result. This treatment cannot be expected to succeed in any case of intussusception except that of the large intestine; even if it be at the ileo-cæcal valve little good usually results from it.

Operation for Intussusception.—If this treatment has failed, the only chance of recovery without operation lies in the sloughing away of the invaginated portion of gut. And what is this chance by natural cure? The answer given by statistics is as follows: J. L. Smith, of New York, collected the details of 59 cases; of these 7 recovered. Haven, of Boston, found that of 59 cases, there were 10; and Duchaussoy, that out of 135 cases, there were 29 recoveries. The chance of life by natural means, therefore, is about 15 per cent., or rather more than one in five—not a very hopeful one, truly. In these circumstances, Surgeons have naturally looked to gastrotomy, and the manual disengagement of the invaginated gut, as offering a better prospect of life. And this operation has undoubtedly in many cases been followed by recovery, since, under the directions of Nuck, the first well-authenticated successful operation of this kind was performed. Ashurst has collected the particulars of 13 cases in which abdominal section was performed for intussusception. Of these, five succeeded; and more recently the operation has been successfully practised by Hutchinson, Howard Marsh, Godlee, and others. But the prospect of success will greatly depend on the nature and seat of the intussusception. If the strangulation be very acute, and if the disease be seated in the ileum, the chances are not so favorable by any means as in the more chronic form of the affection, when the large intestine is the seat of the invagination. In these cases the gut is incarcerated rather than strangulated. There is, as Hutchinson has well pointed out, no

hope of natural cure by gangrene of the included portion, and the patient will die, worn out by irritation and pain, unless relieved by operation.

If the invagination be attended by acute symptoms of strangulation the operation is not advisable, as in these cases it would probably be impossible to disentangle the swollen gut, and moreover, it is in these that there is the best hope of a natural cure by separation of the strangulated portion. In infants under one year recovery very rarely takes place by separation of the invaginated gut, so rarely that not more than one or two cases of spontaneous recovery are on record. In these cases the operation seems to hold out almost the only hope of cure if inflation fails. As to the time at which the operation should be performed, no definite rule can be laid down. In acute cases, the earlier it is done after other means have failed the better, if the case be one in which it is justifiable. If the invagination be chronic, and colic occur in an adult, the urgency for early operation is not so great, though the necessity will eventually be greater.

Treatment of Chronic Intestinal Obstruction.—As before stated, this arises most commonly from one of the following causes: fecal impaction, compression of the great intestine by a tumor, stricture of the large intestine, chronic intussusception, and chronic (tubercular) peritonitis.

Fecal impaction is most common in elderly women. When it is suspected, the rectum should be explored, and if it be found to be blocked up by a rounded mass of indurated and impacted feces, the surgeon must condescend to undertake the duties of the nightman, and empty the human cloaca of its fetid accumulations. This is best done by anesthetizing the patient, then dilating the sphincter ani with the hand, breaking down the indurated mass with a spoon or lithotomy scoop, and washing it away by copious enemata.

If the obstruction arises from the gradual compression of the rectum by an *intropneumatic tumor*, or from the slow constriction of it or the colon by *malignant disease of the walls*, purgatives will be worse than useless; they will irritate, will often induce vomiting, and will always considerably increase the patient's distress, and should not be repeated. The patient should be kept quiet in bed and have a limited supply of food; such as leaves little residue being preferred, the best being beef-tea, meat with arrowroot and a small quantity of brandy. Milk and soda-water is sometimes taken easily, but very often milk in any form and eggs are not easily digested. Enemata may be fairly tried, but if they do not soon overcome the obstruction nothing is gained by persistently annoying the patient with them. In some cases the introduction of the tube of a stomach-pump as far as possible, and the administration of an injection in this way may bring about relief. If the stricture is within reach, a catheter can sometimes be introduced through it, by means of which a large olive-oil enema may be administered, and in this way the obstruction may be overcome. If these means do not succeed, opium may be administered, and very often, sometimes after some weeks, the obstruction may give way. Thomas states this has frequently occurred in his practice, and that he has been able to prevent the early return of the obstruction by keeping the patient on the restricted diet already mentioned.

When other means have failed and the patient is becoming exhausted, operative interference becomes necessary. When, as is the case in the great majority of cases, the disease is seated in or below the sigmoid flexure, the descending colon may be opened; but should there be any reason to believe that the obstruction is situated at a higher point, the operation must be performed on the right side.

In *chronic intussusception* inflation of the gut may be attempted, and if that fails, the only chance for the patient lies in gastrotomy.

In *Tubercular and other forms of chronic peritonitis* no operative interference

is justifiable. It is in these cases that relief has sometimes been obtained by kneading the abdomen (massage), or by electricity.

OPERATIONS FOR INTESTINAL OBSTRUCTION.—**Gastrotomy**, or, as it is more correctly termed, **Laparotomy**, may be required for acute intestinal obstruction, from: 1. Internal strangulation, however produced; 2. Volvulus, or a semi-twist of the large intestine on itself; 3. For intussusception occasionally when acute, and more often when chronic.

In performing the operation of gastrotomy, all the rules already laid down for abdominal operations in general must be attended to (p. 767). The patient must be laid on a high table, the legs being allowed to hang over the end of it, so as to afford a full view of the abdomen. The anæsthetic having been administered, and the bladder emptied, the incision should be made below the umbilicus in the middle line. If the patient be very fat it may be necessary to enlarge the wound upwards. Even in cases, such as intussusceptions, in which the tumor is situated on one side of the middle line, the median incision will always be found the best. It is accompanied by less hemorrhage, and leaves less tendency to the occurrence of a ventral hernia. The linea alba then having been exposed, the incision must be carried through the abdominal wall until the peritoneum is reached; this must then be done by means of a probe-pointed bistoury guided by the forefinger of the left hand. The incision should at first be only just large enough to admit the hand, which may be introduced, without allowing the intestines to escape. It is possible that in this way the constricting band might be felt and ruptured, the intestine relieved from it. If this cannot be done, the hand must be withdrawn, when some of the coils of the small intestine will protrude through the wound, curling over its edges. These must be carefully supported by an assistant, who should press upon them with a soft linen towel moistened with a warm solution of carbolic acid 1 in 50. By following the intestine along, reducing one part as the next is withdrawn, the obstruction may at last be reached. It is usually recommended to find the collapsed part of the intestine and to follow this upwards, but this is more easily said than done, as the distended coils of the intestine above usually obscure the empty part below. It will usually be found that, however careful the Surgeon may be, if there is much distention, a large part of the intestine will be exposed before the obstruction is found. If there be a hernial constriction formed by a large adventitious fibroid band, he may divide the band that constitutes the stricture on a director by means of a probe-pointed bistoury or hernia knife; or he may break it through with the finger: or he may withdraw the constricted coil of intestine from an aperture in the omentum or mesentery into which it has slipped. If it be a case of volvulus, the colon may be untwisted, as in a case on which I operated in 1849.

If the case be one of intussusception, it is usually useless to attempt to reduce the invagination without bringing the whole tumor out upon the abdominal wall. This can usually be done without difficulty, and as the distention in these cases is seldom great, it may be accomplished without allowing the small intestines to escape. Reduction must be accomplished by a process of kneading and drawing down the sheath, rather than by attempting to drag out the entering tube. If reduction is impossible, the Surgeon has three courses open to him. He may return the tumor to the patient to his chance of a natural cure; he may bring out the protruding intestine and make an artificial anus in the wound; or he may excise the whole invaginated part and sew the two ends of the gut to each other. The course to be adopted will depend on circumstances. As it is presumed that the operation has been undertaken because there was no hope of a spontaneous cure, the first course is not likely to be successful, though it may

cases it is the only one that can be adopted, owing to the exhausted state of the patient. The second will leave the patient an artificial anus in the most inconvenient position. The third plan would, therefore, be the best to adopt if the condition of the patient is such as to allow the necessary time for its performance. The chances of recovery are, however, not great, whichever plan be adopted.

After the obstruction, whatever may be its nature, is removed, the intestines must be returned and the wound closed and dressed as described on p. 738. The abdomen must be well supported by a bandage, and the knees must be bent over a pillow. Opium must be continuously administered, and nothing but ice and barley-water allowed for from twenty-four to forty-eight hours. The mortality following gastrotony for the relief of intestinal obstruction is, as might be expected, very high, amounting to about 80 per cent. Thus, Ashhurst finds that, in 57 cases in which the operation was done, there were 11 recoveries only.

Colotomy.—The operation required to give exit to the intestinal contents is of two kinds. In one the intestine is opened in the left iliac fossa, by cutting through the peritoneum covering it. In the other it is opened in the loin by cutting between the layers of the mesocolon, being thus exposed where it is uncovered by peritoneum.

Colotomy may be required for the following conditions:

1. Intestinal obstruction below the descending colon.
2. Intense pain in defecation, in ulcerated cancer of the large intestine or rectum.
3. Cancerous fistula between the rectum and bladder.
4. Congenital absence of the rectum.

Littre's Operation. Inguinal Colotomy.—The first operation, or Littre's, as it has been called, was proposed by a Surgeon of that name, in 1710, who advised that in these cases the sigmoid flexure of the colon should be opened from the left iliac region; but it was not until the year 1776 that any operation of the kind was performed, when Pillore, a Surgeon of Rouen, was the first to make an artificial anus on the adult, for the relief of retention of feces; this he did, not according to Littre's method, but by opening the cæcum from the right iliac region. Pine, of Geneva, in 1797, opened the transverse colon from the umbilical region, in a case of retention of feces produced by "scirrhus" of the upper part of the rectum.

Littre's operation is thus performed: An incision is commenced at the level of the left anterior superior iliac spine, and carried downwards and inwards, nearly parallel to Poupart's ligament for from two and a half to three inches. The muscles and fascia transversalis fascia are then divided in the same way as in the operation for ligature of the external iliac artery. The peritoneum is then opened and the distended sigmoid flexure usually at once presents in the wound. It is then drawn into the wound and secured by a sufficient number of stitches. These should be made to include the peritoneum and skin in the abdominal wall, but should miss the muscles. If the case is not urgent, the stitches may be made to penetrate the muscular and serous coat only, and the gut left unopened till the third or fourth day. If it is necessary to open the gut at once, the sutures may penetrate the whole thickness of the gut. On opening the peritoneum a piece of small intestine may present instead of the colon; this is recognized by the absence of bands and appendices epiploicæ, and by the fact that if its mesentery be gently pulled it will be felt to be fixed towards the right, while the colon is fixed to the left side.

Amussat's Operation, or Lumbar Colotomy.—In order to avoid the complication of wounding the peritoneum, Cullisen, of Copenhagen, in 1796,

proposed opening the colon from behind, in the left lumbar region, where it is not covered by peritoneum. He once attempted this operation on the dead body of a child; but, failing in his endeavor to reach the intestine without wounding the serous membrane, he seems to have relinquished all further idea of it; and it was subsequently rejected as impracticable by all writers on Surgery who treated of this subject.

The operation of colotomy proposed by Callisen, was first practised and perfected by Amussat. It is one of the most important additions to operative Surgery, and affords an admirable illustration of the important practical application of an apparently trivial anatomical fact, viz., the relation of the layers of the meso-colon to the descending colon.

Amussat, at the time when he was attending the celebrated Broussais for that "scirrhus" affection of the rectum, of which he ultimately died, was led to reflect on the resources that Surgery offers in similar cases; and after making some experiments on the dead body, with the view of contrasting the merit of the different operations that have been proposed for the formation of artificial anus in cases of obstruction of the large intestines, he became convinced that the operation proposed by Callisen, if somewhat modified, was not only practicable, but safe. He soon had an opportunity of putting this opinion to the test of actual practice, in 1839, in a private case, at which he kindly invited me, then a student in Paris, to be present; and since this time the operation has taken a recognized position in Surgery.

The following is the best method of performing Lumbar Colotomy: If the operation is to be performed in the ordinary situation, the patient must be placed on his right side, with a firm, folded pillow beneath the flank so that the body may be slightly curved to the right side, and the space between the last rib and the crest of the ilium on the left side made as wide as possible. The Surgeon then measures from the anterior superior to the posterior superior spine of the ilium, carrying the tape straight from one to the other, and not along the crest of the ilium. From the mid-point between the two spines (Heath), or half an inch behind it (Allingham), a vertical line is drawn upwards, as in Fig. 803. This corresponds tolerably accurately to

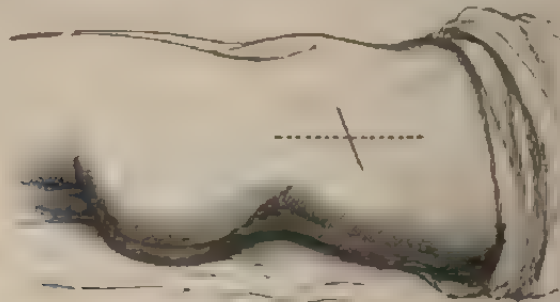

Fig. 803.—Line of Incision for Lumbar Colotomy. Dotted line indicates situation of Descending Colon.

the line of the colon. In this line a point is taken exactly mid-way between the last rib and the crest of the ilium. An incision, either transverse or inclined slightly downwards and forwards (Fig. 803), is then made, passing through this point. It must be from three to four inches in length, half on each side of the vertical line. If the measurements have been correctly taken, the posterior extremity of the incision will be at the edge of the erector spinæ. In fact, the edge of this muscle is practically a better guide

than the vertical line just mentioned. The incision is steadily deepened through the skin and superficial fascia by light strokes of the knife. After these are divided, the external oblique comes into view in the anterior two-thirds of the wound, and the latissimus dorsi in the posterior third; these are divided by drawing the knife lightly along the wound, and the internal oblique is then exposed and cut through in the same way. The fascia lumborum now comes into view. This is the first important rallying point. It must be picked up carefully with the dissecting forceps, and opened with the knife held horizontally; the finger, guiding a probe-pointed bistoury, may then be introduced through the opening, and the fascia lumborum divided freely to the whole length of the wound. At this stage, the last dorsal nerve and the artery accompanying it are usually divided, and the vessel must be twisted or tied. The incision through the fascia lumborum always opens the sheath of the quadratus lumborum, the external border of which must be freely notched if it obstruct the wound. In dividing the muscles, two points must be attended to: first, that these structures are divided to the same extent as the skin, otherwise the Surgeon will continue to dig in a deep and conical pit, and will certainly fail to recognize at the bottom of it the gut of which he is in search; and, secondly, to avoid drifting downwards towards the crest of the ilium, as the incision is deepened from drawing the wound to one side with the left hand.

At this stage of the operation two copper spatulae must be put into the wound, by which it is drawn widely open. Some loose fat then comes into view, which must be carefully torn through with the fingers, no forceps or other instrument being used. In thin patients this fat is wanting. The fascia transversalis next appears. This is a very variable structure; in fat females it is scarcely recognizable, while in a thin male it is often so strong as to be mistaken for the peritoneum or the gut. It must be carefully torn through at the posterior part of the wound. The subperitoneal fat is then exposed, varying in amount with the fatness of the patient, and must be torn through carefully with the fingers. The gut is now reached. If the operation is being performed for obstruction, the colon is tensely distended, of a greenish color, and usually rises up into the wound. In cases in which this operation is being undertaken for relief of pain in cancer of the rectum, the gut may be collapsed. In this state, not only is it difficult to find, but the part uncovered by peritoneum is so small that it is difficult to make an opening without wounding that membrane. All these difficulties are at once overcome by distending the gut with air. Lund has invented an ingenious apparatus for this purpose, but the gut can easily be distended by means of an ordinary enema-syringe, the anus being closed around the tube by a mass of wet or oiled wool pressed against it by the hand of an assistant. As the air enters the gut will be seen and felt rising up in the wound (Fig. 804); and in most cases, if the transversalis fascia have been sufficiently torn through, it will rise up to the level of the skin. If from any reason this fails, the gut may be found by pushing the forefinger into the wound till the lower end of the kidney is felt, immediately in front of which the colon lies. Pressure on the abdomen will sometimes make it appear. In other cases it may be found by turning the patient on his back, passing the forefinger into the posterior part of the wound, and then seizing between it and the thumb the parts in contact with it. The patient is then rolled back on to his side and the gut drawn up into the wound. In whatever way the gut is seized, it must be drawn well up to the level of the skin. Two silk threads, each about two feet long, are then passed through the gut and the skin and fat on each side of the wound in the following way. A curved needle is threaded on the suture; it is first passed through the skin and fat on one

side of the wound, then longitudinally through the anterior part of the gut exposed, including about one inch of it; finally the needle is passed from the wound opposite to the point at which it entered on the other side. A similar thread is then passed in the same way, including the posterior part of the gut exposed. Care must be taken not to puncture the peritoneum with the anterior thread. An incision is then made into the gut between the two sutures, the finger introduced, the loops pulled out and divided and tied. Thus the gut is rapidly secured by four sutures immediately after being opened, and fecal matter is prevented from running into the wound (Fig. 804). More sutures may be put in afterwards if necessary. If much escape of feces is expected, the wound may be touched with chloride of zinc (gr. 40 to 50), and the posterior part over which fecal matter will flow may be smeared with iodo-vaseline ointment or carbolic oil before the gut is opened.

Fig. 804.—Incision in Left Lumbar Region in Amussat's Operation.

Fig. 805.—Colon opened and Sutured to Sides of Incision.

The gut should be brought as far back in the wound as can conveniently be done. After the operation the anterior part of the wound may be closed with sutures, but the posterior should be left partly open, and, if necessary, a drainage-tube introduced to prevent any borrowing of pus in the loose sub-peritoneal areolar tissue. A pad of carded oakum, or some other absorbent antiseptic material, is then applied and changed frequently. A piece of lint soaked in carbolic oil (1 in 10) may be applied next the skin, a hole being cut through it opposite the gut.

After colotomy, the patient will derive much comfort from taking powdered charcoal. It not only deodorizes, but also tends to harden the feces. When recovery has taken place, the aperture in the lumbar region may be kept supported and closed by means of a truss with a large pad.

Wound of the Peritoneum is the most serious accident during the operation, as it may be followed by peritonitis, but is by no means necessarily so. It may occur in three stages of the operation: 1, while dividing the fascia lumborum, from too free use of the knife; 2, the posterior reflection may be torn with the finger by using it as a hook to drag the gut up into the wound; 3, it may be punctured by the needles, or wounded by the knife in opening the gut. In rare cases free gas is met with in the peritoneal cavity, and this may lead to the peritoneum being mistaken for the gut. In some cases there is a complete meso-colon met with, so that it is impossible to open the gut without wounding the serous membrane. In fat subjects the depth of the wound increases the difficulty of the operation, in some cases necessitating a crucial incision to give more space. Different Surgeons have variously modified the operation by making the incision vertical, or semilunar instead of transverse, but the method above described is that usually preferred.

After colotomy two complications are not uncommonly met with, contraction of the wound and prolapsus of the gut. The first must be treated by introducing a conical vulcanite plug, which must be constantly worn; the second by a properly constructed pad, secured by an elastic belt.

The causes of death after colotomy are usually exhaustion, septicæmia,

peritonitis from wound of the membrane, and occasionally secondary peritonitis from burrowing of pus in the subperitoneal fat towards the iliac fossa.

Comparison of Littre's and Amussat's Operations.—When we compare the different operations that have been proposed for the formation of an artificial anus, it will be seen that Callisen's, as modified by Amussat, presents the great advantage of not implicating the peritoneum, and the risk of peritonitis is thus avoided. The danger of death from this cause in Littre's operation does not seem, however, to be so great as might have been supposed, and its advocates claim for it the advantages of being a less severe operation and of placing the new anus in a more convenient situation, as the patient is able to cleanse it himself. Also, when the operation is performed for congenital absence of the rectum, Littre's is said to be preferable, as being much less difficult and more certain to reach the gut, which is often in infants attached by a long meso-colon in the left loin. It is said also that the risk of peritonitis in Littre's method is less than when the peritoneum is accidentally wounded in Amussat's operation, as the uniform pressure of the anterior abdominal wall tends to prevent the entrance of fecal matter into the cavity. The fact that the sigmoid flexure is so often the seat of the disease in malignant stricture is, on the other hand, a very strong argument in favor of Amussat's operation in all such cases.

Cesar Hawkins has collected and analyzed 44 cases, in which an artificial anus was formed by opening the intestine; in 17 of these the artificial anus was made through the peritoneum, and in 27 behind that membrane; but for various reasons, which are stated at length in the paper, Hawkins excludes 5 of the cases of peritoneal section, leaving only 12 to compare with 26 cases of operation behind this membrane. Of the former he finds that 7 died and 5 recovered; the recoveries amounting, therefore, to only forty-one per cent. in the cases of this category; whilst of the 26 cases where the peritoneum was uninjured, 10 died and 16 recovered; the proportion of recoveries in the cases of this category amounting to sixty-one per cent. Though the large intestine was opened in all these cases, the operation was performed on the right side in 10 instances; in 4 cases the right colon and cæcum were opened through the peritoneum, and of these all died; whilst of the remaining 8, in which the right colon was opened behind the peritoneum, 4 recovered. The preference, therefore, as Hawkins observes, on the right side, is certainly due to the lumbar operation. It is remarkable, however, that in the operation on the left colon, the results are somewhat different; for, of 8 cases in which this intestine was opened through the peritoneum, 5 recovered and 3 died; whilst of 20 cases in which the lumbar operation was performed, 11 recovered and 9 died. Hawkins observes, that the inequalities of the numbers appear, however, to leave the question as to the mode of operating on the descending colon still undecided; and that an operator is justified in selecting whichever situation he thinks best for the formation of an artificial anus on the left side of the body.

Van Erckelens, who has collected 262 cases of colotomy, confirms the opinion expressed by Hawkins. Of the 262 cases, 165 were performed by Amussat's method, and of these 63 died, about 38 per cent.; 84 were performed by Littre's method, and of these 39 died, or about 46 per cent. In the remaining cases the method of operating was not recorded. Of the 262 cases, 110 were for cancer, 49 for stricture, 44 for imperforate anus, 43 for intestinal obstruction, and 16 for fistulous openings from the rectum into neighboring passages. The difference in the mortality is, therefore, not great, but yet is distinctly in favor of Amussat's operation. Of those cases in which death has resulted from Amussat's operation, a large proportion appear to have been due, not directly to the operation, but to the influence of the

previous disease, the operation having occasionally been uselessly done at the last extremity. We should, therefore, have less hesitation in performing the extraperitoneal operation in an early stage of those cases in which it is useful, than we should if the section itself were attended with any serious risk to the patient's life.

CHAPTER LXIV.

TAPPING THE ABDOMEN—OPERATIONS ON THE ABDOMINAL VISCERA—TUMORS OF THE GROIN.

TAPPING THE ABDOMEN. PARACENTESIS ABDOMINIS.

THE abdomen often requires **Tapping**, either for general or encysted ascites. This operation, which is one of the simplest in surgery, may be performed as follows. The bladder having been emptied, the patient is seated on the edge of the bed or of a large chair, or if very weak lies on the ear, and has a broad flannel roller, split at each end to within six inches of the middle, passed round the body in such a way that the anterior part covers the front of the abdomen, whilst the ends, which are crossed below, are given to an assistant on each side, who must draw tightly upon them as the water flows. The surgeon then, seating himself before the patient, and having ascertained that there is absolute dulness at the point at which he intends to operate, makes a small incision with a scalpel into the meso- or about two inches below the umbilicus, and through the opening that can be thrusts the trocar; as the fluid escapes, the patient often becomes faint, but this may commonly be guarded against by continuing to draw up the bandage so as to keep up good pressure in the abdomen. After the fluid has escaped, the aperture must be closed with a strip or two of plaster supported by a pad and bandage, or a pad of iodoform or salicylic acid covered with collodion.

The incision through which the trocar is thrust must not enter the peritoneum. The trocar itself must be of full size, with a well-fitting cannula. Sometimes it is convenient to have one fitted with a stop-cock, to the end of which a vulcanized India-rubber tube, as represented in Fig. 708, p. 828, may be adapted, by which the fluid is carried quietly and without coming into the part destined to receive it. Should the particular situation of the accumulation of fluid in encysted ascites not allow its withdrawal by an aperture below the umbilicus, the abdomen may be tapped in any other convenient situation, except in the course of the epigastric vessels.

Ascentic fluid may be removed also by the aspirator, but in the abdomen this instrument presents no advantages over the ordinary siphon trocar.

R. Southey, believing that a gradual withdrawal of the fluid is most advantageous, avoiding the risk of syncope and the necessity of bandaging the patient, has devised a small "drainage trocar," which can be left in and the distention is relieved. The fluid flows steadily from it at the rate from ten to twenty ounces per hour, through a fine India-rubber tube. This method of relieving ascites has been found very efficacious. It has no tendency to set up peritonitis, and is almost painless.

REMOVAL OF PORTIONS OF THE INTESTINE.

The operation of removal of a portion of the intestine for disease, or, as it is termed, **Enterectomy**, or, if performed on the colon, **Colectomy**, was first attempted in 1833 by Keybard. Three inches of the colon were removed, the divided ends united by suture, and the patient recovered. In 1836 Dieffenbach removed a gangrenous portion of the intestine, and sutured the ends of the gut successfully in a case of strangulated hernia. Excision of a portion of the intestine remained one of the curiosities of surgery till within the last few years, during which it has been frequently performed by Gusseubauer, Czerny, Billroth, Madelung, Juillard, and many other continental Surgeons; and by Bryant, Marshall, Treves, and others in this country. In 1882 Madelung collected 88 cases in which the intestine had been united by suture after complete division, with or without removal of a diseased portion. Seven of these were accidental wounds, and of these three died, and in one the result was not recorded. In 44 it was undertaken for gangrene of the gut in strangulated hernia, and of these 23 died; in three for internal strangulation, and all these died; in 22 for the cure of artificial anus, with 8 deaths; and in 9 for tumors of the gut, with 3 deaths. These statistics well illustrate the nature of the cases in which this operation has been undertaken, and the degree of success that has attended it. The cases of tumor most adapted for removal are annular papillomata or columnar epitheliomata of the great intestine, before they have formed connections with surrounding parts. Such tumors may often be recognized by the symptoms of stricture and by feeling the growth through the abdominal wall. Tumors of the small intestine are extremely rare, and could scarcely be diagnosed by external examination.

The symptoms of the various conditions calling for enterectomy have already been sufficiently described, and it remains here only to give a brief description of the operation. If enterectomy is to be performed for artificial anus, the patient must be prepared by a few days' limited diet and an aperient, followed by an enema to empty the bowel immediately before the operation. In other cases this is impossible. The general directions given on p. 737 must be carefully attended to. The patient must be thoroughly under the influence of the anæsthetic; complete relaxation of the abdominal walls being a great assistance to the Surgeon. The incision must be made according to circumstances. In cases of tumor it is most conveniently placed over the growth.

The abdomen having been opened with all antiseptic precautions, the part of the intestine to be removed must be drawn well out so that not only the diseased part but two or three inches of the healthy bowel on each side may be clearly in view. A flat carbolized sponge may then be placed in the abdominal opening to prevent the protrusion of any more of the intestine. The part of the gut that has been drawn out should then be laid on a clean linen rag moistened with some warm antiseptic solution. A solution of carbolic acid (1 in 40) will be found the most efficient, and will not cause any irritation of the gut. If these precautions are carefully taken, should any fecal matter escape on dividing the gut there is no danger of its entering the peritoneal cavity, an accident which would very probably be fatal. The next step is to apply a clamp about two inches distant on each side of the piece of gut to be removed, partly to restrain hemorrhage and partly to prevent a copious escape of feces. A pair of polypus-forceps, sheathed with pieces of drainage-tube, will, in the absence of a special instrument, answer the purpose very well. An India-rubber ring may be put round the handles

to keep them closed. The piece of gut is then cut away between the clamps in the case of small intestine, a V-shaped piece of the mesentery is removed with it. Any feces that escape must now be washed away and the gut thoroughly cleaned, both inside and out, with an antiseptic solution. Any bleeding is then arrested, and the sutures introduced in the manner described at p. 832, vol. i. It is now generally agreed that fine silk, introduced with the finest possible needle, is the best form of suture. It should have been previously rendered thoroughly aseptic. Czerny recommends leaving it for some time in a 5 per cent. solution of carbolic acid, but simply soaking in the solution for twenty four hours is practically sufficient. It is better to introduce all the sutures before tightening any. To overcome the danger of picking up the serous and muscular coats only in the collapsed gut, Treves has invented an India-rubber tampon, which can be introduced at the two ends and distended with air. After all the stitches have been introduced, but before they are tightened, it can be allowed to collapse and is then easily withdrawn. The stitches having been tightened a line of suture is carried along the V-shaped slit in the mesentery, if it be small enough that is being removed, lest an aperture be left which might give rise to an internal hernia from a coil of gut slipping through it. The clamps are then removed. The gut may then be kept out of the abdomen for a minute or two; and should any feces pass into it, it must be carefully examined for any leak. If it be perfectly tight, it is carefully cleaned and put back in the abdomen. In cases of operation for artificial anus or gungon, as it is in hernia, the external wound may have a drainage tube inserted, as when it may be completely closed. In any case, an antiseptic dressing is applied.

In some cases of tumor of the bowel the patient's condition is such that it is impossible to submit him to an operation lasting often an hour or one half to two hours. The tumor may then be removed, and the gut brought out at the wound so as to form an artificial anus. This operation has been performed by Bryant and Marshall. Bryant's patient survived, and was in good health a year after.

EXCISION OF THE PYLORUS.

The possibility of removing the pylorus for cancer was first suggested by Billroth in 1877. Gussenbauer and V. Winiwarter subsequently experimentally demonstrated the possibility of removing portions of the stomach from animals. The first operation on the human subject was performed by Pean, who removed the pylorus in 1879; the patient, however, survived only five days. In 1880, Rydygier repeated the operation, but the patient died in a few hours. In 1881, Billroth performed the first successful operation. The patient was a woman aged 44; she made an uninterrupted recovery and eat a mutton cutlet with the best appetite on the twentieth day after the operation. The patient, however, died four months after the operation from cancer of the peritoneum and retroperitoneal lymphatic glands. The operation has since been repeated in a considerable number of cases by Winiwarter, V. Winiwarter, and others, with a fair amount of success; but the statistics have not yet been collected.

The operation is practicable only in cases in which the pylorus has not formed such adhesions to the surrounding parts as to prevent its being drawn completely from the wound. Before the operation the patient must be confined to liquid food for some days. Immediately before commencing the stomach must be thoroughly cleaned by means of the stomach pump with tepid water. The incision through the abdominal wall must be transverse or nearly so, in direction, placed over the tumor, and free enough to expose

the parts thoroughly. In Billroth's cases, the external wound was four to five inches in length, crossing the middle line above the umbilicus. The great and small omentum must be carefully separated from the parts to be removed, all bleeding vessels being tied as divided. The pyloric part of the stomach is then drawn from the wound and laid on a carbolized cloth or a flat sponge, the subsequent steps of the operation being conducted outside the abdomen. The stomach and duodenum are then cut through with scissors. After each stroke of the scissors any bleeding point is secured. Before dividing the duodenum, a few threads must be passed through its serous and muscular coats, lest it slip back into the cavity of the abdomen. The stomach is then fitted to the duodenum, by the removal of a V-shaped piece of its walls, either in the greater and lesser curvature, or at one side only. Finally, the duodenum and the stomach are united by sutures inserted as already described, the stomach returned to the abdomen, and the wound closed. The operation takes from one to two hours, and fifty to sixty sutures may be required. Success depends upon attention to antiseptic details, and prevention of the escape of any of the intestinal contents into the abdomen. In the after-treatment no food is allowed by the mouth for two or three days, the patient being supported by nutritive enemata. Billroth allowed his case sour milk on the third day.

In a case in which the operation was attempted, but found to be impracticable, V. Winiwarter ingeniously performed an operation to which he has given the name of *gastro-enterostomy*. It consists in drawing up the third part of the duodenum and establishing a fistulous opening between it and the great curvature of the stomach. In the first case it was successful, and gave great relief.

OPERATIONS ON THE LIVER.

Surgical procedures on the liver are required for the relief of abscesses, for the cure of hydatid cysts, and for some affections of the gall-bladder.

Abscess of the Liver.—Abscesses of the liver may be multiple or single. Multiple abscesses are usually the result of pyæmia, and admit of no surgical treatment. The single abscess generally occurs in patients who have lived in tropical regions, and is consequently often termed the "tropical abscess." The diagnosis of the disease belongs rather to the physician than to the surgeon. It will be sufficient to mention here that the chief symptoms are fever, rigors, loss of appetite and health, occasional jaundice, with pain in the region of the liver, and sometimes in the right shoulder. There is increased liver dulness, and in the later stages bulging at some point corresponding to the surface of the liver, either in front or beneath the lower ribs behind. The abscess, if unrelieved, may burst into the pleura, lung, intestine, or peritoneum, but in many cases it points towards the surface, either in the right hypochondriac region, or through the lower ribs behind. The diagnosis of the abscess is made certain by the use of the aspirator. It may be emptied in this way; but this rarely gives more than temporary relief. In order to effect a cure, it is in most cases necessary to evacuate the pus and drain the cavity. The mode of doing this will vary with the depth and the situation of the abscess. In all cases it should be done with the strictest antiseptic precautions.

According to Sir Joseph Fayrer it is always better to open in front if possible. If the abscess is distinctly pointing below the ribs, this may be done by a free incision, as adhesions will certainly be present between the opposed peritoneal surfaces. As the liver substance is cut, there is a most alarming gush of blood, but this soon stops if pressure be applied by means

of a sponge. A large drainage-tube must then be inserted, and the abscess treated antiseptically in the same way as any other abscess. If the abscess point behind, under the lower ribs, it may be necessary to remove a portion of one of the ribs to admit a drainage-tube of sufficient size. If the abscess be deep, and indicated merely by bulging, without evident pointing, the incision cannot be safely made. A large trocar may then be introduced and left in for a few days, being replaced by a drainage tube as soon as the track is sufficiently established. If the puncture is made in front, the peritonitis may ensue if no adhesions are present; to avoid this, Volkmann recommends that the surface of the liver should be exposed by an incision through the abdominal wall with antiseptic precautions. The wound may then be kept open by the insertion of a piece of carbolic gauze between its edges till adhesions have formed, when the abscess may be safely opened as above described. Injection of the abscess is not necessary if the aseptic treatment is carried out, but should this fail, and the discharge become foul, the cavity must be frequently washed out through the tube with some antiseptic solution.

Hydatids of the Liver.—A hydatid cyst is characterized by a gradual progressive enlargement of the liver, regular or lobulated in form, sometimes the surface and rounded at the edge. The general health suffers but there is no fever and no pain until the tumor reaches a considerable size, when it causes local peritonitis with the formation of adhesions. When the cyst is very large, suppuration may take place. For a more detailed description of this disease I must refer the reader to works on medicine.

Surgical interference should never be undertaken until the tumor reaches such a size as to become a source of inconvenience to the patient. If no doubt exists as to its nature this may be at once cleared up by the use of an aspirator, the fluid of a hydatid cyst resembling nothing in the body except cerebrospinal fluid (vol. i. p. 940). The following are the chief methods of treatment which have been adopted in this disease.

Aspiration.—Many cysts have been cured after simple puncture by means of nonpuncture needles repeated at short intervals. It appears that the fluid escapes through the punctures and is absorbed. This simple treatment is, however, very frequently followed by suppuration, necessitating the opening of the cyst to save the patient. It is said also that it is attended by the diffusion of the parasite through the peritoneal cavity with the formation of new cysts.

Electrolysis has been tried in several cases, but presents no advantages over simple puncture.

Aspiration frequently repeated has also cured many cases, and is certainly the best means to be adopted as the first effort at cure. It is now commonly followed by inflammation and suppuration of the cyst.

Injection of iodine after withdrawing some of the fluid by the aspirator does not seem to present any advantages over simple aspiration.

Drainage of the cyst by means of a cannula inserted on a trocar and left in has been successful in some cases. It is always followed by suppuration and is attended by considerable risk of peritonitis.

Opening the cyst by caustics as recommended by Récanier was formerly frequently adopted, the object being to form adhesions between the two surfaces of the peritoneum before the cavity was reached. It is now almost entirely abandoned, and is now seldom adopted.

Opening the cyst by removal of the acrophalocyst was first performed by Volkmann, of Hanover. He divided the abdominal wall by a vertical incision under antiseptic precautions and exposed the surface of the liver. The wound was then held open and a number of fine sutures passed through

ing the peritoneum to the skin. Two strong threads were then passed through the cyst-wall parallel to the edge of the wound, by means of which it was drawn well out of the abdomen. It was then opened freely between the threads and cleaned out as far as possible. Finally the cyst-wall was closely sewn to the skin, a large drainage-tube inserted and an antiseptic dressing applied. This operation was recently performed in University College Hospital by R. J. Godlee. The patient went on well for three weeks, when she died apparently from septiciemia. Volkmann advises that the operation should be performed in two stages, the surface of the liver being first exposed, the wound plugged with carbolic gauze for five or six days till firm adhesions have formed between the liver and the parietal peritoneum, and the cyst is then opened and treated as above described. Further experience is yet wanted to prove the safety of this operation, but it would seem hardly wise to adopt such serious proceedings till simpler means have failed.

A suppurating hydatid cyst must be treated in the same way as a liver abscess.

DISEASES OF THE GALL-BLADDER.—Dilatations of the gall-bladder, sometimes of very great size, are occasionally met with as the result of impaction of a gall-stone in the cystic duct. As the impaction takes place before the junction of the cystic duct with the hepatic, there is no jaundice, and the fluid distending the cyst is not colored with bile. Impaction in the common bile duct if unrelieved is fatal before any great dilatation takes place. In some cases the distended gall bladder has been known to inflame, suppurate, and discharge externally, leaving a fistulous opening through which gall-stones have been discharged. Nelaton advised that this should be anticipated by opening the gall-bladder by means of caustics, and states that he performed the operation. Handfield Jones suggested that the gall-bladder might be opened and the obstructing calculus removed from within it, and Marion Sims was the first to perform this operation, but without success; in 1878, however, Lawson Tait successfully accomplished the removal of the impacted gall-stone, and the patient made a rapid and complete recovery. The diagnosis of distended gall-bladder is not always possible. It is usually freely movable except at its upper attachment, and may resemble a renal tumor. The operation is performed on the same plan as that already described for the removal of a hydatid cyst.

EXTIRPATION OF THE SPLEEN.

B. Cr  d  , of Dresden, has collected 30 cases in which this operation has been performed. In 16 the operation was undertaken for the enlarged spleen of Leucocyth  mia, and in every case it was fatal; in 9 cases for simple hypertrophy, and of these 4 recovered and 5 died; in 2 for cysts, both recovering; in 2 for a movable or floating spleen, both successful, and in 1 for "the spleen lying in a peritoneal abscess," also successful. These statistics show that excision of the spleen is not justifiable in leucocyth  mia, and that in other cases one-third of the patients die. The operation presents nothing special. The tumor is exposed by a free incision, and isolated from surrounding parts, its pedicle being secured by ligature. If adhesions exist, the splenic substance is very likely to be torn, an accident which is accompanied by fearful hemorrhage, which has in several cases been the immediate cause of death.

DISEASES OF THE UMBILICUS.

Ulceration of the Navel is occasionally met with after the separation of the cord in new-born children. It must be treated by cleanliness and the application of some simple ointment. In adults, especially when venereal and uncleanly in their habits, eczema followed by ulceration is not uncommon in the navel. It must be treated by syringing with boracic acid solution and the application of boracic acid ointment. Sometimes a profuse fungating mass of granulations may form, which requires destruction by nitrate of silver. Soft and hard chancres have been met with at the navel, and a purulent discharge, resulting from gonorrhoeal infection, has also been observed.

A Warty Growth is occasionally met with in children springing from the hollow of the umbilicus. It is best removed by ligature.

Epithelioma of the Navel is a rare disease. Should it occur the tumor must be removed freely, if necessary opening the abdominal cavity and closing the aperture by sutures.

Umbilical Fistulae.—*Fecal fistula* at the umbilicus may arise from strangulation and sloughing of an umbilical hernia. They are also occasionally congenital, resulting either from a protrusion of a diverticulum from the ileum or of a portion of the small intestine into the cord and its subsequent inclusion in the ligature at birth. In other cases they arise from perforation of the small intestine by chronic ulceration, usually tubercular, with the formation of a circumscribed abscess amongst the coils of the intestine, and discharging at the navel. The treatment of these fistulae is extremely unsatisfactory. The application of the cautery to the orifice is of little use, and plastic operations almost invariably fail. If the discharge does not give much trouble, it is better treated by the application of a pad and dressing to cleanliness. If there is a complete artificial anus after gangrenous hernia a cure must be attempted by the means already described in the chapter on Hernia.

Urinary Fistulae are very rare, and result from imperfect closure of the urachus. They admit of no treatment. *Biliary Fistulae* also have been met with; their mode of origin is uncertain, and they also do not admit of treatment. *Purulent Fistulae* also are described by some writers; these are local collections of pus usually in the abdominal wall, which have discharged at the navel. They are best treated by enlarging the opening and inserting a drainage-tube.

I cannot close this chapter without an expression of admiration at the great advance that has of late years been effected in all that relates to the treatment of diseases of the abdominal and pelvic viscera by surgical operation, and a recognition of the merits of those Surgeons who truly and bravely have led the advance in this department of our art, and of the great importance of the results thus achieved by them. But whilst thus recording my admiration for the successes that have been secured, I would add a few words of caution to aspirants for distinction in this great practice. I would venture to remind them that an operation is not necessarily justifiable because it is practicable—that every act of surgical audacity is not a triumph of sound and legitimate surgery—and that a patient's life may possibly be prolonged on conditions less tolerable than death.

TUMORS OF THE GROIN.

Tumors of various kinds may develop primarily in the groin, or descend into it from the abdomen. They are of the following kinds: 1. Enlargement of the Lymphatic Glands. 2. Abscess in or around those glands. 3. Abscess descending into the groin from the abdomen—Psoas, Iliac, Pericæcal, Perinephritic, etc. 4. Varix of the Saphena Vein at its entrance into the femoral. 5. Aneurisms of all kinds. 6. Osteo-aneurisms. 7. Cystic Tumors, bursal, and developing in the muscular structures. 8. Simple Solid Tumors, as fatty, fibrous, sarcomatous, or lymphadenomatous. 9. Malignant Tumors, primarily developing in the soft structures in this region, extending into it from the bones, or secondarily from contamination of the glands. 10. Hernie of different kinds—inguinal, femoral, and obturator.

DIAGNOSIS.—In effecting the diagnosis of these various tumors, we must first distinguish the pulsating from those that do not pulsate. The **Pulsating Tumors** must either be aneurisms, osteo-aneurisms, or soft sarcomata or abscesses with communicated pulsation. The diagnosis of these different forms of disease has already been so fully given at pages 136 and 331, vol. ii., that I need not enter upon it here.

The **Non pulsating Tumors** are to be divided into two great classes, viz., the *Reducible* and the *Irreducible*.

The *Reducible Tumors* of the groin are either hernia, varix of the saphena vein, or abdominal abscess presenting under Poupart's ligament. The diagnosis of these different conditions is given at pp. 136, 331, vol. ii. These all have an impulse communicated to them in coughing.

The *Irreducible Tumors* of the groin have further to be divided into those that contain *Fluid* and those that are *Solid*.

The irreducible tumors containing *Fluid* are either abscesses in or around the lymphatic glands, or cystic growths of various kinds. The diagnosis here is easy; the irregular, hardened outline of glandular abscess, its rapid development, and softening from a previously indurated state, will distinguish it from the tense, clearly defined outline, smooth and elastic feel of the slowly developing and very chronic cystic growth. In irreducible hernia, the impulse on coughing, the gurgling, and other peculiar signs characteristic of that disease, will prevent the possibility of error in diagnosis.

The *Solid* tumors in the groin may either be simple or malignant. The history of the case, the feel of the tumor, the rapidity of its progress, the extent of contamination of neighboring parts, and the other signs that serve as diagnostic differences between simple and malignant growths, will enable the Surgeon to effect the diagnosis with sufficient accuracy.

The *Treatment* of many of these tumors, such as abscess of various kinds, aneurism, varix, and hernia, has already been so fully considered in the various chapters devoted to these diseases, that I need not enter upon it here. But the question of operating for the removal of *cystic or solid tumors* of the groin, is one that presents several special points for consideration. These are, the relations of the morbid mass, 1st, to the femoral vein; 2d, to the femoral artery; and, 3d, to the abdominal cavity. If the tumor lie upon or compress the femoral vein, edema of the foot and leg will be the result; and, should the compression have been prolonged and very chronic, this edema may assume a semi-solid character, so as to occasion a condition of the limb closely resembling elephantiasis. Although an intimate relation such as this between the tumor and vein would obviously inculcate the necessity for extreme caution, it need not necessarily preclude the idea of

operating for the removal of the tumor, which may possibly be a large one above, and unattached to the sheath of the vessels. I have successfully removed a mixed and lipomatous tumor of many years' standing, from the thigh where the limb was in a state of spurious elephantiasis from compression of the femoral vein, but the vessel was not involved in the growth. If the femoral artery be compressed to such an extent as to interfere with the circulation through the lower part of the limb, it will most probably be found that the tumor dips under or surrounds the vessel, so as to render removal impracticable. The mere overlaying of the artery by a freely movable mass without any compression of the vessel, need not preclude operation. The growth figured on p. 486, vol. ii., was of this kind. The connection of the tumor with the abdominal or pelvic cavity under Poupart's ligament, or through the obturator foramen, must be most carefully examined. Should this exist, or even be strongly suspected, operation is necessarily quite inadvisable.

CHAPTER LXV.

DISEASES OF THE LARGE INTESTINE AND ANUS.

CONGENITAL MALFORMATIONS.

Congenital Malformations of the anus and rectum are by no means uncommon, and are of considerable importance. They may exist in various degrees, which may most conveniently be arranged under the following heads.

Narrowing and Partial Closure of the Anus—The canal is sometimes very narrow, but not sufficiently so to allow of the bowels being completely evacuated; the contraction usually merely admitting a full sized probe. In some cases the obstruction appears to depend upon constriction of the anal orifice, and in others upon an imperfect septum stretching across it.

Treatment.—This consists in notching the contracted anus with a sharp pointed bistoury, and then introducing a sponge- or luminaria tent, to dilate it to the proper size, to which it must be kept by the occasional introduction of a bougie.

Complete Closure of Anus—The anus may be completely closed by a membranous septum stretching across it, usually having a ray-like depression in its central line, and a slight depression, through which the dark mucous membrane may be seen, and on which an impulse can be felt. This constitutes perhaps the most common form of malformation that is met with.

Treatment.—In this variety an incision must be made through the septum along the middle line, and across on each side when the incision is made, so that the flaps may escape. The four angular flaps that are left must now be removed, and the aperture kept open by the introduction of a well-oiled bougie.

Occlusion of Rectum above the Anus by a Membranous Septum—The anus may remain open; but, at a distance of about half an inch or more from its aperture, the rectum will be found occluded by a membranous septum stretching across it. This is a rare and somewhat peculiar kind of malformation, as in it the infant will be found to labor under

tinal obstruction, and yet, on examination, the anal orifice will be found perfectly formed, and thus the Surgeon may be misled as to the seat of the obstacle. He will, however, detect it by introducing a probe or the end of his little finger into the anus. It can readily be brought into view by inserting the nose speculum (Fig. 656), and throwing light up the bowel by means of a laryngeal mirror.

Treatment.—The operation, of which the following are the details, will be found to be successful.

1. The child is put in the lithotomy position.
2. A trocar-cannula is then passed down to and pressed against the septum.
3. Then the trocar is passed down the cannula and through the septum.
4. The trocar is withdrawn, and the cannula left in.
5. A probe is passed through the cannula, which is then slipped out over it and along the probe, or a director which may be substituted for it, a narrow-bladed pair of dressing forceps is pushed up and opened out so as to dilate the opening in the septum. During this process, the retained feces will have escaped. The aperture must be kept free by the occasional introduction and expansion of the forceps or of a laminaria tube.

It is important to observe that, although the anus may be perfectly formed and patent, with a canal above it about half an inch long, the rectum may be entirely absent, the sigmoid flexure terminating in a dilated pouch opposite the sacral prominence. In such cases it is, of course, impossible to reach the gut through the anus. In a case of this kind, in an infant four days old, in which I was unable to reach the gut through the anal aperture, I performed lumbar colotomy.

Complete Absence of Anus.—The anus may be completely absent, being blocked up by a dense mass of fibro-cellular structure, from half an inch to an inch in thickness, above which the rectum terminates in a kind of *cul-de-sac*.

Closure of Anus with Absence of Rectum.—It has already been stated that in some cases of perfect formation and patency of the anus the rectum is absent, but more commonly the anus is closed when the whole of the rectum is wanting; the intestine (colon) terminating in a large and expanded pouch, situated high up at the brim of the pelvis, opposite the sacral prominence. A case of this kind differs from the last only in the extent of the occlusion, and cannot, indeed, be distinguished from it until the Surgeon has made an incision in the site of the anus, and has failed to reach the gut at the usual distance.

Treatment.—In these cases the Surgeon must first make an attempt to reach the bowel from the perineum, failing which, two courses are open to him. He may open the colon in the left iliac fossa, or he may open it in the left lumbar region by Amussat's operation.

1. *Perineal incision.*—The perineal incision has the advantage of being in the natural situation of the anus, and of being easily practised and usually successful in all those cases in which the anus only is imperforate, the rectum being present. In those cases in which there is congenital absence of the rectum this operation must necessarily fail. The operation is thus performed: An incision about an inch in length should be carefully made from the point of the coccyx forwards. The dissection requires to be carried with caution to a considerable depth along the mesial line; and the Surgeon taking the curve of the sacrum and coccyx for his guide, and bearing in mind the relations of the bladder and large vessels in the neighborhood, carefully proceeds in search of the gut, which may be found at a considerable depth from the surface. A probe may be passed into the urethra of a male child, or the vagina of a female, to serve as a guide to the position of these

canals. The danger of wounding the bladder must also be considered, and may be materially lessened by emptying the viscous by pressing over the pubes before commencing the operation. In four instances of this kind, which I have operated, it was necessary to proceed to a depth of at least one and a half or two inches before the bowel was reached; which, on account of the narrowness of the wound and the small size and important relations of the parts, is not an easy matter. When the gut is reached, it must be punctured and the meconium allowed to escape.

There is one point in connection with the perineal operation to which it is of much importance especially to attend, not only as respects the immediate result of the operation, but as regards the ultimate success of the process. I mean the bringing down of the mucous membrane of the gut, and fixing it to the lips of the external wound. Unless this be done, the line of union will degenerate into a fistulous canal; which, like all fistulae, will have a tendency to contract, and will be a source of endless embarrassment to the surgeon and to the patient. If the mucous membrane can be brought down and fixed to the opening in the integument, this source of inconvenience will be removed, and the patient will be saved all that danger which results from the passage of the meconium over a surface of recently incised granulating tissue. This, however, can be done only when the intestine terminates at a short distance from the surface. If the perineal incision be two or three inches in depth, there will be little probability of the surgeon being able to bring the intestine down to such an extent. In one case in which I attempted to do so, I found that the gut was too firmly fixed to be removed by any traction that it would have been safe to employ.

For some considerable time after the operation, the aperture should be kept dilated by means of bougies; or a gum elastic or pewter tube, through which the feces are allowed to escape, may be fixed in the part.

I have several times operated in this way on imperforate children, but in all instances unsuccessfully. In one case, there was an anal aperture, but with complete occlusion of the rectum. I operated in the fourth lumbar region attempting to reach the gut through the anus; but, failing in this, performed the lumbar operation on the left side.

If it could be ascertained before proceeding to operate, that the rectum is absent, it might be wiser to search for the bowel in the lumbar region. But, as the Surgeon has no means of ascertaining, before making his incision, whether the rectum be one inch or three inches from the anus, he must cut into the perineum in order to obtain the necessary information, and if once he have penetrated to such a depth as to pass beyond the external muscle, or into the deep fascia in this situation, a great portion of the immediate danger of the operation will have been incurred, and few will think it advisable to leave the perineal operation unfinished, and expose the child to the additional risk of opening the colon in the lumbar region. Yet if he have gone as deeply as he dare venture, and have not one alternative bowel, there is no alternative but to open the intestine through the abdominal wall, or to leave the child to its fate. In this alternative, the Surgeon must either open the colon in the left iliac region or in the left loin.

Iliac Incision.—The advantages claimed for the iliac incision, or lumbar operation, are, that it is easy of performance, and that whether the Surgeon reach the colon or not, he is certain to hit upon some part of the abdominal tube, which may be drawn forwards and opened. The objections raised are, that the artificial anus is in an inconvenient situation, that there is a great peritonitis, as the peritoneum is necessarily wounded, and that the sigmoid flexure may not present in the wound, and a portion of small intestine may

be opened instead. These objections are not, however, quite so great as they at first appear. The artificial anus being situated in front has the advantage, that the patient can easily pass his motions into a properly shaped curved pan held in the groin, and can afterwards clean the parts himself. Moreover, diffuse peritonitis by no means necessarily follows. The mortality is no doubt great. Amussat stated, that of 21 children thus operated on, only 4 ultimately recovered; but Richard, of Brest, writing in 1859, gives much better results; for he records 12 cases as having occurred in the practice of himself and other Surgeons in that town, 7 of which recovered.

Lumbar Incision.—The lumbar incision, or Amussat's operation, has been often successfully practised on imperforate children. The advantages of this method consist in the possibility of opening the colon in this situation without wounding the peritoneum. The objections lie in the frequent malposition of the colon and in the still more frequent presence in the infant of a long meso-colon. Moreover, the space, especially in a fat infant, is very limited. It thus frequently happens that the peritoneum is unavoidably wounded. Curling, for these reasons, prefers Littré's operation to Amussat's in these cases. In fact, the arguments for and against the two operations are so evenly balanced that it is difficult to express any strong preference for one over the other. I have myself preferred Amussat's, and have performed it in more than one case. In performing the operation it must be borne in mind that the kidney is very large, extends far outwards, may be enveloped in very little fat, and may thus be easily wounded. If the operation succeeds, the result is very satisfactory. I saw, some years ago, a young gentleman, eight years of age, who had thus been operated upon in Mexico for congenital absence of the anus and rectum. An incision had first been made in the perineum, but, no intestine being met with, the colon was opened in the left lumbar region. The boy was in good health, well-nourished, had no great trouble with the artificial anus, which was covered with a truss-pad, and suffered only occasional inconvenience from prolapse of the mucous membrane. There was a kind of sphincter-like action in the muscles about the orifice, by which the finger was gripped.

Absence of Anus: Opening of Rectum into other Canals.—The anal orifice may be absent, and the gut may open into one of the neighboring mucous canals, as the vagina, the urethra, or the bladder. In such anomalous cases there is usually, I believe, but little to be done, except to restore the anal orifice if possible; but, if this be impracticable, to make a lumbar opening, and then to take the chance of the other preternatural communication closing. This it will sometimes do; and cases have occurred in which, although the whole of the meconium with flatus had escaped *per urethram*, yet, on opening the rectum, the abnormal communication seemed gradually to close, the feces being directed into their proper channel. In a case in which I was once consulted, there were imperforate anus and rectum, and the bowel protruded as a red fleshy tube, discharging meconium, and about four inches in length, from the anterior abdominal wall, just below the umbilicus, and immediately above an everted bladder. In such a complicated malformation, Surgery could evidently do nothing.

STRICTURE—SIMPLE, SYPHILITIC, AND MALIGNANT.

Stricture may occur in any part of the large intestine, but with very varying degrees of frequency in different portions of that gut. Excessively rarely met with in the ascending or transverse, of unfrequent occurrence in the descending colon, it becomes more common in the sigmoid flexure, and very frequently occurs at about the junction of this portion of the colon with

the rectum. In the rectum itself it is most commonly found either in its upper part, from four to six inches above the anus, or else a little above its aperture.

The frequent passage of small quantities of liquid feces, with occasional constipation, should always lead to a suspicion of stricture.

It is of three kinds: 1, the *simple*, dependent on simple thickening of the intestinal coats; 2, the *sphilitic*; and, 3, the *malignant*, consisting of a cancerous growth of the walls of the gut.

1. **Simple or Fibrous Stricture**, though occasionally occurring in the transverse or descending colon, is most frequently met with in the sigmoid flexure or at its junction with the rectum, or at the upper part of the rectum from four to six inches from the anus. This form of stricture of the large intestine commonly occurs in elderly people, and with especial frequency in women. It is usually the result of long-continued diarrhoea or of chronic dysentery. In some cases the narrowing is really caused by inflammation thickening outside the gut, especially in women who have suffered from pelvic cellulitis after labor. This form of stricture is sensed just with a rub of the finger.

Symptoms.—The symptoms of simple stricture of the rectum consist at first of some difficulty in defecation, the patient being obliged to strain at it. The feces will also appear to be flattened, narrowed, or forked in many cases, more especially as the stricture advances, are passed in the form of small scybala, with occasionally a kind of spurious diarrhoea consisting of the passage of the more fluid intestinal contents, whilst the solid masses are left behind. At the same time there are very commonly pain on defecation, and the occasional passage of some mucus or blood; and dyspeptic symptoms, with flatulent distention of the abdomen, are apt to accompany the stricture be within four or five inches of the anus, it may be reached with the finger, and its precise situation and diameter ascertained. Beyond this point, it must be examined by the introduction of a well-greased bougie, attention being paid to the curve which the rectum makes from above downwards as well as from before backwards. In introducing a bougie in order to ascertain the presence of a stricture above the upper end of the rectum, but no information can be gained in many cases, as the point of the instrument is apt to hitch in folds of the mucous membrane, or opposite the promontory of the sacrum; and thus, its onward passage being prevented, there may seem to be a constriction, which in reality does not exist, and unless care is taken the mucous membrane may actually be lacerated, and the instrument forced through it into the peritoneal cavity. In other cases, the bougie may appear to pass, when in reality its point, meeting with an obstruction, is directed downwards into the rectum.

The *progress and termination* of a simple stricture vary in different cases. Many persons will live on in very good general health through a course of years, who present all the symptoms of this simple stricture of the rectum. In others the contraction may go on increasing, until at last complete occlusion takes place, with retention of feces and all the symptoms of obstructed bowels. This condition usually comes on slowly, and the obstruction is complete, life may continue for several weeks; but in some instances the obstruction seems to take place rather suddenly, and with all the symptoms of acute intestinal strangulation, death occurring in a few days. Abscess occasionally forms in the neighborhood of the stricture, and, passing down into the pelvis, may burst either into the rectum, into the space, or into the vagina, or may present upon the nates. The discharge from this source, as well as from the mucous membrane of the stricture, which falls into an ulcerated state, may induce extreme emaciation.

and hectic, to which the impairment of nutrition consequent upon the disturbance of digestion adds materially.

Treatment.—The bowels should be kept moderately open, but purgation carefully avoided, as it is a source of much irritation. Castor oil, Carlsbad salts, or saline aperient mineral waters in small doses suit best. The diet should be carefully regulated, and the strength kept up. An occasional enema will often give considerable relief.

The *surgical* treatment of simple stricture of the rectum consists in dilating the canal at its constricted point. If this be within reach of the finger, the dilatation can be readily carried out. If it be above the upper part of the rectum, and the stricture be tight, it is extremely difficult to introduce the proper instruments with certainty. When the stricture is low down, so that the end of the finger can be introduced into it, it may readily be dilated by introducing a rectum bougie every second day, and gradually increasing the size of the instrument. If the stricture yield but slowly, and be very tight and indurated, I have found it a convenient plan to introduce a sheathed probe-pointed bistoury into it and to notch it towards its posterior aspect, where this may be done without danger to the peritoneum. A tent of compressed sponge or of laminaria digitata should then be introduced, and left in for twelve hours. On its withdrawal, bougies may more readily be passed; or the dilatation may be carried on by means of tents. When the stricture is above the reach of the finger, a good deal of management will be required to make the bougie enter it. This is best done by laying the patient on his left side, and using a moderate-sized elastic bougie, softened in warm water and well greased, which must be passed without the employment of any force. When once the Surgeon has introduced one, others can readily be made to follow in the same track. The great danger in introducing a bougie high up, is that of mistaking the obstruction offered by its point coming into contact with one of the valvular folds of mucous membrane occurring in this situation, for that of the stricture, and, by pushing on the instrument, perforating the bowel—an accident that would probably occasion fatal peritonitis. During the introduction of bougies, the bowels must be kept regular by means of a lenitive electuary, and the occasional use of emollient enemata. If much pain or irritation should be occasioned by their presence, opium should be administered internally or in the form of suppositories. Though a simple stricture of the rectum may be much relieved by the use of bougies, it is seldom, I think, cured by this means; there being a great tendency in it to contract so soon as the treatment is discontinued.

Dilatation may sometimes be very conveniently effected by the use of Todd's dilator (Fig. 806). This is introduced closed, covered with a thin vulcanized India rubber sheath, so as to avoid nipping the mucous membrane. It is then expanded to the required extent by pressing on a trigger in the handle.

If complete obstruction occur, purgatives must on no account be given. An endeavor should be made to relieve the patient by the use of enemata of olive oil, and the strength should be supported by a diet that is nourishing, at the same time that it leaves little or no solid residue. Opium in small doses frequently given will relieve the pain and prevent sickness; under this treatment the bowels may eventually act after a considerable lapse of time.

Fig. 806.—Rectum Dilator.

[illegible][illegible]

The Treatment.—The patient must be put under the usual conditions of treatment for dyspepsia. If ulceration is still present, the best treatment consists in passing bougies of wax or gutta serena each containing about five grains of iodine, into the rectum once a day. If this does not succeed, rubber bougies, containing a small quantity of bichloride of mercury, not exceeding $\frac{1}{4}$ of a grain, may be used instead. In many cases, if the disease exists as long as the diseased surface is irritated by the passage of the bougies, then colotomy must be performed as the only means of giving relief. Should the ulcers heal without necessitating colotomy, the granular condition resulting from them may be treated in the same way as a simple erosion. The extent of the disease usually, however, makes this form of surgery extremely intractable.

Cancer of the Rectum—Malignant Stricture.—The form of cancer met with in the rectum is almost invariably the Columnar Epithelioma, and is often called A lemoid Cancer. Its structure has been fully described in the chapter on Tumors (vol. i. p. 990). In the rectum it varies somewhat

in structure in different cases. In some the epithelial structure is very abundant, the growth resembling a closely packed mass of tubes resembling enlarged crypts of Luberkühn, between which lie the vessels, supported by a delicate connective tissue closely infiltrated with small round cells. In others the glandular element is much less developed, the fibrous stroma being more fully developed, and showing in some cases a tendency to contract like that of a scirrhus. All degrees may be met with between these two extremes. The clinical features vary with the structure. The softer varieties grow more rapidly, implicate surrounding structures more widely, and tend to infect the lymphatic glands and internal organs, but lead to a less complete stricture of the gut. The firmer varieties grow slowly, and often exist a long time without giving rise to secondary growths, while from their tendency to contract they cause great narrowing of the gut. The softer forms usually appear as flat cauliflower growths springing from the inner surface of the gut, and tending in most cases to spread circularly round it. They are usually extremely painful, and bleed readily when examined. They slough early, and cause extensive destruction of the bowel. The firmer varieties form hard, nodulated growths projecting into the gut, narrowing its calibre greatly. They ulcerate slowly and bleed less readily.

True *scirrhus*, that is to say, glandular epithelial cancer with firm fibrous stroma, is said to have been met with in the rectum. If such be the case, it is certainly very rare.

Colloid cancer also, arising apparently from colloid degeneration of a columnar epithelioma, has been met with, but is exceedingly rare.

The tumors described as *Enccephaloid* have probably been soft malignant sarcomata commencing near the gut or in its coats, but these cases are so rare that it is impossible, at present, to speak with certainty as to their structure.

Most usually cancerous disease is seated from three to five inches above the anus, and may implicate a considerable portion of the bowel, extending upwards rather than downwards, giving rise to considerable induration and contraction, and attended, at least in some cases, by complete occlusion of the interior of the gut.

Symptoms.—Cancer of the rectum is met with chiefly in middle life, but sometimes does not occur until advanced age. Both sexes are equally liable to it; if anything, it is more frequent in women than in men.

It is very insidious in most cases in its early manifestations. A sense of uneasiness, a tendency to diarrhoea, a slight discharge of blood or mucus, a feeling as if the patient had piles, are usually the only early evidences of the development of this distressing disease. After a time, the rectal pain becomes very severe. There is now a constant feeling of pain and weight in the gut, with a sensation as if the bowels had not been completely relieved, together with the discharge of mucus, blood, or pus, and some flattening of the feces. On exploring the parts with the finger, the lower portion of the rectum will usually be found unaltered, whilst the tip of the finger will come into contact with the contracted, hardened, ulcerated, and rugged mass; at one part of which an opening will be found leading into an irregular cavity that passes up through the cancerous mass to the healthy gut above. The patient experiences most intense suffering during defecation, in consequence of the passage of feces over the raw and ulcerated surface. This pain is not confined merely to the diseased part, where the sensation is of a hot and burning character, but usually radiates round the loins and down the thighs, and is so severe that the patient looks forward to each action of the bowels with the greatest dread, and restrains it as long as possible. The whole nervous system at last participates in this continually recurring suffering;

the countenance becomes anxious; the spirits are depressed; sleep and digestion are destroyed. The patient's condition is, indeed, truly miserable, between the dread of excessive suffering when the bowels act, on the one hand, and the fear of impending obstruction on the other. In many instances he is worn out by this suffering, occasionally combined with the constitutional cachexy induced by the contamination of the system and the development of secondary visceral growths. Not unfrequently the misery is much increased by the formation of fistulous openings in the neighborhood of the bowel, and communications between it and neighboring parts, such as the

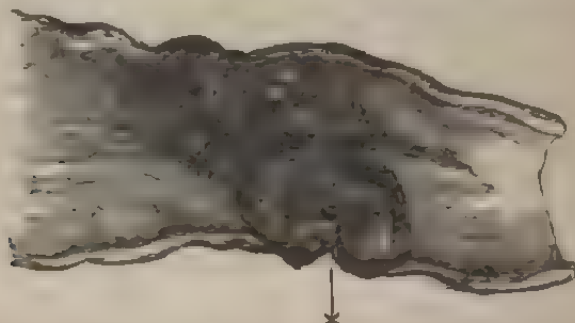

Fig. 867. -Cancer of Upper Part of Rectum. At x, perforation leading to fatal Peritonitis took place, during administration of an Enema.

vagina, bladder, or urethra, with cancerous implication of them. Flatus as well as feces thus get entrance into the bladder and vagina; the flatus passing out with a rush, the feces sometimes obstructing the urethra, and often very seriously irritating the bladder, producing strangury and great pain.

Death may put an end to the patient's sufferings in several ways; by exhaustion from pain and continuous discharge, together with constitutional cachexy; by perforation of the cancerous mass, which, ulcerating through at some point, opens into the peritoneal cavity, and, by hemorrhage, internal or into the gut, inducing fatal collapse, rapidly destroys life; and in other instances, though more rarely, by fecal obstruction, as in the case of simple stricture. The reason why intestinal obstruction is not more common than it is in cancer of the rectum is, that in many cases the diseased mass ulcerates and necroses more rapidly than it grows into the bowel, and thus an irregular chasm is left in its centre, through which the feces passes.

Treatment.—This must necessarily in a large proportion of cases be merely palliative. The bowels must be relieved by occasional doses of castor oil or by emollient enemata. The patient's sufferings may in many cases be much relieved by limiting him to a diet composed solely of material not likely to leave any solid residue, such as carefully prepared and strained arrowroot and meat-broths of various kinds, to which a little brandy or wine may be added. If the patient at the same time be kept warm in bed in the recumbent position so as to economize force as much as possible, he may maintain his strength fairly well on a comparatively small quantity of food. Small doses of opium may be given to relieve pain. On this diet one action of the bowels about every three weeks will be quite sufficient. It will usually occur spontaneously without the necessity of administering a purgative. If there is much pain, hypodermic injections of morphia, often to a large amount, are required to lessen the patient's distress.

As further palliative treatment *Colotomy* may be required. This opera-

tion is performed for one of three reasons: 1. To relieve the intense agony resulting from the passage of feces over the ulcerated cancerous mass; 2. To relieve the suffering and great discomfort occasioned by the feces passing into the bladder or vagina; 3. For the relief of more or less complete obstruction, giving rise to distention of the abdomen, with retained feces. Colotomy as a palliative has proved most successful in affording the desired relief; by its means life may be prolonged as well as rendered more endurable. Attempted dilatation by means of bougies, the application of caustics, or crushing the tumor by means of the finger-forceps, as recommended by Amussat, are worse than useless. They cause great pain and irritation, hasten ulceration, and aggravate the disease.

Excision of the Tumor. *Partial Excision of the Rectum or Proctotomy* is an operation which has lately been revived with considerable success. Récamier, Vidal, and others attempted the removal of the tumors when situated near the anus by ligaturing its base and allowing it to slough away. The only advantage in such a proceeding is the absence of hemorrhage, but this is more than counterbalanced by the dangers arising from the presence of the sloughing mass, by the uncertainty of perfect removal, and by the pain it gives rise to.

Removal of the disease by excision of a portion of the rectum was first performed, according to Velpeau, by Faget, in 1739. He took away an inch and a half of the circumference of the gut and cured his patient. The operation was revived in 1826, by Lisfranc, who removed portions of the rectum in nine cases, with five recoveries. The operation, however, fell again into discredit. In 1854, Chassaignac introduced the *écraseur*, and applied it to removal of rectal growths. Since then Nusbaum and Volkmann in Germany, Jordan, Allingham, Holmes, and others in this country, have done much to revive the operation; and in 1880, Harrison Cripps published an interesting work which has added much to our knowledge of the subject. The cases adapted to removal are not numerous, according to Cripps, forming about one in five of those that come under observation. The conditions which render the operation justifiable are the following: The patient must not be too old, and must be in fair health; the growth must be so situated that the finger can be passed fairly beyond it, and it must be freely movable, not having implicated surrounding parts. The most favorable cases are those limited to one side, especially the posterior. It is an important question how far the dissection can be carried upwards without wounding the peritoneum. Cripps, who has carefully investigated this point, states that in the male the distance from the recto-vesical pouch to the anus is two and a half inches when the bladder is empty, and an additional inch when it is distended. In the female the distance from the recto-uterine pouch to the anus is somewhat greater.

The removal of a malignant growth from the rectum is accomplished as follows: If it be very small, and situated very low down, it may be possible to bring it into view by forcible dilatation of the anus. This is done by inserting the first two fingers of each hand into the anus and forcibly dragging it open. After this the anus will usually be sufficiently relaxed to allow of the affected portion of the gut being seized and drawn out to such an extent as to allow of the free removal of the growth by the *écraseur*, *scissors*, or Paquelin's cautery. Cases in which this is practicable are, however, very rare.

The removal of a portion of the bowel, including the whole circumference or a considerable part of one side, can be safely performed only when the anus has been enlarged by incision, as suggested by Denonvilliers. The operation is thus performed. The rectum having been thoroughly cleansed

with an enema immediately before the operation, the patient is placed in the lithotomy position, and a curved sharp-pointed bistoury, similar to the one used for the removal of the prostate, is passed in at the anus, the handle is then raised so that the point is made to pierce the gut and appear superficially close to the tip of the coccyx exactly in the middle line; the parts between the coccyx and anus are then divided by a single cut. If more room be required during this operation, it may be obtained by removing the coccyx. The bleeding must now be arrested, and a stout ligature may be passed through on each side, by which the two edges of the wound may be held widely apart. An incision is then carried from the margin of the wound on one side in a curved direction round the anus to a corresponding point on the other side. If the anus itself is healthy, this may be made at the junction of the mucous membrane and skin. The gut can now be separated posteriorly without any difficulty by means of the finger, aided by the scissors, at the attachment of the levator ani. When the sides are separated the gut must be turned backwards and separated by careful dissection from the vagina in the female, or urethra and prostate in the male. To avoid any risk of wounding the urethra a large silver catheter should be passed at this stage of the operation, which will be clearly felt from the wound. The gut having been now separated it may be cut away by means of the bistoury, or by Paquelin's cautery. The *dérasseur* has the advantage of preventing hemorrhage, which in so deep a wound might be difficult to arrest. Paquelin's cautery has the disadvantage of hardening the edges of the wound, so that it is difficult to ascertain if they are free from disease. During the operation hemorrhage must be arrested, partly by the pressure of sponges, partly by the use of forcepressure forceps. The hemorrhage can in this way be easily kept under control, and seldom causes any great trouble. After the operation, it is useless to try to bring the mucous membrane up to the anus. As Cripps points out, the stitches always gave way and nothing is gained. The wound should be thoroughly sponged out with some antiseptic solution, chloride of zinc, (gr. 40 to 50), being far the most efficient. It may then be sprinkled with iod-form. In most cases it is better to leave the whole incision to close by granulation, as free drainage is then easier to be obtained. Volkmann recommends closing the anterior part by inserting a large drainage tube behind, but there seems little advantage in so doing. The after-treatment consists in well syringing the wound twice a day with some antiseptic solution, and the application of a little iod-form. The bowels must be prevented from acting for ten days or a fortnight by proper diet and the administration of opium. Healing takes place slowly, and the mucous membrane becomes drawn down considerably towards the skin. A strictured anus almost necessarily results if the whole circumference of the bowel have been removed, but this may usually be kept sufficiently patent by the constant use of bougies. Incontinence of feces is more rare. Cripps states that it occurred in seven cases out of thirty-six, and in six more it occurred slightly when the motions were small.

Removal of a part of the circumference is a much more successful operation. It is performed in the same way as that just described, but the mucous membrane and the corresponding part of the anus must be preserved uninjured, a longitudinal incision with scissors being carried up the gut on each side of the morbid growth. It is seldom followed either by incontinence or serious stricture of the bowel.

Wound of the peritonæum is a most serious but not necessarily fatal accident. If the opening be small and within reach, an attempt may be made to close it by sutures. If this cannot be done, according to Bardenheer

patient is given the best chance of life by the introduction of a full-sized drainage tube into the peritoneal pouch from the rectum.

The mortality from the operation is considerable, as judged by statistics. C. Kelsey, of New York, collected 140 cases, and states that in 22 of these rapid death followed; in 10 from peritonitis, in 4 from pelvic cellulitis, and in 3 from hemorrhage. In only 6 had a permanent cure resulted. There seems no doubt, however, that in well-selected cases, taken early, the operation holds out a fair prospect of prolonged relief, or even cure.

Cancer of the Anus.—The anus may be affected by extension of cancerous growths from the rectum. When the disease is primary, it is always squamous epithelioma (Fig. 404, p. 993, vol. i.), occurring at the anus, just as it does at other muco-cutaneous surfaces. It forms a nodular projection, often resembling a swollen external pile, for which I have more than once seen it mistaken. It ulcerates later than the same disease in other situations, the mass often reaching the size of a pigeon's egg before the surface gives way. If limited in extent and detected in good time, it may be advantageously excised by an operation similar to that for removal of the lower part of the rectum. At a more advanced period such a practice can scarcely be adopted with any prospect of success, in consequence of the impossibility of removing the whole of the structures implicated.

Sarcomata of the Rectum are very rarely met with. Rokitsansky has described a nodular form of spindle-celled sarcoma. I have seen such growths forming large and somewhat pale tuberos masses projecting into the interior of the gut, and even protruding through the anus, giving rise to the same train of local symptoms as characterize cancer of the gut, but with less pain. In such cases as these, the disease may, if limited or pedunculated, be removed by the *écraseur*. By means of this instrument, I have removed from the inside of the gut a tumor of this kind nearly as large as the fist. Recurrence may of course be expected, but the patient will get relief for a time.

Papillomata.—Large papillomata, the papillae of which branch repeatedly and are covered by columnar epithelium, are occasionally met with in the rectum. They closely resemble cancer, but are recognized by their slow growth and by their being pedunculated. They cause hemorrhage and some obstruction of the bowel. They can be readily removed by the *écraseur* or by ligature, and seldom return.

Polypi are by no means uncommon in children, and should always be

Fig. 808.—Polypus of the Rectum with Pedicle, removed from child 7 years old.

Fig. 809.—Polypus of the Rectum cut open, showing Cysts lined by Columnar Epithelium.

looked for when a child passes blood from the bowel, and suffers from prolonged irritation, perhaps associated with prolapse of the rectum. They are sometimes fibrous in structure, smooth on the surface, and covered with

columnar epithelium. In other cases they are lobulated (Fig. 300) or papillary, and may contain cysts lined with columnar epithelium (Fig. 301). They are easily removed by the application of a ligature, or by twisting the neck if it be long.

In adults, similar growths are less commonly met with. They are not common near the anus, and in some cases are found associated with a very intractable ulcer at the point at which the free end touches the gut. They are best removed by ligature of the neck, after which the body may be cut away.

RECTAL FISTULE.

Fistulous openings occasionally occur between the rectum and the bladder in men, or between the gut and the vagina in women.

Recto-vesical Fistulæ are not of common occurrence, and usually result either from organic disease of a cancerous character, establishing a communication between the rectum and the bladder; or from a wound of the gut during the operation of lithotomy. In rare cases they may arise from tubercular abscesses in the vesiculæ seminales or prostate, establishing an opening into the rectum and bladder simultaneously. In these cases the urine escapes *per anum* in greater or less quantity, occasioning constant irritation or excoriation, with a sort of liquid diarrhoea; and the wet state in which the patient is kept by the dribbling of urine gives rise to an offensive acrid odor about him. If the communication between the rectum and bladder be cancerous, feculent matter and flatus pass through the opening, and escape from time to time by the urethra; perhaps even more abundantly than the urine does *per anum*. There is this difference then between the traumatic and cancerous fistula, viz., that when traumatic the chief escape is into the bladder into the rectum; when cancerous, of the contents of the rectum into the bladder. It is remarkable how little irritation is often set up by the admixture of feces with urine in the bladder. The fistulous aperture in the rectum, if traumatic, can readily be detected by passing the finger into the gut, or examining its interior with the speculum *an.*, when cancerous it is high up for this.

Treatment.—If the fistula be cancerous, nothing can be done in the way of treatment beyond keeping the parts clean, or diverting the feces by colostomy; but if it be traumatic in its origin, of small size, and more especially if recent, its closure may not unfrequently be accomplished by touching the nitrate of silver, or the thermo-cautery through a speculum *an.* If, however, the fistula be of old standing, and the aperture large, cauterization will not succeed, and the only mode of treatment that can be adopted will be to introduce a grooved staff into the bladder, and cut through the septum upon this, thus laying the parts into one, and converting the anal into a perineal fistula. By draining the bladder, granulations will spring up and deep union be accomplished. In cancerous recto-vesical fistulae of a bad character, colostomy may be had recourse to with every prospect of curing the patient's sufferings (vol. ii. p. 821) and of thus prolonging life.

Entero-vaginal Fistula. It has happened that a communication has been set up between the small intestine and the vagina, an artificial anus in fact, forming in this cavity. These cases, however, are very rare, and are not indeed, to be looked upon as incurable. Roux and Casanovi, in 1820, succeeded in establishing, by a deep and difficult dissection, a communication between the small and large intestine; but the operation, as might have been expected, proved fatal.

Recto-vaginal Fistulæ may arise from two causes: 1st, sloughing of the posterior wall of the vagina, in consequence of undue pressure exercised upon it during parturition; and, 2d, its perforation by syphilitic ulceration. They may be ranged in two classes: those consisting of a buttonhole opening (and these are often syphilitic), and those complicated with more or less extensive laceration of the perineum. The size of these fistulous openings, when uncomplicated with rupture of the perineum, varies greatly; in some cases there is merely a small perforation, in others there may be loss of the greater portion of the posterior wall of the vagina. Whatever their size, they are necessarily sources of very great discomfort and annoyance, both physical and mental, to the patient. The recognition of the disease is, of course, at once made; the escape of the feces and flatus into the vagina being obvious, and digital or ocular examination by means of the duck-bill speculum at once detecting the seat and extent of the aperture. As there is just possibility of a communication existing between the vagina and the small intestine, it may be useful to bear in mind that, in this case, the matter that escapes has been found to be yellower and less stercoraceous than when the rectum is opened.

The *Treatment* of the non-syphilitic fistula will vary according as the fistula is simple, or complicated with lacerated perineum.

Simple uncomplicated Recto-vaginal Fistula, if it be small and recent, may occasionally be closed by attention to cleanliness, at the same time that its edges are touched with the nitrate of silver, a hot iron wire, or the platinum loop. If it be very large, the greater part of the posterior part of the vagina having been destroyed, it will probably be incurable; but even here the patient should not be left to her fate, and some operation should be attempted which may lessen its size, even if it do not completely close it. The kind of fistula which is here met with usually consists of a circular aperture, that readily admits the point of the finger, situated just above the sphincter ani. The operation for the closure of a recto-vaginal fistula of this kind consists, after emptying the patient's bowels by purgatives and an enema, and the bladder by the catheter, in introducing a duck-billed speculum into the vagina, and freely paring the edges of the aperture. As the fistula is always low down, this is readily done by placing the patient on her back, and tying the hands and feet together, as in lithotomy. The vaginal mucous membrane should be dissected off towards the fistula. The next point is to bring its edges into apposition, in a direction transverse to the axis of the vagina; and in doing this, the recommendation made by Copeland and Brown, of dividing the sphincter ani, should always be acted on, as it is a most important auxiliary to the success of the operative procedures that are required; for, as there is always loss of substance in these fistulæ, there is necessarily a tendency to tension on their sides when any attempt is made to draw them together; and it is also of importance that any muscular movement about the parts in the neighborhood of the fistulæ should be arrested, as this might otherwise break down union after it had taken place between the edges. The sides of the fistula must then be drawn into apposition by silver sutures introduced by means of the hollow needle. I have always found that these sutures are most easily introduced if passed *from above downwards*—the mucous membrane being then drawn upon by the needle, which more readily transfixes it than if it be introduced from below upwards, when it is left to push the membrane before it. The wires are thus passed across the fistula and out through the vaginal mucous membrane, half an inch beyond the freshened surfaces, care being taken not to include the rectal mucous membrane. They may then be twisted, or brought through a leaden plate and clamped by shot. The success of the procedure depends not only on the proper completion of

the steps of the operation, but greatly on the after-treatment. This should consist in the administration of opium, to prevent the bowels from acting, for ten or twelve days; indeed, until firm union has taken place between the edges. They may then be moved by means of laxatives and enemata carefully given. During the treatment, the parts should be disturbed as little as possible, the patient lying on her side. The water should be drawn off by a catheter twice a day. The parts should be washed twice a day with boracic acid lotion or a solution of boroglyceride, or some other simple antiseptic. The patient must be kept upon a very moderate diet, and the stitches may be left in for eight days, when they must be taken out and carefully removed. Should any point of the fistula not be closed, the application of the nitrate of silver may induce proper union of it.

If, as very commonly happens, the *Recto-vaginal Fistula be complicated with a Lacerated Perineum*, the operation for that condition, described at vol. i., must be performed, and the edges of the fistula, being deeply incised, brought together at the same time. Sometimes in these cases it happens that the perineum unites, leaving an aperture above this in the recto-vaginal septum: if this aperture be but small, it may be closed by its edges being touched from time to time with the actual cautery; if it be large, we will allow the introduction of the finger, I believe that it is generally vain to attempt to close this aperture by itself; but the perineum should again be divided, and the whole operation repeated.

When the recto-vaginal fistula is of a syphilitic origin, there is usually some degree of stricture of the rectum associated with it, and an extensive excoriated and diseased state of the vaginal mucous membrane. In these cases the sufferings of the patient are often very great, and the only means of relief open to the Surgeon is the performance of colotomy.

Entero-vesical Fistulae.—A fistulous communication may be established between the intestine at some point above the rectum and the bladder. The fistula usually forms between the sigmoid flexure of the colon and the upper and left lateral part of the bladder. It is possible that the small intestine may be the seat of this fistula, but most certainly such an occurrence is rare.

In these entero-vesical fistulae there is usually a long antecedent history pointing to cancer of the intestinal wall. Some obscure hardness, with tenderness or occasional shooting pains, is then met with, and sooner or later the patient observes in his urine some dark offensive deposit, which, on examination, proves to be feculent matter, with or without the escape of flatus to the urethra. In other cases, after more than usual pain, with rigors and constitutional symptoms indicative of suppuration, the urine will be found to be loaded with pus of a stinking character. In a few days feces will appear in it, and flatus pass through the urethra. In either case, adhesion has formed between the intestine and the bladder. Perforation takes place and the intestinal contents escape either directly into the bladder or through the cavity of an intervening abscess. The bladder irritation is usually at first but trifling; but after a time cystitis is developed and phosphates appear.

The treatment in the early stages should consist in clearing out the bowels with castor oil, and then locking them up for 10 or 14 days with opium, in order to give the fistula a chance of closing. Should this fail, the bladder should be washed out twice daily, and if the patient's sufferings increase so as to render life a burden, colotomy—a palliative measure—may be resorted to. Colotomy may be done, and thus a wider outlet for feces, urine, and gas afforded through the perineum than the urethra permits.

ULCER AND FISSURE OF THE ANUS.

This disease, though trivial in point of size and in its pathological relations, is of great practical importance, on account of the excessive local pain and great constitutional irritation to which a patient laboring under it is often subject. Ulcer and fissure commonly exist together in this situation, though it by no means unfrequently happens that the two conditions occur separately. The ulcer is usually of small size, seldom larger than a silver three-pence, of a circular or longitudinal shape, situated between the folds of the mucous membrane in the upper part of the anus, or rather the lower part of the rectum, just above the ring or ledge formed by the sphincter, and is usually met with towards the posterior part of the gut on one side of, or opposite to, the point of the coccyx. Occasionally more than one ulcer exists in this situation. If a fissure accompany the ulcer, it commonly leads from this across the face of the sphincter to the verge of the anus; but in many cases one or two fissures, sometimes even three or four, exist without any ulcer. The fissures are usually slightly indurated and cord-like, extending merely through the mucous membrane, scarcely, if at all, implicating the deeper structures; and not unfrequently their external termination is concealed by a small red pile or flap of integument.

The existence of the ulcer may usually be determined by exploring the rectum with the finger, which, if practised in these examinations, will detect a small, soft, and velvety patch at the diseased spot; on touching this, the patient will usually complain of acute and burning pain. In some cases the ulcer may be brought into view by examining the rectum with the speculum ani, here delineated (Figs. 810 and 811). The fissure may always readily

Fig. 810. Anal Dilator.

Fig. 811. Speculum Ani.

be detected by everting the mucous membrane of the anus, and by lifting up or turning aside the pile that covers the lower end of the crack. During this examination, it will usually be found that the sphincter ani is in a more or less spasmodically contracted state, admitting the finger and instrument with difficulty.

Symptoms.—The symptoms of ulcer or fissure in the anus are very characteristic. The patient complains of pain, usually of a severe burning character, on the passage of a motion, especially if a hard one; it commonly occurs at the time of defecation, but occasionally commences a few minutes afterwards,

and continues from half an hour to several hours. This pain is very severe, and peculiarly wearing and burning; it is generally most felt opposite the sacro-iliac articulation, but not unfrequently radiates round the pelvis or down the thighs. In many cases it produces a good deal of continued irritation about the genito-urinary organs, giving rise to symptoms of spasmodic stricture; a frequent desire to urinate, tenderness about the prostate, and seminal emissions. The pain is sometimes so severe that the patient avoids defecation as long as possible, and even abstains from food with the view of lessening the necessity for the frequency of this act. Very commonly in women, the pains produced by the rectal disease simulate those occasioned by uterine irritation; and in both sexes they may after a time become continuous, and be attended by a good deal of constant uneasiness in sitting, so that the patient is obliged to raise the hip of the affected side. There is often a streak of pus or blood on the feces, and commonly a good deal of mucous exudation, with some tenesmus on defecation; but in some instances these symptoms are altogether absent, and the patient never suffers any local inconvenience except from the pain.

The constitutional irritation is often very great, the nervous system generally sympathizing with the local mischief. The countenance becomes pale, anxious, careworn, and the patient's expression is indicative of constant suffering.

Causes.—This affection most commonly occurs in women, especially in those of a hysterical temperament and weakly constitution. In some cases it seems to have arisen from injury during labor. When met with in men, it is most frequently seen in debilitated subjects, and appears to be the result of a broken state of health. In persons who have been the subjects of the chronic dysentery of hot climates, I have several times noticed a peculiar form of patchy ulceration within the rectum, of an extremely irritable and very intractable character. I have in several instances observed it in women to be of a syphilitic nature, and in such cases it is situated generally towards the side or the anterior part of the anus.

The rectum may be injured by blows or falls upon the sacrum or coccyx. Fissure, laceration of the mucous membrane, rupture of the muscular fibres, or even detachment of the whole of the rectum from its connections with the sacrum and coccyx, may ensue from these injuries.

Treatment.—The treatment of fissure or ulcer of the anus, when the disease is met with in the early stages, may sometimes be successfully conducted by the application of nitrate of silver to the fissure, and the use of an anodyne or astringent suppository. I have found a very excellent and useful suppository in this and many other painful affections of the anus to be composed of 2 grains of extract of belladonna, 2 grains of the acetate of lead, and 4 of tannin, made up to a proper consistence with a little cocoa-butter. This may be introduced into the rectum every night and allowed to dissolve there; the bowels should at the same time be kept gently open with castor oil, or the lenitive electuary. In those cases in which the disease has been of some standing these means will not suffice, and it becomes necessary to have recourse to a very simple operation to effect a cure. This consists in dividing the affected mucous membrane through the ulcer or fissure, with possibly some of the subjacent fibres of the sphincter muscle, by which the part is set at rest, and cicatrization speedily takes place. The relief after the operation is usually immediate; indeed, after its performance, a patient who has been suffering severely for months or years, will often get complete and almost instantaneous relief. The merit of introducing this plan of treatment for the cure of ulcer and fissure of the anus into surgical practice is due to Sir B. Brodie. Boyer had previously recommended that the sphincter

should be cut completely across, in order that its action might be paralyzed; but Kræke found that the ulcer could be made to heal as readily by the incised incision above mentioned. The operation is readily done by introducing the left forefinger into the rectum, guiding along it a probe-pointed bistoury, and then cutting downwards and outwards, carrying the knife about the eighth of an inch in depth. No dressing is required after this operation; but, if the incision do not readily heal, it should be touched from the bottom with the nitrate of silver. The patient's bowels should be well opened before the operation, and a dose of castor oil may be given on the second or third day after it. During the process of cicatrization it will often be advantageous to give iron, and to put the patient on a nourishing diet.

Spasmodic Contraction of the Sphincter Ani is usually associated with a sore or ulcer of the anus, or inflammatory irritation of some neighboring organ; but occasionally it occurs without this complication, and in all cases it may be connected with a neuralgic condition of the part. In hysterical women, this neuralgia and spasm are especially apt to occur; though it is not improbable that, in many of the so-called cases of neuralgia of the anus, some positive disease, such as a small ulcer or fissure, may be detected on close examination, as I have had several occasions to verify.

The *Treatment* of contraction of the sphincter, whether associated with neuralgia or not, consists in the employment of local sedatives, especially the extract of belladonna, gr. j to gr. ij as a suppository; the bowels being kept relieved by enemata and confection of senna. Should these means fail, the patient must be anesthetized, and the sphincter forcibly dilated with the surgeon's fingers.

Atony of the Rectum is common in middle age, in those who lead sedentary lives, and especially in women. This condition is the consequence of not tending to habitual constipation, the walls of the rectum becoming expanded and pouch-like. It may occasion the retention and impaction of hardened feces. A mass of clayey consistence, and as large as the fetal head, forming in the rectum and interfering seriously with defecation, becomes a source not only of great discomfort but of serious ill-health. Like all retained excreta, it slowly poisons the system, giving rise to foul breath, dirty grayish complexion, and mental depression.

The *Treatment* of atony of the rectum consists in scrupulous care in emptying the bowels by the administration of cold enemata. If impaction of feces have occurred, this is to be remedied only by putting the patient under chloroform, forcibly dilating the sphincter with the hand, and breaking down the hardened mass with a lithotomy scoop or iron spoon, washing it away with enemata, and thus clearing out the bowel.

ABSCESS AND FISTULA.

Abscess not unfrequently occurs in the vicinity of the rectum and anus. It may either be superficial, being confined to the muco-cutaneous structures, and presenting the ordinary characters of acute subcutaneous abscess; or it may be deeply seated, forming in the ischio-rectal fossa. It is these ischio-rectal abscesses that are of the most practical importance. They may be of two kinds—**Acute and Chronic.**

Acute Ischio-rectal Abscess—This forms deeply in the fossa, with throbbing, shooting, and stabbing pains, through the anus, rectum, and perineum; on examination, a hard brawny substance may be felt in the areolar tissue by the side of the gut, either by examination from without, or by exploration through the rectum. It speedily softens, and will, unless an outlet be

made for it, burst either externally, or into the cavity of the gut, or in various ways. (Vide p. 895, vol. i.)

Chronic Ischio-rectal Abscess occurs insidiously in persons of exalted, broken, or phthisical constitutions. Without much pain or local tenderness, a collection of pus forms, which is usually limited to the ischio-rectal fossa, but in other cases acquires considerable magnitude, extending the gut to a considerable extent; in fact, almost surrounding the rectum, and then spreading widely on the nates or hip, presenting the ordinary characters of a chronic abscess. This kind of purulent collection may form in this as in any other situation in the body, as the result of congestion or of some local irritation. I have several times seen it follow cold blows, or bruises of the lower part of the body, or as a consequence of the lowering of the vitality of the mass of areolar adipose tissue on the ischio-rectal fossa by weakly persons sitting on a cold stone, or standing for a long time on the ice or snow. In other cases the mischief appears to originate around the prostate, and an abscess forming in this situation may run its way down by the side of the rectum. Sir B. Brodie attributed these abscesses, and the consequent fistulae, to perforations of the mucous membrane of the gut; and, although I think he exaggerated the frequency of the mode of production of the abscess, yet there can be no doubt that, in some cases, at least, it occurs as the result of perforation of the bowel, either by irritation from within, by the formation of a fissure, or by some foreign body, such as a fish-bone, transfixing it, and thus inducing inflammation in the tissue outside the rectum.

These abscesses are most common in young adults—not unfrequently in middle age, but rare at either of the extremes of life. I have, however, seen several cases in children, two or three years of age, and they may sometimes require operation in septuagenarians.

Treatment. In the treatment of these abscesses, the principal point is to prevent extensive denudation of the gut. In order to do this, the abscess must be opened, as soon as the formation of pus can be ascertained. This is taken place, by making a free, and, if necessary, a deep incision into the ischio-rectal space by the side of the bowel. Unless this be done, the abscess either bursts into the interior of the gut, or spreads widely upon the nates, and then gave way. The pus that is let out of these collections is always extremely offensive, even though not mixed with any feculent matter. In the neighborhood of the bowel appearing to determine some change in the feces, that renders its smell peculiarly stercoraceous. After the evacuation of the abscess, the patient feels easy, and thinks that all is well, the discharge gradually lessening and the cavity contracting; but it does not close, as a fistula will be left, which continues to exude a thin, watery pus, or a feculent matter, perhaps, accumulates from time to time, giving rise to local outbreaks and extensions of the disease.

Anal Abscess—Besides the two forms of abscess just described as occurring in the ischio-rectal fossa, another is commonly met with to which the term anal abscess may be applied. It commences in the substance of the rectum, the gut immediately above the anus. Its cause is not always evident. It may arise from suppuration taking place beneath an inflamed fissure, or a wound of the mucous membrane by some solid body, such as a splinter of the feces, or from the formation of a encysted tubercular nodule in the mucous tissue. The pus thus formed burrows downwards between the mucous and muscular coats of the bowel till it reaches the anus, and then passes out beneath the skin and forms a small, rounded swelling at the margin of the anus. If unrelieved, it may burrow still further into the cutaneous tissue. The pus in this case lies superficial to the sphincter

These abscesses may be acute or chronic; when chronic, they are frequently tubercular, advancing slowly and containing thick, curdy pus. They burst usually both internally and externally, and are, perhaps, the most common cause of the ordinary fistula in ano. By early opening, and dressing with wet boracic acid lint, and frequent bathing with a concentrated solution of boracic acid, they can sometimes be got to heal without leaving a fistula. If they are tubercular, this seldom happens, and the best treatment is to lay them thoroughly open into the bowel, to scrape the surface well with a sharp spoon, and to dress them with iodoform ointment.

FISTULA IN ANO.—The sinus left by the contraction of the cavity of an ischio-rectal or anal abscess constitutes a *fistula in ano*; an affection that has attracted a good deal of attention from the frequency of its occurrence, and from the difficulty of curing it without having recourse to operation.

Extent.—When following an anal abscess, the fistula is very limited, being merely the sinus left in the submucous areolar tissue of the anus after the bursting of the superficial collection of pus in this situation, extending to a short distance up the gut inside the sphincter. This form of fistula constitutes a kind of spurious variety of the disease; for the true fistula in ano is outside the sphincter in the surrounding areolar tissue, extending always as high as the upper margin of that muscle, and frequently stretching to a considerable distance up the side of the gut. Most frequently the lower and external aperture of the fistula is single, and is situated by the side of the anus in the ischio-rectal fossa, just beyond the sphincter; but not unfrequently the aperture is in the perineum, or posteriorly in the coccygeal region. Occasionally there is a fistulous opening on each side of the gut; or several openings may exist, and then sinuses extend from these upwards and outwards to a considerable distance, undermining the integuments of the perineum about the buttocks, even stretching away towards the trochanters, and opening at a great distance from the bowel. These extensive fistulae and sinuses are frequently connected with stricture of the gut; but they may occur without this in old and neglected cases of the simple disease.

The fistulae are usually oblique, but straight in their direction from a point half an inch or an inch from the anal aperture, running upwards to above the sphincter. In some cases they are tortuous; and, occasionally, when opening at a distance from the gut, and extensively undermining the integuments, they are angular, having, as it were, an elbow at that point where the superficial sinus meets the deep fistula. This peculiarity will prevent the passage of a probe through their whole length until the external sinus has been slit up, and the commencement of the deep fissure reached, and may lead to the supposition of the fistula being more superficial than it in reality is.

Varieties.—Fistula in ano is said to be **Complete** when it communicates by one end with the interior of the rectum, and opens by the other upon the external surface. It is said to be **Incomplete** when it has only one aperture, whether that be external or internal.

Complete Fistula is the most common form. It probably arises in the majority of cases from some source of irritation seated within the bowel, by which the mucous membrane of the rectum has been perforated, and an abscess has formed in the areolar tissue outside the gut. The external opening in this form of fistula is usually from half an inch to an inch from the margin of the anus; though it may be seated at a greater distance than this, as upon the hip. It is commonly small, and has a vascular granulation projecting from or occluding it; and a thin purulent discharge usually drains away from it in small quantities, moistening the surrounding integuments. The internal opening is usually situated just above the sphincter, where the

the bursting of the abscess, or at any time if there be much inflammation going on, the wound is apt to assume a somewhat sloughy condition, and to heal with great difficulty. The most important question usually connected with the operation of fistula, is the propriety of performing it in phthisical subjects. It is a well-known fact that fistula in ano is especially apt to occur in consumptive individuals, and it is often a nice point to determine whether an operation should or should not be performed in them; how far the drain from the fistula may keep up or even generate the tendency to phthisis, or how far it may be salutary in acting as a counter-irritant, and in preventing

the morbid condition of the lung from developing. Theophilus Thompson has stated that the coexistence of fistula with phthisis appears to retard the progress of the latter disease, acting as a derivative; and in some instances this may be so. I have, however, in several cases found considerable advantage result from operating for fistula in the early stages of phthisis, or in suspected cases of that disease, the patient's health having considerably improved after the healing of the fistula. But in confirmed, and still less in advanced phthisis, no operation should ever be practised; as the wound will not heal, and the patient must be weakened by the additional discharge.

The operation for *complete* fistula should be performed in the following way. The bowels having been well cleared out the day before with a dose of castor-oil, and an enema administered on the morning of the operation, the patient should be laid on his left side, with the knees projecting over the edge of the bed; a probe must then be passed through the fistulous track into the rectum, and the Surgeon, introducing the forefinger into the gut, feels for the end of the instrument; he then passes a short strong-bladed probe-pointed bistoury of about the size and shape of that represented in Fig. 812 through the fistula, using the probe as a guide, though in some cases this may conveniently be dispensed with. When he feels the end of the knife projecting into the rectum through the internal aperture of the fistula, he hooks his forefinger over it (Fig. 813), after withdrawing the probe, and by a sweeping and pressing cut, raising the handle of the instrument at the same time that he pushes down its point, brings both finger and blade out at the anal aperture, cutting through the whole thickness of the parts between this and the fistula, so as to lay the two cavities into one. Care should be taken to divide the sphincter in a direct and not an oblique manner, lest a flap or fold be left which will interfere with the proper healing of the wound. In performing this operation, the Surgeon should cut with his left hand if the fistula be upon the left; and in either case should be careful not to wound his own finger, as such cuts often prove troublesome in healing. Where the external aperture or apertures of the fistula are at some distance from the gut, the integuments being undermined to a considerable extent, perhaps thinned, slit, and bluish, all the superficial sinuses should be slit up; and, in those cases in which the course of the fistula runs more or less at a right angle with

The first of these is the question of the proper use of the word "wound." The word "wound" is commonly used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue. The word "wound" is also used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue. The word "wound" is also used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue.

The second of these is the question of the proper use of the word "injury." The word "injury" is commonly used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue. The word "injury" is also used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue. The word "injury" is also used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue.

The third of these is the question of the proper use of the word "fracture." The word "fracture" is commonly used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue. The word "fracture" is also used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue. The word "fracture" is also used to denote a break in the continuity of the skin or mucous membrane, and is often used to denote a break in the continuity of the underlying tissue.

salicylic or iodoform wool, and a firm pad applied by means of a T-bandage. Should profuse bleeding, in consequence of the division of some of the hemorrhoidal vessels, come on a few hours after the operation, all coagula should be cleared away, the gut washed out with ice-cold water, and then securely plugged either with a piece of compressed sponge, or with a lithotomy or œsophagus tube, surrounded by lint soaked in a solution of perchloride of iron, and pushed into the bottom of the sinuses that have been laid open.

HEMORRHOIDS OR PILES.

By **Hemorrhoids** or **Piles** is meant a morbid condition of the bloodvessels of the anus and lower part of the rectum, especially of the veins of the sub-mucous or subcutaneous areolar tissue, giving rise to more or less intumescence of the part, which may or may not be attended with a discharge of blood. Surgeons are commonly in the habit of classifying piles, according as they bleed or not, into **Open** or **Blind**; or, according as they spring from above or below the verge of the anus, into **Internal** or **External**; the internal being always within the gut, the external habitually protruding out of or around the anal aperture. The first may either bleed or not; the latter are always blind. To this division into external and internal, B. Cooper has added an intermediate variety, the **Intero-external**, which is partly within and partly without the anus. These divisions are of much practical moment, as the treatment is very materially modified according as the hemorrhoid is situated above or below the anal verge.

PREDISPOSING CAUSES.—We must look to the peculiar arrangement of the veins of the rectum as directly predisposing to the occurrence of piles. The lower part of the rectum and the verge of the anus are composed of a plane of muscular fibre and a mucous-cutaneous surface, with an intervening stratum of loose areolar tissue, in which a close interlacement, or network, of tortuous veins is situated. The blood, from this plexus of hemorrhoidal veins, finds its way into the general system through two distinct channels. By far the greatest portion of it is carried into the inferior mesenteric vein, and thence into the vena portæ, through the medium of the superior hemorrhoidal vein, which may be looked upon as the extreme radicle of the portal system; and some passes into the internal iliac vein through branches that accompany the middle and inferior hemorrhoidal arteries. We may, therefore, look upon the hemorrhoidal plexus as being placed midway between the portal and general venous systems, being the point indeed at which they touch; but as belonging rather to the portal than to the systemic veins. In these arrangements we see all the elements that would predispose to congestion, and consequent dilatation of the vessels of a part. There is a large and intricate plexus of veins in which, as in all similar networks, there is a tendency for the blood to circulate slowly at times; the natural tendency to stasis of the blood being much increased by the dependent position of the part, and by the anatomical fact that, in consequence of the absence of valves in the superior hemorrhoidal vein and in the vessels into which it pours its contents, the whole pressure of the column of blood in the portal system may be brought to bear upon the hemorrhoidal plexus. The circulation through the portal system is likewise subject to much interference in consequence of hepatic and intestinal obstruction, and in these changes the blood in the hemorrhoidal plexus also participates; and, were it not for the provision that exists by which this plexus may free itself to a certain extent from over-distention by its communication with the internal iliac through the medium of the middle hemorrhoidal vein, piles would be much more frequent than they even now are, as a consequence of obstructed portal

circulation. Another great cause of hemorrhoidal enlargement is to be found in the want of support that the veins of this portion experience in their mucous aspect during defecation. Situated as they are in areolar tissue, between a plane of muscular fibres on one side and a thin delicate membrane on the other, when distended by the congestion which they undergo during and after the expulsion of the contents of the rectum they necessarily give way on that side on which they have the least support being forced down and elongated, together with the mucous membrane over which they ramify, and which has a natural tendency to become slightly everted during the act of defecation. It will be found that all the more immediate or exciting causes of piles act by unduly increasing one or other of these natural tendencies that exist in the system, by favouring the congestion or determination of blood, at the same time that they produce a lax state of fibre.

Age exercises considerable influence in predisposing to piles. This disease is not unfrequently met with in young men of eighteen or twenty years of age; more especially if they be of a relaxed and phlegmatic temperament with languid circulation, and be charged to lead a more sedentary life than is natural or proper at that age. After this period, the liability to the disease diminishes until middle age is reached, when the tendency to hemorrhoidal affections is again increased, and becomes more marked than at any later period of life, owing to the more active operation of those causes that tend to impede the return of the portal blood.

Sex appears to exercise more influence on the occurrence of hemorrhoids at particular periods of life, than on the general liability to the disease. It certainly appears to be more frequently met with amongst men at an early age than in young women; but at a later period of life, so far as occupation goes, the disease occurs with nearly equal frequency in both sexes. The comparative exemption of young women is readily accounted for, by the periodic discharges from the uterus preventing the congestion that might otherwise occur in the parts in its vicinity. The greater frequency in females at a later period of life is attributable not only to the pressure of the gravid uterus on the veins, but also, after the cessation of the menses, to the stimulation that is apt to be set up in certain organs of the female system, and to the retardation of the portal circulation by the accumulation of blood and by other causes; these conditions occur chiefly in women of a plethoric habit of body.

A *sedentary life* with indolent habits constitutes, perhaps, the most powerful predisposing cause of the disease; more especially if habitual constipation be combined with want of proper and sufficient exercise. Indolent, dissipated and luxurious habits of the more opulent classes, by diminishing, at the same time that they occasion plethora and a tendency to arterial engorgement, exercise a considerable influence on the occurrence of the disease, which is much more frequent amongst them than in persons of the humbler walks of life.

Alcoholic excess is amongst the most common causes of piles, owing to the hepatic congestion it commonly gives rise to. If it be carried to the point of causing cirrhosis of the liver the condition becomes aggravated. Under these circumstances bleeding piles may serve as a sort of safety valve to the overloaded portal circulation, and should on no account be interrupted. So important is this that in all cases of piles before undertaking an operation the symptoms of cirrhosis—morning vomiting, failure of appetite and intermittent diarrhoea and occasional slight jaundice—should be inquired for.

There are a number of minor conditions which are commonly looked upon as predisposing causes of this disease, though it is extremely difficult to

determine the precise share that each has in its production. Amongst these may be mentioned intemperance in food; residence in warm, moist, and relaxing climates; the use of soft and warm beds, or the opposite condition of sitting on a cold stone or damp cushion. Over-excitement of the generative organs also will occasion it.

EXCITING CAUSES.—Amongst the exciting causes may be mentioned *local irritation* of any kind. Thus, in some people hard riding will bring on an attack of piles. The *habitual use of drastic purgatives*, more especially of *laxa*, rhubarb, etc., is well known to occasion the disease; though it must be observed that individuals, who make habitual use of these remedies, often labor under some of those obstructions of the abdominal viscera that have already been noticed as conducing to piles. The existence of other *diseases about the rectum and anus*, such as fistula, ulcer, or stricture, by inducing *local congestion and irritation*, may excite the disease; so also, *uterine affections* and various *diseases of the genito-urinary organs* may give rise to this affection.

The most direct exciting cause of piles is certainly a *retardation to the return of the portal blood*. Any impediment to the onward current of the blood through the hemorrhoidal or mesenteric veins, the trunk or ramifications of the *vena portæ*, exercises a marked influence on the tendency to congestion of the hemorrhoidal plexus. Habitual constipation; the accumulation of hardened feculent masses in the large intestine; the want of due secretion from the mucous surface; obstruction to the proper action of the liver, and consequent congestion of that organ; the pressure of abdominal tumors, or of the gravid uterus, are all active exciting causes, interfering as they do with the proper return of the portal blood. In some cases, even the existence of an obstacle to the circulation in the systemic veins may occasion this disease; thus it will arise from the pressure of an aneurismal tumor on some of the large venous trunks within the chest.

STRUCTURE.—A pile, whether external or internal, consists essentially in the first instance of a varicose condition of a portion of the hemorrhoidal plexus, or rather, of the small veins of the submucous tissue that pour their contents into this; this varicose condition, becoming prominently developed at certain points, gives rise to small knots or tumors. A pile in this state is quite soft and compressible, and can readily be emptied by pressure; and when cut into, it will be found to be composed of one or more cysts filled with blood, and surrounded by areolar tissue. The appearance of cysts is, however, deceptive, being occasioned by a section of the anastomosed and dilated veins that enter into the composition of the tumor. After the piles have existed for some little time, or after they have once become inflamed, the tissues that enter into their composition undergo modifications that induce corresponding alterations in the character of the tumor. The coats of the veins become thickened; their cell-like dilatations are filled with coagulated blood; the investing areolar tissue is hypertrophied or thickened; and, on being cut into, the pile is seen to be composed of a spongy kind of tissue filled with blood. External piles, when examined after removal, often resemble in structure a mass of hypertrophied cutaneous and subcutaneous tissue, in which a number of small vessels of uniform character run, but without any appearance of cyst-like spaces. Internal piles, on the contrary, contain more of the venous, and less of the areolar element. They are also commonly furnished with a small central artery, which is apt to bleed freely, or even dangerously, if the tumor be cut across; hence, provided they are not clogged with coagulated blood, they may readily be injected from the inferior mesenteric artery.

In studying the structure of hemorrhoids, it is of importance to observe that they occur under two different forms; one in which there are distinct

tumors, within or external to the anus, and another in which there is merely a varicose condition of the veins of this region, without distinct tumescence.

In those cases in which there is merely a general varicose state of the veins of the submucous areolar tissue of the anus, without any distinct tumor springing above the level of the membrane, it will be found that the smaller branches of the hemorrhoidal plexus, and the small twigs that enter them from the submucous areolar tissue, have undergone varicose dilatation, being apparently greatly increased in number, as well as in size. The mucous membrane is of a deep mulberry or port wine color, and becomes covered after each motion. There is usually some mucous secretion about the anus, rendering the part moist, and the patient complains at times of weight and of bearing down, with pains either in the part itself, in the sacro-anal region, or in the thighs. The notions, more especially if hard are streaked with blood, and more or less of this fluid drops in a rapid manner after the passage of the feces. There is seldom much blood lost; but at times there is an exacerbation of all these symptoms, and the hemorrhage, as well as particularly be mentioned hereafter, may become very abundant. The condition of the mucous membrane may proceed, and is frequently found to accompany the true pile, whether external or internal, and may be viewed upon as constituting the first stage of this disease. If this state of things is allowed to continue unrelieved, the tendency to congestion increases, and more of the mucous membrane is everted and protruded after defecation; the submucous areolar tissue becomes stretched and lax, and the case is apt to become one of prolapsus ani.

External Hemorrhoids are those that are situated below the verge of the anus, and that are invested by cutaneous, or, at most, by mucous-cutaneous tissue. Before appearing as defined tumors they usually constitute longitudinal folds that surround the anal aperture, or radiate from it as from a centre; and their tegumentary covering consisting of the thin skin of the part they resemble folds of this tissue rather than of mucous membrane. In color, they vary from that of the natural structures to a pink or purplish hue. Their size varies, according to the state of congestion, and hence the same tumor may at one time be soft, flaccid, and loose, apparently paler than more than a fold of integument, and at another may become tense, elastic, and ready to burst.

Symptoms.—When of small size and recent formation, external piles do not in general give rise to much distress, but merely some local heat, swelling, and itching, with a sense of fulness after defecation; but when of large size, and inflamed or irritated, they may occasion very acute suffering. There is not only deeply seated, dull, aching and throbbing pain in the part itself, but this shoots up the side of the rectum, through the perineum, and even the testes, and is much increased when the patient stands or walks. After a few days these symptoms subside; suppuration either taking place in the tumor, or the blood contained in it coagulating. The parts are, however, left in a thickened and indurated state, and do not really resume their former soft and flaccid condition, inflammatory effusion taking place into the areolar tissue, and the contained blood perhaps coagulating, so that the tumor can no longer be emptied by pressure, but assumes the form of a broad, rounded, or indurated mass.

Internal Piles.—When the pile is situated altogether within the verge of the anus, it is called internal; of these there are two principal varieties, the *Longitudinal* and the *Globular*.

The **Longitudinal**, or, as it is sometimes called, the **Fleshy pile** is met with about an inch or two up the rectum. It is spongy, elastic, and

tough, of a dark reddish or dusky brown tint, tapering upwards from a broad base. It seldom bleeds or varies much in size; between the piles are found small curtains, valves, or folds of mucous membrane, forming sacculi or pouches, with their concavities looking upwards. These sacculi are apt to become distended and pressed downwards by the feces, especially if the motions be hard and the bowels have been constipated, thus giving rise to a tendency to prolapsus.

When the hemorrhoid assumes a **Globular** form, it constitutes the ordinary bleeding pile. It may be situated on a broad base; or, as not unfrequently happens, its point of attachment to the mucous membrane becoming elongated, it assumes a pedunculated shape, hanging downwards into the cavity of the rectum. It is of a dark bluish color, and numerous small vessels of a brighter hue than the body of the pile may be seen ramifying on the mucous membrane investing it. Its surface is at first smooth and shining, and may continue so throughout, being covered with a thin and delicate prolongation of the lining membrane of the gut. Not unfrequently, however, superficial ulceration takes place, and then it has a granulated strawberry-like appearance.

Symptoms.—Internal piles are usually attended by a sensation of heat, itching, pricking, or smarting about the anus, and a feeling as if there were a foreign body within the gut. After defecation these sensations are increased, and are often accompanied by a bearing down, as if the bowel were not emptied of its contents, that is peculiarly distressing and sickening. This is occasioned by the piles, or the elongated and condensed mucous membrane to which they are attached, being protruded during the expulsion of the feces, and not returning sufficiently quickly, being grasped by the sphincter ani and constricted by it. This feeling of discomfort and bearing down is much increased, if the patient stand or walk much after having had a stool, or if he have a confined state of the bowels. If this state of things be not properly attended to, the symptoms become increased in severity; the bearing down sensation amounts to true teneismus, and the act of defecation becomes so painful that the patient defers it as long as possible, and then when it does take place, in consequence of the accumulation of the excreta and their indurated character, the suffering is much increased. External piles now usually make their appearance, if they have not existed before; the mucous membrane of the rectum becomes prolapsed, and an increased secretion of thin mucus takes place from the orifice of the gut, moistening the part and soiling the patient's linen. Irritation in the neighboring organs is frequently set up; occasionally to so great an extent as to mask the original complaint, the patient referring his principal pain and discomfort to these sympathetic disturbances. There is often a dull aching fixed pain at the lower part of the lumbar spine, and more frequently opposite the sacrum or the sacro-iliac articulation on either side; this is sometimes very severe, perhaps runs down the thigh, or round the groin; irritability of the testicles may come on, or irritation about the neck of the bladder, causing frequent desire to micturate, and increasing the patient's sufferings by the straining that takes place. The general health now suffers, the patient may become emaciated, and the countenance often presents a peculiarly anxious, drawn, and careworn look.

The symptom, however, that first of all and most prominently fixes the patient's attention, is **Hemorrhage**. This varies greatly in quantity; at first there may merely be a few drops falling after the passage of a motion, or the cylinder of feces may be stained on one side by a streak or spots of blood, or the bleeding may amount to several ounces or even pints.

The hemorrhoidal flux is connected with, and in the great majority of

cases dependent upon, the existence of distinct hemorrhoidal tumors. Occasionally, however, it appears to occur when there is no distinct separate tumor projecting above the surface of the membrane; but in these cases there is general intumescence and congestion of the whole of the rectal membrane of the lower part of the rectum, from which the blood exudes in drops, or it may even spirt in a distinct jet from the open mouth of a blood vessel. It is frequently ushered in by an exacerbation of those symptoms that commonly accompany piles, such as a sensation of fullness, weight, and tension about the parts. But the symptoms that precede its occurrence are often much more imperfectly marked than is usually stated, and are frequently absent altogether.

The discharge of blood may be periodical, especially in women, occurring every month, or at intervals of two, three, or six months; and it may be remittent or intermittent. When once it has set in, it usually continues for three to six days, increasing in quantity up to the third or fourth day and then lessening.

When moderate in quantity and short in duration, it is often a source of relief to the patient; but if a very large quantity be lost at one time, and it continue for too long a period, it becomes a source of great distress, and harm is usually done to the patient by its long continuance, than by an excessive quantity at any one time. The patient may become faint, nervous, and anemic; nervous headaches, pallor, palpitations, and syncope may result. In some cases this discharge is of service, acting as a derivative, and preventing disease from falling on more important parts; it has actually been looked upon as, and doubtless is in many cases, a safeguard from complex and visceral congestions and obstructions, particularly when it occurs as a consequence of cirrhosis of the liver, or in plethoric and corpulent persons who habitually live too highly. In other cases it may be considered as critical; especially when it occurs about the cessation of the menstrual period. But as a rule, the continued loss of blood from piles is undoubtedly injurious to the patient's constitution.

Hemorrhage from piles is sometimes vicarious with, and at other times arrests the menstrual flow. In a case, which I attended with Gerard, the patient had suffered from the hemorrhoidal flux and piles from the age of puberty. She menstruated for the first time when thirty-seven years of age; up to that period the hemorrhoidal discharge had occurred about once in monthly intervals. After the late establishment of the menstrual flow, the piles continued to bleed, but less regularly, and she became more emaciated, and debilitated to the last degree. When she was forty-three years of age, I saw her for the first time; the piles, which were very large and vascular, were ligatured, and she made a most perfect recovery in good health.

The color of the blood is most generally florid, as if it came from the small arteries or capillaries of the part rather than from the veins. It would appear that, in consequence of the over-distended and varicose condition of the veins of the part, the onward flow through the arteries and capillaries leading to them is obstructed, and that, in consequence of the increased pressure on those vessels, their parietes give way, allowing the blood to escape from the arteries.

Very commonly the internal piles, when brought down, present somewhat granular surface, in consequence of ulceration having taken place, and the whole surface will be seen to exude blood in drops. In other instances the blood appears to come from a cavity in one side of the hemorrhoid, as if rupture had occurred from over-distention at that part.

The hemorrhoidal flux may be accompanied by, or alternate with, a

glairy mucous discharge from the rectum and diseased structures; this would appear to be nothing more than excessive secretion from the membrane, in consequence of the irritation set up by the presence of the piles; it is seldom in sufficient quantity to produce much annoyance, or to be of much moment to the patient.

COMPLICATIONS.—Piles are not uncommonly complicated with other diseases of the rectum, such as fissures, fistula, or prolapsus. When connected with fissure, the hemorrhoid often, as Symp has remarked, assumes a peculiar form and appearance, presenting itself as a small red colored body, like a pea in size, firm, and seated at the base of the fissure, which it often conceals; to a practised eye, however, the presence of a pile of this peculiar color and shape is sufficient to indicate the existence of a fissure.

In that form of fistula in which the aperture is near the anus, one or more external piles of small size are often found situated at the orifice of the fistula; and prolapsus rarely, if ever, is met with in adults, without the simultaneous occurrence of piles.

TERMINATIONS.—Hemorrhoidal tumors may terminate by Subsidence, Coagulation, Suppuration, or Sphacelus.

Subsidence.—Complete subsidence of a pile can take place only when the disease is of recent occurrence. When of long standing, and after it has been exposed to successive attacks of inflammation and turgescence, an external pile never subsides completely; and the areolar tissue and the mucous membrane structures, becoming hypertrophied, form elongated pendulous flaps around the margin of the anus.

Coagulation of the contents of the pile is the result of inflammation having taken place in it. When it takes place, the tumor, after more or less active inflammation becomes hard, incompressible, and indolent, permanent in size, and of a purplish or plum color. The coagulum thus formed may excite suppuration, or may be absorbed, the hypertrophied tissues forming one of the usual anal folds if the pile be external. In some rare instances, the coagula may be calcified and form phlebolithes.

Coagulation takes place more frequently in external than in internal piles, owing to the great impediment to the return of the blood from them, and to their greater liability to inflammation, their exposed situation leading them to be bruised or otherwise injured. When it occurs in internal piles, it most commonly affects those that are of a columnar or longitudinal shape, and least frequently the globular variety.

Suppuration is not an uncommon termination, if acute inflammation have been set up in internal piles, more especially in those that have previously been coagulated. When the abscess is discharged, small coagula escape with its contents, the cavity granulates, and becomes obliterated, and the pile is cured.

Sphacelus.—In some cases, when there is much elongation of the mucous membrane from which the pile springs, prolapsus of that membrane and of the piles may take place; and, this being grasped after it has descended by the contraction of the sphincter, the same effect may be produced as if a ligature were applied. The tumor becomes much swollen, hard, livid, and tense; there are much constitutional disturbance and restlessness; but after a few days the part that is constricted sloughs and drops off, and all the symptoms are relieved.

DIAGNOSIS.—The diagnosis must be regarded in two points of view: 1, as regards the *Hemorrhoidal Tumors*; and, 2, with reference to the *Hemorrhoidal Flux*.

1. **Hemorrhoidal Tumors** must be diagnosed from prolapsus ani, polypus of the rectum, epithelioma of the anus, and condylomata about the anus.

From prolapsus the diagnosis is not always easy; indeed, the two diseases are so generally associated, that it is of little moment to attempt it. In true prolapsus, ocular examination will suffice to distinguish the membranous wall of the intestine, forming a smooth, rounded, and somewhat annular protuberance, from the isolated tumors of piles. In polypus its history, the case, the pedunculated and solitary character of the tumor, its large size, and comparatively slight tendency to periodical hemorrhage will enable the Surgeon to make the diagnosis. **Epithelioma** is easily recognized by its hardness and by its deep infiltration of surrounding parts. In any case of doubt, a digital examination of the rectum will make its nature evident. From **condylomata** the diagnosis is easy; the soft, flat masses and wartlike character of these growths, their history, and their occurrence at other points, as the perineum, scrotum, vulva, and buttocks, will enable the Surgeon to distinguish them without any difficulty.

2. The **Hemorrhoidal Flux** must be distinguished from other intestinal hemorrhages. This may be done by attention to the character of the blood, which will enable us in many cases to determine its source. When it comes from piles it is liquid, of a more or less florid color; not unfrequently quite bright, staining or coating the feces rather than being mixed up with them. When, on the contrary, the blood is poured out at some higher point in the intestinal canal than the usual seat of hemorrhoids, it is of a dark, sooty character, mixed up with liquid feces either in a diffused form or in small black conglobula, and no fresh or bright blood will be visible. Digital exploration of the rectum in cases of piles, and the presence of symptoms indicating the existence of mischief at a higher part of the intestine, as the anus in cases of melena, will also serve to point to the seat of the lesion.

TREATMENT.—In conducting the treatment of a case of piles that Surgeon will succeed best who looks upon the disease not as a local ailment merely requiring manual interference, but as a symptom, or rather an effect of remote visceral obstruction and disease, the removal of which may be sufficient to accomplish the cure, without the necessity of any local interference; or, should it be thought necessary to have recourse to operative procedure, this must be made secondary to the removal of those causes which have primarily occasioned the congestion and dilatation of the hemorrhoidal vessels. The treatment of piles, therefore, must be considered, 1, *as regards the Removal of these Constitutional Conditions or Visceral Obstruction* which occasion the disease, together with any Topical Applications that may be considered necessary; and, 2, with reference to the *Operative Procedure* that may be required for the removal of the affection.

2. The **Constitutional Management** of piles necessarily varies considerably according to the condition of the patient in whom they occur, and the visceral obstruction to which they may be referable. Thus, when they occur in debilitated persons, apparently from relaxation of the vessels, most benefit will be derived from a mild tonic and nutritious plan, at the same time that the bowels are kept regular by some of the aperients that will be mentioned. In these cases, also, much advantage is often obtained by the administration of the confection of black pepper, which acts as a local stimulant to the vessels of the rectum. A cold water regimen after each motion is very useful in these cases. In the great majority of instances, however, more particularly when occurring about the middle period of life, piles are connected with a plethoric state of system, and obstruction of the abdominal viscera. In these circumstances, our efforts should be directed to the reduction of the plethoric condition, by putting the patient on a proper regimen, prohibiting the use of stimulants, and lessening the quantity of animal food that he is in the habit of taking. When piles arise from a

pressure of a gravid uterus or other abdominal tumor, little can be done; except by local palliatives and mild aperients, to moderate the inconvenience attending them.

In all cases of piles, but more particularly in those arising from hepatic obstruction, mild aperients are of essential service; by removing feculent accumulations, and establishing a free secretion from the intestinal surface, they tend materially to prevent congestion of the portal system. At the same time, drastic purgatives of all kinds should carefully be avoided. The most useful aperients are the electuary of senna, sulphur, and castor oil; one or other of which should be taken regularly twice or thrice a week at bedtime, in as small a quantity as will be sufficient to keep the bowels free. In many cases, the confection of senna may advantageously be given in combination with precipitated sulphur and the bitartrate of potash, equal parts of each of these being made into a mass with twice their quantity of the confection and a little syrup; of this electuary, a dessertspoonful may be taken every night or every second night. If there be a relaxed condition of the rectum and anus conjoined with the piles, as not unfrequently happens in old as well as in young people, the administration of an electuary composed of equal parts of the confections of senna and of black pepper, or of cubebs, will be found very useful. In fact, in all cases in which the black pepper is administered, an aperient should be given from time to time, to prevent its accumulation in the large intestine. When the liver is much obstructed, the treatment should be specially directed to the relief of this organ; with this view, a course of Plummer's pill, followed by taraxacum, and, in relaxed constitutions, the mineral acids, will be found especially serviceable, at the same time that the bowels are kept free by gentle aperients.

The habitual use of lavements, consisting either of soap and water or thin gruel, will be found advantageous in many cases of piles, though in some they appear to irritate, and rather to increase the disease. When the piles occur in relaxed constitutions, the lavement should be used cold; but when the patient is of full habit of body, a tepid one will usually be found to agree best. In the general management of piles, it need scarcely be observed that any habits which favor the disease should be sedulously avoided.

The **Local Treatment** of piles is of considerable importance. The parts should be regularly sponged with cold water, morning and evening. If there be much relaxation, and the piles be internal, benefit may result from the employment of some astringent injection, such as a very weak solution of the sulphate of iron, or of the tincture of the sesquichloride—a grain of the first or ten drops of the second, to an ounce of water; of this, about two ounces may be injected every night and left in the rectum. The application of an astringent ointment, such as the unguentum galle co., extract of witchhazel, or the employment of the anodyne and astringent suppository already recommended for fissure of the anus, will be attended with much benefit.

If external piles become inflamed, the patient should keep his bed, and leeches should be freely applied around but not upon the tumors. Tepid lotions, poultices, and poppy fomentations, must be assiduously used, a very spare diet enjoined, and the bowels opened by mild saline aperients. If a coagulum form in an external pile, as the result of inflammation, the tumor should be laid open with a lancet, and its contents either squeezed, or turned out with the flat end of a director. If abscess form, it must be punctured in the usual way, and the part afterwards fomented or dressed with boracic lint soaked in warm boracic lotion. Should strangulation of the piles take place, the protruded swelling must be returned by gentle, steady pressure, and the part afterwards well poulticed.

2. Operation.—The means above indicated are usually sufficient in ordinary cases of piles; but if the disease attain an inconvenient size, giving rise to general irritation and local uneasiness, or if the abundance of the hemorrhage be such as seriously to interfere with the health of the patient, it becomes necessary at last to have recourse to operative interference, with a view of removing the diseased structures. No operation should ever be undertaken whilst the pile is in an inflamed state, lest unhealthy inflammation be set up in the part; it is also well to get the patient's health in a good state, as erysipelas may otherwise follow the operation, and before proceeding to perform it, care should be taken that the bowels have been well opened. If the patient is suffering from cirrhosis of the liver, no operation is justifiable.

There are five plans of treatment commonly adopted for the removal of piles, viz., excision of the tumor, its strangulation by ligature, its destruction by the clamp and caustery, by crushing, and by the use of caustics. These methods of treatment should not be employed indiscriminately. The first is alone applicable to external piles; the others to the internal form of the disease.

Excision.—The removal of external piles is readily effected. The tumor should be seized with a vulsellum or hook, drawn forwards, and snipped off with a pair of knife-edged scissors, curved upon the flat. At the same time when the external piles are removed in this way, any pendulous flap of skin in their vicinity should be excised, lest they become irritated, and constitute the basis of a fresh pile. After the excision of external piles, there is usually but trifling hemorrhage, which may readily be arrested by the application of cold lint, or a pad and T-bandage. Should any small artery bleed, it may be pinched, and the hemorrhage thus stopped. The hemorrhage attendant on this little operation is sometimes rather profuse.

Ligature.—Internal piles are usually removed by the ligature; indeed, it may be laid down as a rule in surgery, that no internal pile should ever be treated by excision. The reason of this difference in the practice to be adopted, according as the pile is situated above or below the margin of the anus, is the liability to hemorrhage in the one case, but not in the other. The bleeding that follows the excision of an external pile is not only small in quantity, but may readily be arrested by cold or pressure. With internal piles, however, it is different; these tumors are not only more vascular, being often fed by a large central arterial twig, but are deeply seated and do not readily admit of the application of means for the arrest of the flow of blood from them. So difficult is it to stop the bleeding from the internal pile in some cases, that patients have actually lost their lives from this cause after its excision, even in the hands of some of the most distinguished surgeons. The excision of internal piles has, consequently, been very properly abandoned.

The *Operation for the Ligature of Internal Piles* may most conveniently be conducted in the following manner. The patient, having had his bowels cleared out by a dose of castor oil on the day preceding that fixed for the operation, should have an abundant lavement of warm water administered about an hour before the Surgeon arrives; and he should then be directed to sit for half an hour on a bidet, or over a pan containing hot water, sitting down at the same time, so as to cause the piles to protrude. When he is ready, he should be laid on the bed on his left side, with the knees well flexed; the Surgeon then seizes the most prominent pile with a ring-forceps (Fig. 814), draws it well forwards, and ties its base as tightly as possible with a thin whipcord ligature. The ring-forceps may be replaced by a clip or by a strong India-rubber ring on the shank, which does not

drawn down to the handles. He does the same to one pile after the other, until all that can be met with have been strangulated in this way. In some cases the pile is so broad at the base, that the ligature will not include it. In such cases some Surgeons employ transfixion; this may usually be done readily enough by means of a naevus-needle, or by the instrument represented in the annexed drawing (Fig. 815), Bushe's Needle, which consists of a steel shank fixed in an ivory handle, and having its free end perforated for the reception of a needle-eye near its point. In this instrument, not only is the angle formed by the needle and the shank a very convenient one for passing a ligature through a pile inside the anus, but more particularly, as the needle can be detached, it may, as soon as it is carried across the base of the tumor, be separated and so withdrawn more readily than it otherwise could. Transfixion of the pile and its ligature in two halves is, however, a very dangerous procedure, and should never be had recourse to if it can possibly be avoided. The danger of this operation

Fig. 814 — Ring forceps.

Fig. 815. — Bushe's Needle for applying Ligature to Piles.

consists in the possibility of a hemorrhoidal vein being transixed, and the two halves then tied separately. In this way, the vessel is left open and cannot collapse, and the risk of direct septic absorption becomes very great.

Transfixion may usually be avoided when the pile is large and round, by snipping through the cutaneous portion by means of curved scissors, thus leaving a deep groove for the reception of the ligature, which then constricts only the substance and mucous surface of the hemorrhoid. If the pile be longitudinal, it may be deeply notched with scissors in a direction upwards from its lower attachment, at the line of juncture between the skin and mucous membrane, and the ligature tied in the groove thus formed. In whatever way the ligatures are applied, care should be taken that they are tied as tightly as possible, so that the piles may be effectually strangled at once; as in this way they separate much more readily, and with far less pain to the patient than if loosely tied. When all the tumors requiring ligature have been tied, the ends of the threads must be cut off close, and the strangulated mass pushed back into the bowel. If there be any external piles, these must now be cut off; for, unless this be done, they become irritated, swollen, and inflamed by the presence of the ligatures, and constitute a source of much distress. A morphia suppository is administered and the patient must now return to bed, and should keep the recumbent posture until the ligatures separate, which usually happens from the sixth to the eighth day, when an ulcerated surface will be left, which, however, speedily closes and contracts. In some cases this process may be facilitated by the application of the nitrate of silver through a speculum ani. On the third or fourth day after the operation, the bowels may be opened with a dose of castor oil.

In the after-treatment of the case, care must be taken to prevent the recurrence of those causes that gave rise to the affection in the first instance.

After piles have been tied, more particularly if they be seated towards the anterior part of the rectum, there is frequently great irritation set up in the neck of the bladder, so that the patient experiences difficulty in passing

Fig. 816 - Smith's Clamp

his urine, and sometimes suffers from complete retention; a warm bath, and a full dose of hyoscyamus and nitrous ether, will usually relieve him, and enable the urine to pass; if it fails a catheter must be passed. In some cases, where the piles are very large and vascular, and the patient debilitated, the ordinary rule of cutting them off may advantageously be deviated from, and a combination of the treatment by excision and ligation be adopted. In such cases an incision may be made through the integuments of the rectum, and then the pile tied in the course of the groove thus formed. By these means the pain and constitutional disturbance consequent on the inclusion of a portion of the integument in the ligature are avoided, at the same time that the risk of hemorrhage is not increased.

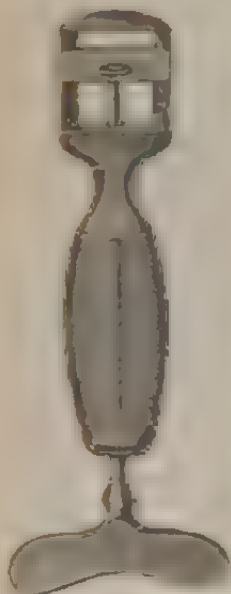

Fig. 817 - Allingham's Clamp.

The treatment of piles by ligation is not altogether devoid of danger in persons of feeble constitution. I have more than once known them from pyæmia result in these cases.

Smith's Operation. Piles may be removed with but little fear of hemorrhage by the method introduced by H. Smith, which is as follows. The pile is brought down and seized in a clamp (Fig. 816) fixed by a few turns of the screw, and turned off with a cautery. The clamp is then slowly released, and should any bleeding take place as it becomes loose it is again tightened, and the cautery applied once more. The operation is usually followed by a constant catarrh of the rectum, and is followed by equally satisfactory results.

hemorrhage is prevented, and cicatrization facilitated.

The Removal of Piles by the Galvanic Ecraseur may easily be effected, the pile being drawn down with ring-forceps, and its base constricted by the platinum-wire of the écraseur, which, being tightened, cuts off the pile very readily. This treatment is, however, more troublesome, and presents no advantages over the method by the clamp and cautery.

Crushing.—The plan of removing piles by crushing has been suggested by Podlock. By this method the hemorrhoid, after having been carefully freed by snipping with scissors, is seized in a pair of screw-forceps, and is tightened so as to compress the pile into a narrow line at the part seized. The projecting portion is then cut off and the instrument removed. Allingham has invented a clamp (Fig. 817) for this purpose, which is more portable than the forceps and very easy of management.

Caustics.—In certain kinds of internal piles, the application of nitric acid has been recommended by Houston, of Dublin, and H. Lee, and may certainly be adopted with advantage. It must not, however, be applied to the external or to the intero-external pile, as it will produce extreme irritation; nor can it be looked upon as a substitute for the ligature or the cautery in internal piles generally. It is especially in the granular pile, having an ulcerated surface, that this mode of treatment is useful; as in these cases it appears, by destroying a portion of the mucous membrane, not only to cure the pile to which it is applied, but, by producing an ulcer, to give rise to a cicatrix, which, by contracting, consolidates the parts in its vicinity, and so lessens the relaxed state of the rectum, which favors the hemorrhoidal tendency. The acid may conveniently be applied through a glass speculum, having an aperture on one side (Fig. 818). This should be introduced well oiled, until the pile projects through the opening in it, when it must be freely rubbed with a piece of stick, or a glass rod, or brush, dipped in the acid, the

Fig. 818.—Speculum Ani.

Fig. 819.—Gilt Clip.

surface is then immediately wiped with a piece of lint saturated with prepared chalk and water, and the instrument removed. Or the gilt clip (Fig. 819) may be used, so as effectually to protect the neighboring parts from the action of the acid. A thin slough separates, leaving a raw surface, which gradually cicatrizes and contracts. The application of the acid occasions but little pain when fairly made within the rectum; but if a drop of it accidentally come into contact with the muco-cutaneous surface, a vast deal of irritation and inflammation is excited. This plan of treatment, though useful in particular forms of pile, as when the tumor is granular and flat, so as not to allow of ready removal by the ligature, should not be practised when other means can be employed, as it is by no means so certain a mode of treatment. It cannot be considered altogether devoid of risk; for I have known one instance in which fatal erysipelas followed the cauterization of piles with nitric acid.

Dangers attending Operations for Piles.—The operation for the removal of piles may be attended by three sources of danger. After excision, and even the application of the ligature or of nitric acid, erysipelas may develop. If the objectionable practice of transfixing the pile by the needle be followed, and it be tied in two separate parts, a hemorrhoidal vein may thus be opened, and its sides held apart by the action of the ligatures, and thus a tendency to direct pyemic infection be induced; and lastly, I have seen a kind of erysipelatous colitis follow the operation, leading to profuse muco-purulent discharge and high fever. I have also in one case seen pelvic cellulitis set

up. But all these various secondary affections—erysipelas, pyoderma, and cellulitis—are happily of rare occurrence.

A permanently moist condition of the skin around the anus is not infrequent, as the result of portal congestion or a hemorrhoidal tendency. It is best removed by the habitual use of aperient salines, or of aperient mineral waters, as those of Polina or Friedrichshall.

Pruritus Ani is often an extremely troublesome affection, the nature and general irritation about the anus being almost unbearable. In some cases it is due to the presence of external piles or worms. In others it results from the irritation of the skin from the mucous discharge just mentioned. In others again it is due to eczema. Excess in alcoholic stimulants, habitual constipation, and other conditions may give rise to it; but frequently the most careful investigation fails to detect any cause. The treatment must have reference to the cause if one can be found. If there be an external pile, the removal of it; if worms, their expulsion will probably cure the condition. If it is due to eczema, boracic acid ointment with a drachm of extract of belladonna added to each ounce will frequently bring about a speedy cure. If there is a mucous discharge, the frequent application of boracic acid lotion may give relief. In some cases it seems dependent on gout, and the treatment for that disease removes the pruritus. In other cases arsenical preparations will be found useful, together with the local application of chlorinated lotions or those containing hydrocyanic acid. Sometimes tar applied by means of a piece of oakum gives complete relief, but in many cases nothing succeeds.

PROLAPSEUS ANI.

Prolapsus Ani consists in a protrusion of the mucous membrane of the rectum through the anal orifice; the areolar tissue that lies underneath it being also, in the majority of instances, much thickened and elongated. In the ordinary prolapsus, the muscular structures of the gut are not protruded; yet occasionally the muscular coat descends with the mucous membrane in invagination of the bowel taking place, which constitutes a far more serious condition. The former condition alone is correctly termed prolapsus, and the latter is more correctly spoken of as prolapsus or proctodiarrochia. Prolapsus recti is rarely met with in adults, and is in them never extensive. In children it is the common condition, true prolapsus ani being very rare. The prolapsus of children is therefore, better considered separately from that of adults.

Causes of Prolapsus Ani.—In weakly persons generally there is a natural tendency to prolapsus; the slight protrusion of the mucous membrane which takes place during defecation being increased by any constitutional condition that gives rise to atony of the muscular system, especially if irritated. The intestinal mucous membrane be conjoined with this, as in dysentery, or diarrhoea, etc. So, again, the habitual constipation, often occurring in persons of a relaxed habit of body, apparently proceeding from want of power in the rectum to expel its contents, and requiring constant straining at stool, predisposes to this affection. It is especially common in those who labor under stricture, stone, or any other disease about the urinary organs that require considerable effort to be made in expelling the contents of the bladder. In persons whose constitution has been relaxed by a long residence in a warm climate the disease also frequently occurs. In other cases, and, indeed, most cases, the prolapsus is associated with piles, the weight and dragging of the hemorrhoids drawing down the mucous membrane. This is especially apt to happen when there is general hemorrhoidal tendency about the anus. In such cases

causes of prolapsus may be summed up under three heads: 1. Simple relaxation of tissue, such as is met with in weakly persons; 2. Sympathetic irritation, as in chronic tenesmus, stone in the bladder, etc.; 3. A hemorrhoidal or polypoid condition of the mucous membrane of the rectum.

DIAGNOSIS.—Prolapsus is readily recognized. It consists in the protrusion of a ring of mucous membrane of a red or purplish color, and having a somewhat turgid look, rather lobulated in shape, and varying in size from half a walnut to a small orange (Fig. 820). The mucous membrane covering

Fig. 820.—Prolapsus Ani

this ring will be found to be continuous with that investing the sphincter, and this constitutes the mark of distinction between ordinary prolapsus, a projecting intussusception or a protruding polypoid growth. In prolapsus there is, when the protrusion is down, a dragging and smarting sensation, often attended with a good deal of spasm about the neck of the bladder, and not unfrequently with symptoms of stricture. In chronic cases, the anal aperture appears to be permanently relaxed; and, on introducing the finger into it, it is found to be widened and weakened. The folds of skin in its neighborhood are relaxed and elongated, radiating from it as from a centre; they are commonly bluish, soft, somewhat swollen, and pendulous, and often the seat of a good deal of irritation. The protrusion at first occurs only after defecation, and then readily goes back of itself, or is reduced by steady pressure upon it; after a time, however, it will come down at other periods; thus it may protrude during riding, walking, or even standing, and is returned with much difficulty.

Strangulation of the prolapsus may occasionally occur, if it be allowed to protrude for a considerable length of time without a proper attempt being made to push it back. It then becomes swollen and livid, with great pain and tenesmus, discharges a fetid ill-conditioned pus, and may eventually fall into a sloughy state, and, thus separating, undergo a spontaneous cure.

There is a form of prolapsus that arises from complete atony of the levator ani and sphincter ani muscles. For this nothing can advantageously be done by operation. Palliation by simple support is the sole treatment.

TREATMENT.—The treatment of prolapsus may be said to be palliative and curative. The **Palliative Treatment** consists, in the first place, in reducing the tumor when protruded. This, in ordinary circumstances, the patient does for himself; but, if it become congested, it requires the help of the Surgeon to put it back. This may occasionally be readily done by laying the patient on his side, or making him lean over the back of a chair; and then greasing the mass with some oil, seizing it with a soft towel, and gradually compressing it, working it back. It may be kept up by wearing a belt with a pad and elastic support. Olive-shaped pewter pessaries are occasionally employed, with the

view of preventing the protrusion; but I have never seen them of any service, the sphincter being usually too relaxed to keep them up, and their pressure appearing to excite irritation.

The regulation of the bowels is as important in prolapsus as in piles. It is usually best done by the administration of those laxatives that have been recommended for the latter disease. It is a good plan in prolapsus to get the patient to have his daily motion at bedtime instead of at the usual hour in the morning; the recumbent position and the uniform temperature of the bed preventing the irritation of the sphincter and spasm of the anal muscles that commonly continue for some time after the reduction of the prolapsus, and which are a source of great discomfort when occurring in the early part of the day.

Curative Treatment.—The relaxation of the mucous membrane of the rectum that essentially constitutes prolapsus, may often be obviated by astringent injections or suppositories. The best injection is that of the sulphate of iron, in the strength of from one to three grains in an ounce of water, thrown up in small quantities sufficient for the bowel to retain. In mild cases of prolapsus, conjoined with a relaxed state of the mucous membrane of the rectum and relaxation of the sphincter, the use of the iron injection will be found particularly beneficial, at the same time that the action of the bowels is regulated by means of an electuary taken in the morning or at night. By thus giving tone to the bowel, at the same time that constipation is prevented, the disease will occasionally undergo a cure, provided it be not associated with any affection in other organs.

In those cases in which the prolapsus is hemorrhoidal or polypoid, the protrusion being dragged down by the weight and strain of the pile or polypus, the same treatment must be adopted as has been recommended for the latter disease; and usually, after the ligature and removal of the pile or polypus, the prolapsus will be cured. In slight cases of prolapsus, in which the disease appears rather to be owing to the relaxation of the sphincter and of the tissue external to it, the muco-cutaneous integument hanging in loose folds around the anus, considerable benefit will commonly result from snipping off these pendulous flaps of skin; the cut surface that is left cicatrizing, and by its contraction bracing up the part, and thus preventing its further protrusion. These pendulous flaps are best removed in a direction radiating from the anal orifice, with curved knife edged scissors.

When the prolapsus is considerable, and the ordinary palliative treatment after a proper trial fails in effecting a cure, it will be necessary to remove the protruded mucous membrane by operation. This should be done by the application of the ligature, or by the clamp and cautery; excision, though easy, being objectionable in this as in the case of piles, on account of the danger from hemorrhage.

Application of Ligature.—The patient having had the bowels freely opened on the preceding day, and an enema of tepid water on the morning of operation, should be directed to sit over a pan of hot water, in order to make the prolapsus descend; a portion of it may then be seized with a pair of broad ended forceps, such as are represented in Fig. 814, drawn well forwards and firmly tied with a strong piece of whip cord. A similar process is then repeated on the opposite side of the anus. Should there be any difficulty on account of the shape of the protrusion in ligaturing the base firmly, this may be obviated by transfixing it with a hemorrhoidal needle, and tying it on each side. I think, however, that it is better, if possible, to avoid doing this. If the protrusion be very large the ligatures should not be made to include too much, lest the muscular coat, or perhaps even the serous, have also descended, and should be accidentally included, or lest a

stricture of the bowel should follow the operation. The ends of the ligature must then be cut short, the whole protrusion returned into the bowel, the external flaps of skin cut off, and a morphia suppository introduced into the bowel. Small doses of opium or morphia may subsequently be administered, so as to arrest all peristaltic action for a few days. Should the ulcerated surface show any difficulty in healing, it must be touched with the nitrate of silver. This operation always leaves a permanent cure.

The ligature of prolapsus, like that of *internal piles*, is not very painful, and for it chloroform need not be administered; indeed, in some cases it is, perhaps, better that it should not be given, as the protrusion is apt to slip up under its influence, the patient not being able to exercise the proper expulsive efforts. But, as the excision of the external flaps and piles is attended by very sharp suffering, it is as well to administer the anæsthetic at the time when they are being removed.

If the clamp and cautery be used, they are applied in the same way as for *piles*.

Should a prolapsus become strangulated, it would be necessary to try to reduce it through the sphincter by the employment of the taxis; if this cannot readily be accomplished, free incisions may be made into it; if it be not reduced, it will slough away, and thus undergo permanent cure.

Prolapsus of the Rectum.—As before stated, this is rare in adults and is seldom extensive. It can only be suspected when the amount extruded from the anus is very large. In children, on the other hand, a prolapsus almost invariably includes the whole of the coats of the bowel. It presents a smooth red surface and projects usually for some distance from the anus. As much as six or seven inches have been known to be extruded. It has before been pointed out that intussusception commencing at the ilio-cæcal valve may reach the anus and actually project from it. In this condition the valve itself forms the apex of the protrusion. If the intussusception occur in the rectum, it may still more readily project from the anus. These conditions are easily distinguished from true prolapsus of the rectum, for in the latter condition the mucous membrane covering the protruded gut is continuous with the skin at the margin of the anus, while in an intussusception the finger can be passed into the bowel by the side of the projecting invagination. Prolapsus of the rectum is seldom much swollen and very rarely becomes strangulated.

The *Causes* of prolapsus of the rectum in children are various. It is common in connection with dysenteric diarrhœa, especially in weakly children. The irritation of worms is one of the most frequent causes. Polypus of the rectum is an occasional cause, and is easily recognized by the protrusion of the tumor with the bowel. Stone in the bladder is most frequently accompanied in children by some protrusion of the bowel during the straining to pass water. On the other hand, an extensive prolapsus may cause irritation of the bladder in a male child and thus simulate stone.

Treatment.—As the protrusion consists of the whole bowel, it is evident that any operative interference would be accompanied by danger of wounding the peritoneum, and is consequently unjustifiable. Superficial cauterization and removal of pieces of mucous membrane have been recommended, but they are never necessary. In the vast majority of cases the tendency to prolapsus speedily disappears if the cause be removed. Tonic medicines, especially iron, regulation of the bowels by mild aperients, and the administration of a moderate quantity of unstimulating food will soon relieve it if due merely to weakness. If worms are present, salt and water or quassia injections will soon get rid of them. If there is any urinary disturbance the child should be sounded for stone, the removal of which will at once

cure the prolapsus. The prolapsed bowel should in all cases be bathed with cold water, and then reduced by gentle pressure with some oiled rag. Should it become strangulated, a condition of extreme rarity, an attempt must be made to reduce it by pressure, but if this fails it must be allowed to slough off, while opium is administered to relieve pain and arrest any action of the bowels. In this way it may safely separate without the occurrence of peritonitis.

Protrusion of an Ovarian Cyst from the Anus occurred in a unique case recorded by Stocks, of Salford. The cyst, which was the size of a coconut was removed by incision through the coats of the bowel, which were forced out before the tumor; and after the wound had healed, the gut was returned.

DISEASES OF THE GENITO-URINARY ORGANS.

CHAPTER LXVI.

SECONDARY DISEASES OF THE URINARY ORGANS ARISING FROM SURGICAL CAUSES.—PYÆMIA AND SEPTICÆMIA IN URINARY DISEASES.

THE great majority of cases of stone in the bladder, stricture of the urethra, cystitis secondary to paralysis, retention from enlarged prostate, tumors of the bladder, and, in short, of every disease tending to hinder the escape of urine from the bladder, or to induce chronic inflammation of that organ, terminate, if not relieved, by giving rise to fatal disease of the kidneys. This fact alone is sufficient to make the study of the secondary affections of the kidney of the greatest importance to the practical Surgeon; and the obscurity which surrounds their diagnosis, and the general impotence of treatment intended for their relief, render the subject well worthy of the fullest investigation.

Morbid Conditions of the Bladder.—If we examine a case in which death has occurred from one of the above-named diseases, we find that the mucous membrane of the bladder shows signs of both recent and old *inflammation*. The recent is indicated by the swollen and softened condition of the mucous membrane, and the intense purple of the summits of the rugæ, and possibly by patches of ulceration, the ulcerated surfaces being often covered by a thick slough closely resembling diphtheritic membrane. The old inflammation is indicated by the dark slate-gray pigmentation which affects the greater part of the mucous membrane, and which has resulted from repeated attacks of intense congestion, in which red blood-corpuscles have become extravasated, and, after breaking up and becoming absorbed, have left their pigment behind them. The muscular wall of the bladder is found to be *hypertrophied*, or not, according to circumstances. If, in order to expel the urine, it have been called upon to make a greatly increased pressure on its contents, the hypertrophy will be very marked. If the obstruction to the flow of urine have been of a valvular nature, as is often the case in enlarged prostate, then *dilatation* of the bladder will greatly exceed the hypertrophy of the muscular walls. It may, therefore, always be supposed, when great hypertrophy with contraction of the bladder is found, that increased difficulty existed in expelling the urine, but the increased power of the bladder proved equal to the occasion. When dilatation is found combined with hypertrophy, we must conclude that increased power was required to expel the urine, but the increase of muscular tissue was not quite sufficient, and that the bladder suffered frequently from over-distention. When dilatation alone is found with scarcely any hypertrophy, we know either that the bladder has been paralyzed, or that the obstruction to the exit of urine was valvular in nature, so that increased force applied to the contents of the bladder could only shut the valve more closely; and over-distention, with such an amount of

stretching of the neck as to render the valve incompetent, and thereby means by which urine could be passed without arterial aid. This condition is peculiar to prostatic disease, and some cases of tumor of the bladder. In all cases of great hypertrophy of the muscular walls of the bladder the bundles of fibres form ridges on the surface, giving rise to the condition known as *fasciculation*. In many cases in which great prostatic hypertrophy has existed in the bladder, either from the forcible contraction of hypertrophied walls on the contained urine, or from simple overdistention from retention arising from a valvular obstruction in the prostate, the serous membrane becomes thrust between the bundles of muscular fibres, forming pouches called *sacculi*. These sacculi are most frequent in the posterior part of the bladder, and, in most cases, their walls are composed of the mucous membrane and peritoneum. Sometimes, however, a layer of muscular fibres is also found. These sacculi form pouches in which putrid urine accumulates, and frequently gives rise to inflammation of the mucous membrane, sometimes ending in ulceration, and possibly perforation of the bladder. Much more often it gives rise to attacks of local peritonitis, the portions of intestine may so become adherent to the bladder.

The *causes* which give rise to an increased demand for force in expelling the urine, and consequently to hypertrophy of the bladder, are various. The most common is perhaps obstruction in the urethra from stricture. In some cases it may arise from an irregular enlargement of the prostate, in which the obstruction is not valvular in character. Villous growths and other tumors of the bladder may call for increased force from partially obstructing the orifice of the urethra. Chronic cystitis, from the altered character of the urine, always causes more or less hypertrophy. Stone in the bladder causes obstruction of the flow of urine, partly mechanically and partly by the chronic cystitis to which it gives rise. The thick ropy mucus of chronic cystitis undoubtedly offers considerable obstruction to the flow of the urine. All these causes, therefore, may give rise to more or less hypertrophy. There is no evidence of more frequency of action plays any important part in the production of hypertrophy. In the few recorded cases in which there was great freedom of micturition with healthy urine in cases of calculous pyelitis, no marked hypertrophy is made of any marked hypertrophy.

There is every reason to believe that hypertrophy of the bladder plays a very important part in the production of kidney disease. In no case is the result of obstruction to the exit of urine from the bladder do we find the valves of the ureters incompetent. In the simple dilatation from valvular obstruction in the prostate, they are closed more firmly than natural. A regurgitation takes place, but of course the pressure in the ureters and kidneys will be increased, while the bladder is over-distended. In cases of simple swelling of the walls, we find also a certain amount of obstruction to the entrance of urine into the bladder, as the ureter has to pass obliquely through the thickened wall, and is doubtless often pressed on by thickened bundles of muscle. The swelling of the mucous membrane at the orifice of the ureter in distended bladder probably adds to this obstruction. Here then, even if there may be no over-distention of the bladder, there is increased pressure in the ureters and kidneys, the force of secretion remaining unaltered, and the obstruction to the onward flow is offered by the partially obstructed orifice of the ureters. The degree of obstruction offered by a hypertrophied bladder varies much, as it is not uncommon to find considerable thickening of the wall of the bladder without any marked signs of pressure on the ureters or kidneys. In cases of villous tumor of the bladder, the ureters and kidney only may be found to be affected, and it will then be possible

ence of which to say the least was improbable. Later observations by Koch, with improved methods of staining, have clearly demonstrated the fact that, in every case of disseminated suppuration following on septic changes of the urine in the pelvis, colonies of micrococci are found scattered throughout the kidney, distending and obstructing the urinary tubules. These micrococci are similar to those found in putrid urine, and are believed to be the ferment to which the change is due. The abscesses of the kidney thus arising in acute suppurative nephritis must not be confounded with those seen in pyæmia. These are usually larger, are more distinctly wedge-shaped, and sometimes

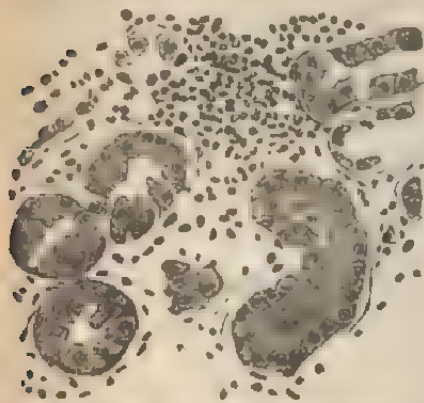

Fig. 822.—Acute Interstitial Nephritis; Condition of Epithelium.

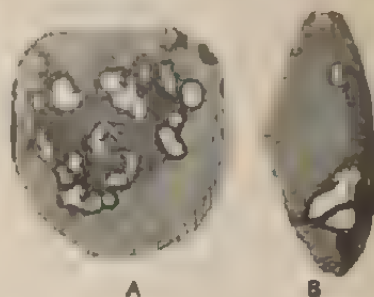

Fig. 823.—A. Group of Abscesses on Surface of Kidney. B. Vertical Section of the same.

surrounded by a zone of hemorrhage. They are always in the cortex, and the pyramids show no signs of disease. Pyelitis is absent, but, as before stated, it may be wanting, or feebly marked in cases of genuine interstitial nephritis, secondary to affections of the bladder. Koch has, moreover, pointed out an important microscopic distinction. Micrococci are found in the pyæmic kidney as well as in pyelo-nephritic kidney; but in the former they are in the vessels, especially in the Malpighian loops, while in the latter they are in the tubules. Microscopic examination of a pyæmic kidney further shows an absence of the general diffused inflammation characteristic of the ordinary septic kidney.

3. *Effects of Former Attacks from which the Patient has Recovered.*—It is possible that the kidney may undergo extensive intertubular change, and yet, if the cause be removed, the inflammatory growth may be completely absorbed, and the organ regain its normal condition. More commonly, however, the new growth undergoes a development into fibrous tissue, a change corresponding exactly to that which occurs in the cicatrization of a granulating sore, and accompanied by a similar process of contraction. Thus we get an increase in the intertubular connective tissue, and at the same time a contraction and induration of the whole organ, so much so that it is sometimes reduced to less than a quarter of its normal bulk. If the pyramidal portion have undergone absorption, this is never repaired, but, as its function seems merely that of a duct, its loss is of no great moment. In a kidney of this kind, we find the fat adherent to the capsule, and the capsule to the gland-tissue. It strips off with difficulty, and is thick and opaque. The surface of the kidney is irregular, granular, or perhaps even puckered by cicatrices. Scattered over the surface, in most cases, are numerous small cysts. These are supposed to be due to the strangulation of the tubules by

cystitis, and no instrument had been passed during life. In this case the ureters were greatly dilated, and the pelvis on each side was expanded so as to contain many ounces of fluid. The kidneys were somewhat increased in size, and before being opened felt like great thick-walled bags, and giving all over a distinct sense of fluctuation. On being cut open they presented the following appearances. The capsule was tough and opaque, and separated with difficulty from the kidney-substance, slightly torn, in so doing, and leaving the surface coarse and irregular. The surface was uniformly pale, and whitish in color. No trace of the pyramids was to be seen, but where each should have been was a deep hollow lined with a smooth membrane continuous with that lining the pelvis of the kidney. The cortex was of about normal thickness, but in some parts thinner than natural; it was somewhat tough in consistence, and presented a uniform opaque whitish tint. The whole kidney was thus converted into a great sacculated bag, composed on one side of the dilated and thickened pelvis and on the other of the expanded cortex of the kidney. There were no signs of past or present acute inflammation. On microscopic examination of a section of the cortex, the chief change noticeable was an abundant small round celled infiltration of the intertubular tissue of the kidney. Every tubule was separated from its neighbors by rapidly growing vascular connective tissue, crowded with small round cells, and this by pressure on the vessels, had given rise to the pale color above noted. The new growth was most abundant round the Malpighian bodies, the capillaries of which were greatly thickened; so much so, that in many the vessels had yet strangled and obliterated. The amount of change was not uniform, its growth being more abundant in some parts than in others. The tubules themselves showed no great signs of change. They were slightly dilated, in some parts, and the epithelium looked as if flattened by pressure, in other respects it was perfectly healthy. This case shows that unobstructed tension from partial obstruction of the ureter gives rise to a gradual absorption of the pyramids, and to a condition of interstitial inflammation of the kidney, probably varying in severity with the degree and acuteness of the obstruction. In more extreme cases than that above described, the atrophy of the cortex becomes much more advanced, till nothing may be left but a layer of kidney-substance not thicker than a shilling. The microscope shows also more dilatation of the tubules and flattening of the epithelium. It is an interesting fact to be noted, that in the case above described the secretion of urine was abundant, its specific gravity was 1000 and it was free from albumen and casts. It is also evident that, if such a kidney as this were exposed to any additional source of irritation, more acute inflammation is compatible with life would readily be set up.

2. *Acute Diffuse Interstitial Inflammation.*—In this condition the kidney is soft and swollen. The capsule is opaque, and small vessels are seen ramified in it. It separates easily, but tears the kidney substance in so doing. The surface of the kidney is coarse and irregular. The color of the surface is mottled, the greater part being usually of a pale yellowish tint interspersed with purple patches. Sometimes the mottling is very fine, almost granular. The venous sinuses always seen on the surface of the kidney are in this case show out prominently. On section, the cortex is found to be abnormally soft, and to present the same mottled color as the surface. Sometimes the part of the cortex corresponding to one pyramid may present a more or less formidably pale appearance than that belonging to another. Small red spots, looking like minute collections of pus, may be present, which are, however, on section found to be solid, though very soft. The pyramids are usually intensely injected, and contrast strongly with the paler cortex. The

by suppuration, after the operation of lithotrity. Cases of this kind have occurred in which the cystitis was not increased by the operation, in which the decomposition of urine remained unchanged, and no altered circumstance existed, except the mechanical injury of the passage of the instrument, to account for the sudden supervention of acute nephritis. In these cases signs of chronic disease, which has been rendered acute by the additional irritation, are always present. Lastly, a few cases have been observed at University College Hospital after operations for stricture, with the view of ascertaining if any change could be found in the urine as the direct result of the operation. In three cases of Holt's dilatation, the urine was found to be free from blood, or to contain no more than could be accounted for by the operation, during the first hour or hour and a half after the operation, and then to become gradually more and more bloody for another hour or hour and a half, and after that to become gradually free from blood. In one case there was almost total suppression for the first hour and a half, followed by very bloody urine. In one case of internal urethrotomy, during the first hour the urine flowed away in great quantities, and was almost free from blood. For the next six hours it was passed in moderate quantity, and was very darkly tinged with blood. In all four cases, there was some reason to believe that the blood came from the kidney. It occurred after the hemorrhage from the wound would have ceased; it was uniformly mixed with the urine, and free from clots. These cases are of course insufficient in number to draw any conclusions from them; but, as far as they go, they tend to show that, in all cases of operation on the urethra, there is a miniature representation of that intense congestion of the kidney which is found in cases of death from suppression of urine after simple catheterism. Possibly in some cases the dilatation of the vessels is preceded by a contraction of longer or shorter duration, giving rise to the suppression noted above. In a healthy kidney such an attack of acute hyperemia soon passes off and does no harm; but, supposing the kidney to be already diseased, the subacute condition may readily become acute and terminate fatally. Repeated attacks of such hyperemia, which probably result from the irritation of a stone, or passing urine through a bad stricture, would in all probability be alone sufficient to lead to a chronic interstitial change in the kidney. It is a matter of observation, that fatal affections of the kidney scarcely ever result from operations performed on the penile portion of the urethra.

3. *The presence of Septic Matter in the Pelvis of the Kidney.*—This plays the most important part in producing the final acute condition which so often kills the patient. In the first place, the mere presence of such an irritating substance as ammoniacal urine in the pelvis of a kidney already diseased, would certainly intensify the existing inflammation. It seems probable, however, that in many cases the septic matter thus pent up at a mere degree of pressure (for the thick mixture of mucus, pus, and urine cannot pass the valves of the ureter, already somewhat obstructed by the swollen mucous membrane and perhaps by a hypertrophied or distended bladder, so readily as healthy urine) becomes absorbed by the lymphatics of the kidney, and thus gives rise to a diffuse intertubular inflammation rapidly running on to suppuration. This would account for the pale streaks seen running in many cases parallel to the straight tubules in the pyramids, and expanding in the cortex. The presence of the micrococci in the tubules may also be taken as evidence that the decomposition of the urine may extend far into the kidney substance from the pelvis. Probably this condition alone is sufficient to account for many cases of acute suppurative nephritis, but it must be remembered that suppuration of the kidney does occur, occasionally, in cases in which the urine in the pelvis is free from decomposition. George Johnson

the papilla, or, if that have been partly destroyed by pressure as far as the point at which the tubules open into the pelvis. This condition is not invariable, as sometimes the abscesses are perfectly isolated, and show no connection whatever with the pyramidal portion of the kidney. One or more, or more of the abscesses may burst beneath the capsule, separating it from the kidney, and, giving rise to further suppuration, may invade the organ in a large collection of pus. This form of kidney, which is perhaps that most frequently met with in the post-mortem room, is frequently associated with the signs of pressure, absorption of the pyramids and dilatation of the pelvis. The microscope shows that in this form of kidney the appearances are essentially the same as in the last; the chief change being the accumulation of crowds of small round cells in the intertubular spaces, the degree of cell-infiltration varying in almost every field of the microscope. At the point at which an abscess is forming, or at the margin of one already formed, the crowds of small round cells are seen to press upon the tubules, separating them widely, and squeezing their walls together (Fig. 821). Then the wall becomes indistinct; then only a few epithelial cells

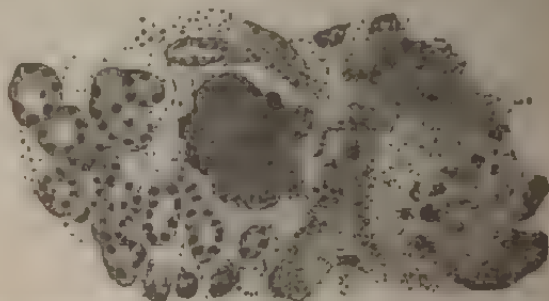

Fig. 821.—Acute Interstitial Nephritis. Scattered Abscess. Margin of abscess to the right. Malpighian body in the middle. Comparatively healthy tubules, with interstitial cell-infiltration, to the left.

can be recognized in the crowd of leucocytes; lastly, nothing but leucocytes can be seen, and a little nearer the centre the intercellular substance becomes fluid, and the cells float free, and pus is thus formed. The red areas are found to be due to extravasation, although hemorrhages may exist scattered through such a kidney. The yellow streaks in the pyramids are found to be due to a similar condition of intertubular cell-infiltration. Sometimes they may be seen in the vessels of the pyramids. These are probably associated to the inflammation of the parts surrounding the vessels. As to the latter variety, small round cells may be found in the tubules as well as about them. The epithelium is usually much swollen, and sometimes desquamated, the choking the tubules (Fig. 822), but this is only in those areas in which the interstitial inflammation is most advanced. In others it may appear almost healthy. In the pyramidal portion of the kidney many of the small tubes are found to have lost their epithelium by desquamation. This part of kidney merges into the diffuse variety, the solid yellowish spots to be mentioned representing points which, had the patient lived longer, would have softened into abscesses. Klebs, many years ago, described the presence of microscopic organisms in the suppurating kidney, but the means of investigation were at that time so imperfect that considerable doubt existed as to the correctness of the observation, more especially as he described a mycelium subsequently developing a branching mycelium—a form of growth the

streaks can often be seen running parallel to the straight tubules. These are most frequent in those cases in which the pelvis is filled with putrid urine. The pelvis is found in some cases free from any signs of acute inflammation, though more frequently it is much affected and filled with foul urine and mucus. The appearances here described are often conjoined with the signs of pressure mentioned above, varying from mere flattening to complete destruction of the pyramids. The microscope shows that this condition is a mere exaggeration of that found as the result of simple pressure. The change is chiefly and primarily interstitial, but the small cell-growth is so abundant as in many parts to press upon and even destroy the tubules, areas being found in which nothing but crowds of small round cells can be seen. These, when large, form the small yellowish spots visible to the naked eye. It requires only an increased intensity of the inflammation and a softening of these spots to convert them into minute abscesses. As in the form of interstitial nephritis first mentioned, the cell-infiltration is most marked round the Malpighian bodies. The change is rarely uniform throughout the kidney. It varies in degree usually in every field of the microscope, and parts may be found apparently almost healthy. The epithelium throughout the kidney is usually swollen and granular, and readily washes out in preparing the specimen, but it does not choke the tubules as in acute catarrhal nephritis. In very acute cases, small round cells, similar to those outside the tubules, are seen in the lumen of the tube surrounded by epithelium. These have probably found their way in from the outside, and, if washed on by the secretion from above, would appear as pus-cells in the urine. The vessels are often seen to be gorged with blood, and occasionally minute hemorrhages are present. It is not always easy to distinguish this form of disease by the unaided eye, as, from the pallor caused by the pressure on the vessels from the small cell-infiltration, it closely resembles the fatty kidney or some cases of catarrhal nephritis. The microscope alone can decide the question with certainty. Even in such a kidney the secretion of urine may be moderately abundant. In a case at University College Hospital, the patient excreted over 300 grains of urea on the last day of his life.

3. *Acute Interstitial Nephritis with Scattered Abscesses.*—(Suppuration of the kidney—suppurative nephritis; when accompanied by pyelitis—pyelonephritis [Rayer].) This is usually found in conjunction with that form of acute pyelitis in which the pelvis of the kidney is filled with putrid urine, pus, and mucus, but is by no means constantly so. In one case which was observed at University College Hospital, both kidneys were equally riddled with abscesses, but in one the pelvis was acutely inflamed and filled with foul urine, while in the other it was free from disease, and the urine it contained acid, and without unpleasant smell. The kidney is generally swollen and enlarged. The fat surrounding it is usually abnormally adherent to the capsule. The capsule is thick and opaque, and marked by ramiform vessels, showing clearly on the surface. It separates easily, but in so doing tears the kidney-substance. The surface of the kidney presents a more or less mottled appearance. The chief tint is the same as in the diffuse form just described, and is, in fact, due to the existence of the same condition; but scattered here and there, usually in groups, are bright yellow spots, surrounded by a dark red areola, and varying in size from a pin's head to a split pea (Fig. 823). On cutting into these yellow spots, each is found to contain a drop of pus. These minute abscesses are usually grouped in areas corresponding to that part of the cortex which belongs to a single pyramid. If now a section be made of the kidney, the points of suppuration will not be found to be limited to the surface. Often they are continued down towards a pyramid, and are connected with a yellow streak running parallel to the straight tubules as far as

the fibrous growth. The color is usually dark and somewhat red from numerous small, dilated veins showing on the surface. On section the cortex will be found to be greatly thinned, being sometimes not thicker than a shilling. The pyramids, unless absorbed from previous pressure, are a little altered. The whole organ is of a leathery toughness which is peculiar. The pelvis may be pigmented from previous inflammation. The microscope shows a great increase of the intertubular tissue, which has a dense fibroid character. The tubules vary in size; some are strangled and compressed, others are dilated above the strangulation. Many of the Malpighian corpuscles are obliterated, leaving merely capsules containing the remains of the obliterated vessels. The capsules of all the Malpighian bodies are greatly thickened. The epithelium may be flattened by pressure, or normal. The small arteries usually show some hypertrophy of their muscular coats. Such a kidney as this may undergo a second attack of acute inflammation, and we then find a combination of the form of the contracted kidney with the color and softness, and, possibly, the severe abscesses, of the acute variety. It will be seen from the above description that this form of kidney differs in no way to the naked eye from the ordinary granular, contracted, or gouty kidney. We do not, however, find the peculiar changes associated with that disease. In a case which lately occurred at University College Hospital, in which this condition was well marked as a result of stricture of the urethra, there was no hypertrophy of the heart, and no change could be recognized in the walls of the small vessels in other parts.

Causes of Interstitial Inflammation.—The following may be stated as the causes which, in varying degree, take part in the production of interstitial inflammation of the kidney: 1. Tension; 2. Reflex irritation of the kidney; 3. The presence of septic matter in the pelvis of the kidney. Each of these acting singly may induce serious disease, or perhaps even cause death, but we seldom see such cases. More often, two at least are in action.

1. *Tension.*—It has been shown before how this is induced by any obstruction to the free entrance of urine into the bladder. Every practical surgeon is acquainted with the fact that tension is one of the most powerful irritants to which the living tissues can be exposed. In the liver Wickham-Jones and others have shown that ligature of the bile-duct causes interstitial hepatitis. In the kidney, no recorded case is to be found of suppuration occurring as the result of simple tension, but in all cases in which evidence of tension exists, that is to say, dilated ureter or pelvis of the kidney, or some source of sudden obstruction as a more or less impacted calculus entrance interstitial inflammation will be found. It seems almost as if the reaction to growth were a conservative change intended to strengthen the tissues to resist the increased pressure. However this may be, a kidney in this condition is in a state in which a little further irritation from any cause may turn it on to fatal and acute inflammation.

2. *Reflex Irritation of the Kidney.*—Mechanical injuries to the neck of the bladder or posterior part of the urethra, and probably diseases of these parts which constantly recurring irritation is present, react upon the kidney through the influence of the nervous system. It is needless here to attempt any explanation of the exact manner in which this takes place, as it will be merely a matter of speculation; but a few facts may be given as proof of the assertion. It is well known that several cases are on record in which death has occurred from suppression of urine following the simple introduction of a catheter, the *post-mortem* examination showing a condition of intense congestion of the kidney. Again, patients with stone in the bladder occasionally die from acute inflammation of the kidney, often accompanied

ence of which to say the least was improbable. Later observations by Koch, with improved methods of staining, have clearly demonstrated the fact that, in every case of disseminated suppuration following on septic changes of the urine in the pelvis, colonies of micrococci are found scattered throughout the kidney, distending and obstructing the urinary tubules. These micrococci are similar to those found in putrid urine, and are believed to be the ferment to which the change is due. The abscesses of the kidney thus arising in acute suppurative nephritis must not be confounded with those seen in pyæmia. These are usually larger, are more distinctly wedge-shaped, and sometimes

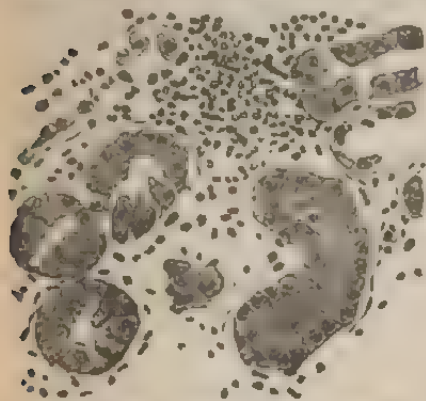

Fig. 822.—Acute Interstitial Nephritis; Condition of Epithelium.

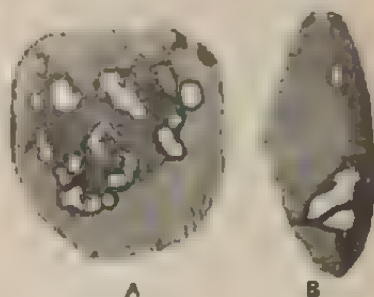

Fig. 823.—A. Group of Abscesses on Surface of Kidney. B. Vertical Section of the same.

surrounded by a zone of hemorrhage. They are always in the cortex, and the pyramids show no signs of disease. Pyelitis is absent, but, as before stated, it may be wanting, or feebly marked in cases of genuine interstitial nephritis, secondary to affections of the bladder. Koch has, moreover, pointed out an important microscopic distinction. Micrococci are found in the pyæmic kidney as well as in pyelo-nephritic kidney; but in the former they are in the vessels, especially in the Malpighian loops, while in the latter they are in the tubules. Microscopic examination of a pyæmic kidney further shows an absence of the general diffused inflammation characteristic of the ordinary septic kidney.

3. *Effects of Former Attacks from which the Patient has Recovered.*—It is possible that the kidney may undergo extensive intertubular change, and yet, if the cause be removed, the inflammatory growth may be completely absorbed, and the organ regain its normal condition. More commonly, however, the new growth undergoes a development into fibrous tissue, a change corresponding exactly to that which occurs in the cicatrization of a granulating sore, and accompanied by a similar process of contraction. Thus we get an increase in the intertubular connective tissue, and at the same time a contraction and induration of the whole organ, so much so that it is sometimes reduced to less than a quarter of its normal bulk. If the pyramidal portion have undergone absorption, this is never repaired, but, as its function seems merely that of a duct, its loss is of no great moment. In a kidney of this kind, we find the fat adherent to the capsule, and the capsule to the gland-tissue. It strips off with difficulty, and is thick and opaque. The surface of the kidney is irregular, granular, or perhaps even puckered by cicatrices. Scattered over the surface, in most cases, are numerous small cysts. These are supposed to be due to the strangulation of the tubules by

the fibrous growth. The color is usually dark and somewhat red, with numerous small, dilated veins showing on the surface. On section, the cortex will be found to be greatly thinned, being sometimes not thicker than a shilling. The pyramids, unless absorbed from previous pressure, are but little altered. The whole organ is of a leathery toughness which is quite peculiar. The pelvis may be pigmented from previous inflammation. The microscope shows a great increase of the intertubular tissue, which is of a dense fibroid character. The tubules vary in size; some are strangulated and compressed, others are dilated above the strangulation. Many of the Malpighian corpuscles are obliterated, leaving merely capsules containing the remains of the obliterated vessels. The capsules of all the Malpighian bodies are greatly thickened. The epithelium may be flattened by pressure, or normal. The small arteries usually show some hypertrophy of their muscular coats. Such a kidney as this may undergo a second attack of acute inflammation, and we then find a combination of the form of the contracted kidney with the color and softness, and, possibly, the scattered abscesses, of the acute variety. It will be seen from the above description, that this form of kidney differs in no way to the naked eye from the ordinary granular, contracted, or gouty kidney. We do not, however, find the general changes associated with that disease. In a case which lately occurred at University College Hospital, in which this condition was well marked as the result of stricture of the urethra, there was no hypertrophy of the heart, and no change could be recognized in the walls of the small vessels in other parts.

Causes of Interstitial Inflammation.—The following may be stated as the causes which, in varying degree, take part in the production of interstitial inflammation of the kidney: 1. Tension; 2. Reflex irritation of the kidney; 3. The presence of septic matter in the pelvis of the kidney. Each of these acting singly may induce serious disease, or perhaps even cause death, but we seldom see such cases. More often, two at least are in action.

1. *Tension.*—It has been shown before how this is induced by any obstruction to the free entrance of urine into the bladder. Every practical Surgeon is acquainted with the fact that tension is one of the most powerful irritants to which the living tissues can be exposed. In the liver, Wickham Legg and others have shown that ligature of the bile-duct causes interstitial hepatitis. In the kidney, no recorded case is to be found of suppuration occurring as the result of simple tension; but in all cases in which evidence of tension exists, that is to say, dilated ureter or pelvis of the kidney, or some source of sudden obstruction as a more or less impacted calculus, subacute interstitial inflammation will be found. It seems almost as if the new cell-growth were a conservative change intended to strengthen the tubules to resist the increased pressure. However this may be, a kidney in this condition is in a state in which a little farther irritation from any cause may hurry it on to fatal and acute inflammation.

2. *Reflex Irritation of the Kidney.*—Mechanical injuries to the neck of the bladder or posterior part of the urethra, and probably diseases of those parts in which constantly recurring irritation is present, react upon the kidney through the influence of the nervous system. It is needless here to attempt any explanation of the exact manner in which this takes place, as it would be merely a matter of speculation; but a few facts may be given as proof of the assertion. It is well known that several cases are on record, in which death has occurred from suppression of urine following the simple introduction of a catheter, the *post-mortem* examination showing a condition of intense congestion of the kidney. Again, patients with stone in the bladder occasionally die from acute inflammation of the kidney, often accompanied

even months, the patient gradually becoming weaker and weaker, until he is carried off by some intercurrent disease, or dies of pure exhaustion. More commonly, however, an acute attack supervenes on the subacute, either spontaneously or as the result of some surgical interference, and, rapidly ending in suppuration of the kidney, terminates fatally. On the other hand, the symptoms often gradually subside, the temperature becomes normal, and the patient gains strength. The improvement usually coincides with some diminution of the local irritation at the primary seat of disease, such as results from rest in bed in a case of stone, or from the cleansing of a foul bladder. As the symptoms are somewhat indefinite, it is often difficult to say how much is due to renal mischief and how much to the primary affection; but wherever we find a dry tongue, a persistent nocturnal elevation of temperature, loss of appetite, general weakness and emaciation, we ought to make every attempt to get rid of these symptoms before undertaking any serious surgical procedure, such as the treatment of stricture, lithotomy, or lithotripsy, the irritation of which might start the smouldering inflammation into activity.

Acute interstitial and suppurative nephritis gives rise to much more manifest symptoms, often supervening on those just described. The attack, which is often induced by some surgical procedure although it may commence spontaneously, begins with a severe rigor, followed by profuse sweating. The temperature may rise to 105° F. or 106° F. After the rigor it falls, but remains somewhat above normal. The rigors and sweating may be repeated more than once. The tongue becomes rapidly dry, red, and fissured, looking like a piece of broiled ham, and sordes accumulate on the teeth. There is complete loss of appetite, and rapid emaciation; nausea is almost a constant symptom, and actual vomiting is common. Diarrhoea may occur. The patient soon sinks into a heavy drowsy state, often with contracted pupils, so that the condition may closely resemble that of opium poisoning. He can be roused and answers rationally if spoken to, and in most cases complains of little pain or discomfort. The temperature now usually falls, sometimes below normal, and the skin feels cold and clammy. In this form, there is usually some tenderness on pressing firmly in the region of the kidneys. As the case progresses, muttering delirium sets in, followed by more complete insensibility, but it rarely reaches a condition of absolute coma. Convulsions are extremely rare. There is no oedema at any time. The urine varies much. It usually becomes more or less bloody, and in rare cases is suppressed; much more frequently a considerable quantity is passed up to the time of death. It is usually in such a state from decomposition and the presence of pus, blood, and mucus, as to render accurate chemical and microscopic investigation impossible. Puscells are constantly present, but whether they come from the kidney or the bladder in any particular case cannot be ascertained, unless they are found, as in rare cases they are, in the form of pus casts. In some anomalous cases, diarrhoea forms a very prominent symptom. In one case that occurred in University College Hospital, the stools exactly resembled those of typhoid fever, and the *post-mortem* examination, in addition to suppuration of the kidney, showed ulceration of the lower part of the small intestine.

Malherbe, who has written an admirable treatise on uræmic fever, describes a form of this disease in which several large abscesses appear in various parts, the contents of which have an urinous odor. It is doubtful if this is not in reality a form of pyæmia.

The duration of an acute attack as above described, when terminating fatally, varies from a few days to a couple of weeks. In favorable cases, even after very marked symptoms, such as rigors, dry tongue, vomiting,

suggests that the scattered abscesses may occasion the tubules and local extravasations of urine softened by acute interstitial nephritis, it is occur. Dickinson accounts for the abscesses

in the veins, a sort of local pyæmia; but the and the fact that every stage is found local inflammation and the fully formed view. Goodhart, of Guy's Hospital, between erysipelas and suppuration

Prognosis.—The prognosis in acute affections of the kidney, secondary to other disease, is always grave; but even the most unpromising case may recover. Vomiting, delirium, partial insensibility, and a very dark color of the urine, are unfavorable symptoms.

even months, the patient gradually becoming weaker and weaker, until he is carried off by some intercurrent disease, or dies of pure exhaustion. More commonly, however, an acute attack supervenes on the subacute, either spontaneously or as the result of some surgical interference, and, rapidly ending in suppuration of the kidney, terminates fatally. On the other hand, the symptoms often gradually subside, the temperature becomes normal, and the patient gains strength. The improvement usually coincides with some diminution of the local irritation at the primary seat of disease, such as results from rest in bed in a case of stone, or from the cleansing of a foul bladder. As the symptoms are somewhat indefinite, it is often difficult to say how much is due to renal mischief and how much to the primary affection; but wherever we find a dry tongue, a persistent nocturnal elevation of temperature, loss of appetite, general weakness and emaciation, we ought to make every attempt to get rid of these symptoms before undertaking any serious surgical procedure, such as the treatment of stricture, lithotomy, or lithotrity, the irritation of which might start the smouldering inflammation into activity.

Acute interstitial and suppurative nephritis gives rise to much more manifest symptoms, often supervening on those just described. The attack, which is often induced by some surgical procedure although it may commence spontaneously, begins with a severe rigor, followed by profuse sweating. The temperature may rise to 105° F. or 106° F. After the rigor it falls, but remains somewhat above normal. The rigors and sweating may be repeated more than once. The tongue becomes rapidly dry, red, and fissured, looking like a piece of broiled ham, and sordes accumulate on the teeth. There are complete loss of appetite, and rapid emaciation; nausea is almost a constant symptom, and actual vomiting is common. Diarrhœa may occur. The patient soon sinks into a heavy drowsy state, often with contracted pupils, so that the condition may closely resemble that of opium poisoning. He can be roused and answers rationally if spoken to, and in most cases complains of little pain or discomfort. The temperature now usually falls, sometimes below normal, and the skin feels cold and clammy. In this form, there is usually some tenderness on pressing firmly in the region of the kidneys. As the case progresses, muttering delirium sets in, followed by more complete insensibility, but it rarely reaches a condition of absolute coma. Convulsions are extremely rare. There is no œdema at any time. The urine varies much. It usually becomes more or less bloody, and in rare cases is suppressed; much more frequently a considerable quantity is passed up to the time of death. It is usually in such a state from decomposition and the presence of pus, blood, and mucus, as to render accurate chemical and microscopical investigation impossible. Pus-cells are constantly present, but whether they come from the kidney or the bladder in any particular case cannot be ascertained, unless they are found, as in rare cases they are, in the form of pus-casts. In some anomalous cases, diarrhœa forms a very prominent symptom. In one case that occurred in University College Hospital, the stools exactly resembled those of typhoid fever, and the *post-mortem* examination, in addition to suppuration of the kidney, showed ulceration of the lower part of the small intestine.

Malherbe, who has written an admirable treatise on uræmic fever, describes a form of this disease in which secondary abscesses appear in various parts, the contents of which have an urinous odor. It is doubtful if this is not in reality a form of pyæmia.

The duration of an acute attack as above described, when terminating fatally, varies from a few days to a couple of weeks. In favorable cases, even after very marked symptoms, such as rigors, dry tongue, vomiting,

and diarrhoea, the patient may slowly recover. The immediate cause of death in many cases seems to be poisoning from absorption of the effused matter from the kidney rather than uræmia. Certainly the mode of death differs greatly from that of acute Bright's disease, the profound coma and convulsions being very rarely present.

The *Diagnosis* has to be made from pyæmia, peritonitis, typhoid fever, and ague. From pyæmia the diagnosis is somewhat difficult, the most important points being the vomiting, the absence of secondary abscesses, the drowsy state into which the patient soon falls, and the fact that the temperature often remains for days before death, below normal. The vomiting and extreme illness may resemble the low, diffuse, painless form of peritonitis sometimes seen in affections of the bladder, but the vomiting has not the pumping character of that in peritonitis, and the elevation of temperature for the first few days is unlike that form of peritonitis in which the temperature is persistently low. Suppurating kidney can resemble typhoid fever only in rare cases, and the absence of spots, and the temperature which may serve to distinguish them. In the case above mentioned, the temperature was below normal for three weeks before death. From ague, the disease is diagnosed by the absence of the complete intermission after the sweating stage; but it must be always remembered that patients who have suffered from ague are singularly liable to attacks of fever after any operation on the urinary organs.

Urethral Fever or Uræmic Fever.—This term has been somewhat loosely used to signify a rigor followed by sweating, and more or less prolonged elevation of temperature, consequent on some operation on the urinary organs, or, possibly, arising spontaneously. It will be seen at once that the definition includes acute interstitial nephritis, as above described, and pyæmia. When a patient has been said to have died of "urethral fever," one of these two conditions has been invariably found, although the surgeon would intentionally include pyæmia under urethral fever. It is probable that the real nature of the affection is, at least in the great majority of cases, a disturbance of the circulation in the kidney, or some interference with its function, due to reflex irritation from the passage of the instrument as before described in speaking of the sources of irritation to the kidney. That it is not due to absorption of urine from a wound in the urinary passages is evident from the fact that rigors are rare after lithotomy, and are not a marked symptom of extravasation of urine, and that wounds of the urethra anterior to the scrotum scarcely ever give rise to them. This view of the renal origin of so-called urethral fever is supported by Malherbe, in his treatise on *Uræmic Fever*, as he would call it. It is difficult to obtain direct proof, but further knowledge might be gained by carefully examining, hour by hour, the quantity and quality of the urine secreted after any urethral or vesical operation, and at the same time accurately observing the changes in temperature, even when the rigor does not occur. Malherbe states that the temperature rises in almost every case; and in one of the four cases of stricture mentioned before, the temperature rose to 100.3° F. about three hours after the operation, when the urine became bloody. It fell to 99.2° F. when the blood disappeared; but, three hours afterwards, a little more blood showed itself, and the temperature again rose to 100.3° F.

Prognosis. The prognosis in acute affections of the kidney, secondary to bladder disease, is always grave; but even the most unpromising cases may recover. Vomiting, delirium, partial insensibility, and a very dry tongue, are all bad signs. A marked diminution of the quantity, and much blood in the urine, are unfavorable symptoms.

Treatment.—Prevention is, of course, first to be aimed at. No patient should, therefore, be submitted to an operation on the urinary organs, except in cases of necessity, without a careful examination of the whole day's urine as to specific gravity, the presence and quantity of albumen, and the microscopic appearances. If possible, the temperature should be observed night and morning for two or three days. If any suspicion arise as to the condition of the kidneys, that operation should be selected, when practicable, which gives rise to least irritation. Soft instruments should be employed instead of metal, and a sufficient interval allowed between their use. Above all, any treatment calculated to cause cystitis, or to give rise to decomposition of the urine, should be avoided. As there can be no doubt that the causes of decomposition are often introduced into the bladder by catheters or other instruments, these should be kept scrupulously clean. For this purpose the instruments may be greased with carbolic acid and oil (1 to 10). If decomposition already exist in the urine, it should, if possible, be arrested by washing out the bladder with some antiseptic, for which purpose quinine and diluted sulphuric acid, in the proportion of gr. ij and ℥ij to an ounce of water, will be found very efficacious; or, better still, 10 grains of iodoform to 4 ounces of water, and ʒss of mucilage. If the cause of the renal mischief be stricture of the urethra or stone, some operation must, of course, be undertaken; but if the temperature be elevated, or there be other signs of renal disease, it should be delayed until an attempt has been made by rest and other remedies to bring the kidneys into a healthy state. If, after a few days, no improvement be seen, and it seem probable that the disease is kept up by the presence of the stone or stricture, further delay is useless; and, choosing the least severe and irritating procedure, the Surgeon must operate at once.

The treatment of well-marked interstitial nephritis is extremely unsatisfactory. If there be any tenderness in the loins, dry cupping may be of service. The bowels should be well acted on by purgatives, and the skin by hot-air baths, to relieve the kidneys as much as possible. Heroic operations undertaken during acute nephritis, in the hope of removing the cause, are almost always, if not invariably, fatal. Quinine and opium have been recommended for the prevention of the rigors that frequently follow catheterism or other operations on the urinary organs. Opium is probably of service, but must be given with great caution if any symptoms of uræmic poisoning exist; but quinine has not, according to most who have tried it, proved of any use. A pure milk diet will usually be found the best in all cases if the patient can take it; stimulation must be regulated on general principles.

Sir Andrew Clark has recently suggested the quaint name of "catheter-fever" for those cases in which, shortly after the commencement of the habitual use of a catheter, obscure febrile symptoms set in gradually, terminating in death in a large proportion of the cases affected. The symptoms most commonly develop about a week after habitual catheterism has been commenced, and almost invariably in those cases in which it is rendered necessary by enlargement of the prostate or atony of the bladder with partial retention of urine. With the ordinary symptoms of febrile disturbance, there is a diminution of the specific gravity of the urine and in the amount of solids excreted by the kidney. There are at the same time but moderate symptoms of cystitis. The symptoms may gradually pass off, or the patient may die exhausted at the end of three or four weeks. At the post-mortem examination it is said that the kidneys are found perfectly healthy, and no definite organic change is present to account for death. Sir Andrew Clark is inclined to attribute the fever to repeated disturbance of the nervous

system by the passage of the instrument. The attention drawn to the subject by Sir Andrew Clark cannot fail to be productive of further investigation and increased knowledge concerning it; but it remains to be seen how many cases will be left to be included under the name of "catheter fever" after the elimination of chronic septicæmia and pyæmia, and of those cases in which the kidney shall have been proved by microscopic examination to be affected by chronic or subacute interstitial inflammation aggravated by the reflex irritation of the passage of instruments. The treatment of these cases must consist of rest in bed, bland diet, especially milk, and the use of opium in moderate doses.

Pyæmia and Septicæmia in Diseases of the Urinary Organs.—These conditions are not uncommonly the cause of death after operations on the urinary passages. Their general symptoms and pathology have been already fully described; but a few words on the peculiarities they frequently manifest when secondary to affections of the urinary organs may not be out of place here.

Pyæmia may assume the ordinary rapid course of embolic pyæmia, with secondary abscesses in the viscera; but this is not of very frequent occurrence. Should it occur, softening thrombi will usually be found in the prostatic plexus or in the vesical branches of the internal iliac vein. More commonly visceral abscesses are wanting, the secondary seats of suppuration being most frequently the joints and subcutaneous tissue. In such cases the progress, though bad, is not hopeless. The disease not uncommonly assumes a chronic form, and the patient may recover after long suffering, possibly, with one or more joints stiffened.

Septicæmia may appear under the forms of septic poisoning and septic infection. Poisoning from the absorption of the chemical products of putrefaction is probably the immediate cause of death in many of those cases in which the bladder, ureters, and pelves of the kidneys are filled with decomposing urine and mucus. Its symptoms present nothing peculiar. Septic infection may be assumed to be the cause of death in those cases in which there is febrile disturbance of varying severity, preceded or not by a rigor, and ending in death from exhaustion in a period of from a few days to a fortnight or three weeks, and in which at the post-mortem examination a definite source of infection can be found, without the presence of such an accumulation of putrid matter in the urinary tract as to render such septic poisoning probable, and without evident fatal disease of the kidney. Such cases are not uncommonly met with, especially after operations on the urethra, and less frequently after those affecting the bladder. In one case at University College Hospital the source of infection was a slight injury at the point of a catheter to a prominent ridge of a fasciculated tubercle. In these cases the wound is found to be covered with an adherent gray material, closely resembling the false membrane of diphtheria. A section carried through this, and the parts beneath, shows that the membranes are composed of a coagulated fibrinous exudation, everywhere crowded with micrococci. The submucous tissue and the parts beyond, show the ordinary appearances of inflammation, and in many cases the micrococci can be recognized invading the affected tissues. In some cases further investigation shows the nearest lymphatic glands to be swollen, and micrococci may be found forming colonies in their substance. Under these circumstances it is strong reason to believe that the diseased spot has been the source of the mischief, and that some infective material has found admission from it, and by infecting the whole system has been the cause of death. The relation of these cases to the chronic form of pyæmia is very close: possibly, the conditions are identical, the presence or absence of secondary abscess being

merely an accidental variation. The chief peculiarity of the condition is that, although there seems good evidence of a general infective process, it tends to run a somewhat chronic course, sometimes lasting for weeks before terminating fatally, and, probably, in many cases ending in recovery.

CHAPTER LXVII.

SURGICAL OPERATIONS ON THE KIDNEY.

UNTIL within the last fifteen years, although some doubtful cases of removal of renal calculi by operation had been recorded, but few affections of the kidney were considered within the reach of surgical interference. Renal abscesses, when distinctly pointing in the loin were opened, and calculi had been in exceptional cases discharged from the opening then made; but until Simon, of Heidelberg, in 1869, successfully removed the kidney, no definite operations were systematically undertaken on that organ.

At the present time the following distinct operations are performed on the kidney: 1. Exploration by acupuncture. 2. Aspiration. 3. Nephrotomy, or incision of the kidney. 4. Nephro-lithotomy, or removal of a stone from an otherwise healthy kidney. 5. Nephrectomy, or complete removal of the kidney. 6. Nephrography, or fixing a movable kidney in the loin.

The various morbid conditions for which these operations are required are fully described in works on medicine; and it is impossible to give here more than the briefest possible summary of the chief symptoms of each, indicating at the same time the operation required for its relief.

Stone in the Kidney.—Deposits of uric acid and oxalate of lime frequently take place in the kidney. In the great majority of cases the calculous matter passes down into the bladder, either in fine particles, when it is commonly spoken of as *gravel*, or in larger masses, when it is termed a *renal calculus*. The passage of any mass of sufficient size to offer resistance on its way down is accompanied by the symptoms of renal colic. There is intense agonizing pain shooting from the loin downwards to the groin, and usually into the spermatic cord and testicle of the same side. In many cases it radiates into the inner side of the upper part of the thigh of the same side. There is retraction of the testicle, and sometimes much nausea or actual vomiting and faintness. As the stone enters the bladder the patient experiences sudden relief. The stone may be passed by the urethra, often with considerable pain and irritation, or may lodge and form a vesical calculus. In many cases, perhaps, after many stones have been passed at different times, one lodges permanently in the kidney, and then gives rise to the symptoms of stone in the kidney. A renal calculus may form in one calyx, and be permanently fixed there, or it may be situated in the pelvis and send branching processes into the surrounding calyces. The symptoms of renal calculus are the following: There is pain usually referred to the loin, but occasionally radiating downwards in the line of the ureter or to the testicle. The pain is sickening in character and variable in intensity. It is in most cases distinctly aggravated by movement. In some cases walking gives most uneasiness, apparently from the movement of the muscles upon which the kidney lies. In other cases

walking causes but little pain, while jolting of any kind causes intense suffering. In other cases any kind of movement is almost unbearable. There may be acute tenderness on pressure over the affected kidney, but in the stage of the disease no enlargement is to be recognized. Frequency of micturition may or may not be present. In some cases it forms one of the most prominent symptoms, so much so that the case may be mistaken for that of disease of the bladder. The urine almost always contains a trace of blood to be recognized by the microscope, and occasional attacks of *pus* or *hematuria* are common, most frequently brought on by violent movement. In the early stages *pus* is absent, or only a few corpuscles can be found. Cubical cells are said to occur similar to those forming the superficial layer of the epithelium lining the pelvis of the kidney, but these are not sufficient to draw any conclusion from them, as similar cells may be derived from other parts of the urinary tract.

Treatment—During the descent of a renal calculus, which always occupies many hours, and perhaps some days, the patient should have *opium* administered, drink bland diluents freely, be put into a warm bath, and have hot fomentations or mustard poultices applied to the loins; the bowels should also be thoroughly emptied by enemata. It is well to bear in mind, that a somewhat similar train of symptoms to that induced by the descent of the calculus, may be excited by some forms of irritation or violent distention of the cecum and descending colon, which will require appropriate treatment.

Should the stone fail to descend and give rise to the train of symptoms just described, medical treatment may be of much use. An attempt may be made to dissolve the stone by the administration of doses of *potash* or *soda* sufficient to keep the urine persistently alkaline. At the same time the case must be strictly attended to on the principles laid down in the chapter on Urinary Calculi. The patient must use distilled water only for drinking purposes. By this treatment the stone appears in some cases to have been dissolved sufficiently to allow of its passage by the ureter. If the patient's circumstances allow of it, several months' rest in the recumbent position may be tried, as under this treatment the calculus becomes encrusted and fixed in one calyx, and may cease to cause trouble. If these means fail, the question arises of performing the operation to which the term *nephrolithotomy* has been applied by Morris, who was the first to undertake it. This operation differs so essentially from that performed in the later stage that it well merits a distinctive name. It must not be assumed, however, that every case of renal calculus is one for operation. The conditions justifying surgical interference are the following: 1. The disease must have lasted sufficiently long to make it certain that there is no hope of permanent cure by spontaneous expulsion. 2. The inconvenience caused must be such that it seriously interferes with the patient's enjoyment of life. 3. Medical treatment must have been fairly tried and have failed. 4. The patient must not be passing gravel habitually, as it is evident that under these circumstances a fresh stone would probably form in the injured kidney and necessitate after the operation. 5. The symptoms must be distinctly unilateral. 6. The patient must be otherwise in good health, not too old, and not excessively fat. 7. Lastly, if in spite of treatment the symptoms of irritation of the pelvis come on, especially a steadily increasing amount of *pus* in the urine, the operation may be undertaken in the hopes of saving the kidney and of preventing the occurrence of *pyonephrosis*, provided that other conditions are favorable.

Calculous Pyelitis forms the second stage of stone in the kidney. It has the same symptoms as above described persist, but the pain is more constant.

though often less acute. There may be great frequency of micturition. The urine, which remains acid, contains a gradually increasing amount of pus, reaching sometimes to many ounces daily. If the several quantities of urine passed during the day be collected, it may be found that the pus is variable in quantity, and may even disappear for a few hours, or even days, its reappearance being accompanied by some relief of the pains in the loin. Intermittent pus in acid urine may be regarded, as Rayer pointed out, as undoubted evidence of pyelitis affecting one kidney only. Before long, the ureter and pelvis, partly obstructed by the stone, become insufficient to drain the pus away, and distinct and often very great enlargement of the kidney sets in. The swelling assumes the ordinary form of a renal tumor, to be subsequently described. The pelvis becomes dilated, the calyces enlarged, the pyramids destroyed, and at last the kidney may be reduced to a multilocular sac, the walls of which are composed of the thinned cortex surrounded by the thickened capsule and the indurated perinephritic fat. Fluctuation is often distinctly perceptible. This condition is termed **Pyonephrosis**. If the disease be allowed to progress unrestrained by treatment, the dilated pelvis or the thickened cortex may give way, and a perinephritic abscess form. The pus then gradually points towards the surface in the loin, but before doing so it may extend widely, from the iliac fossa to below the ribs. In other cases rupture into the colon may take place.

In these cases medical treatment is useless, and early surgical interference gives the only chance of cure. Three operations may be performed; aspiration, nephrotomy, and nephrectomy. Aspiration is seldom of any use in calculous pyonephrosis, except as a means of diagnosis, the needle sometimes grating against the stone as the puncture is made. It may, however, be advantageous to attempt to reduce the bulk of the tumor by aspiration, repeated at short intervals, three or four times before proceeding to nephrotomy. Nephrotomy is the operation specially indicated in these cases. Nephrectomy has been frequently performed for calculi pyonephrosis, but the general opinion at present entertained is that much better results are obtained by nephrotomy with antiseptic drainage, followed at some months' interval by nephrectomy if recovery does not follow the simpler operation. The calculus which has been the cause of the mischief is removed at the time the nephrotomy is performed. The removal of a stone from what must be regarded as the cavity of a large abscess is, as Morris points out, a very different operation from nephro-lithotomy, and should certainly be distinguished by another name, otherwise great confusion must arise in our statistical records.

Tubercular or Scrofulous Kidney.—The pathology and symptoms of this disease are fully described in works on medicine. It will be sufficient to allude here merely to those points that have a bearing on surgery.

Tubercular disease of the kidney is indeed of considerable interest to the Surgeon, not only because he may be called upon to perform nephrotomy or nephrectomy for this cause, but because in a considerable proportion of cases the early symptoms are referred by the patient to the lower urinary tract, and may closely simulate stone and various other vesical affections. Tubercle of the kidney may form merely a part of general tuberculosis, but in these cases the infection occurs late in the disease and gives rise to no symptoms. Primary tuberculosis of the kidney may commence in that organ, and be limited to it for some time, or it may be merely a part of general tubercular disease of the genito-urinary tract. When the disease begins in the kidney, it commences by the formation of a caseating centre in the cortex. This softens and gradually extends till, by the destruction of the pyramid corresponding to the affected part, it reaches the pelvis, and the products of the

process mixed with pus are discharged with the urine. Several case have in various stages of softening and disintegration are usually met with in the same kidney. The mucous membrane of the pelvis then becomes affected, and the disease extends to the bladder. In some cases the disease takes the reverse course, commencing in the prostate or bladder, and extending upwards to the kidney. It frequently happens in the later stages that the ureter becomes obliterated. The disease then follows one of two courses: either the chronic suppuration continues and the remains of the kidney become distended into a huge abscess which may finally point in the back, or burst into the gut, or the fluid parts of the pus may be absorbed and the residue form a thick patty-like mass, which may remain undestroyed for months or years. The former condition must necessarily occur if any solid substance remains undestroyed in the kidney. The *post-mortem* appearances of a kidney in the advanced stages are the following. The kidney is greatly enlarged, often to five or six times its natural size. The perinephritic fat is densely indurated by chronic inflammation, and intimately blended with the capsule; the capsule is thickened but separates with moderate ease from the cortex; the cortex if any remains is thin and tough; the pyramids have disappeared, the pelvis and calyces are dilated, and the whole cavity is filled with a thick creamy or patty discharge having a sour offensive smell. In less advanced cases only one or two portions with the corresponding part of the cortex may be affected. Two important facts with regard to this affection are, first, that in the great majority of cases both kidneys are implicated, though the disease is always more advanced in one than in the other; and, secondly, that if it is at all advanced, the morbid condition extends a greater or less distance down the ureter. The *symptoms* may in the early stage be referred chiefly to the bladder. There may be great irritation and an almost constant desire to pass water with scalding pain during the act. There is at the same time pain in the loin, usually dull and aching, and not radiating to the testicle or groin. It may be increased by movement, especially of the neighboring members. When both kidneys are seriously affected, constant vomiting may form a marked feature of the case. The urine contains pus, often in considerable amount, and intermittent, and the bacillus of tubercle has been recognized in it, and the diagnosis thus established. Blood may occur, but is seldom abundant, and often completely wanting. If both kidneys are affected, the quantity of urine gradually diminishes, and the amount of solids excreted becomes less. As the disease advances, the enlarged kidney becomes more sensitive, presenting the ordinary signs of a renal tumor. A chronic empyema gradually forms in the loin in many cases; general tubercular disease takes place, and the patient dies of exhaustion. The diagnosis of the case is often extremely difficult until the enlarged kidney can be examined. Repeated vomiting, progressive emaciation, the persistent dull character of the pain, the comparative absence of blood in the urine, and the existence of tubercle elsewhere, as in the prostate or lungs, are the chief points attended to; but in spite of every care these cases cannot always be distinguished from stone. The *treatment* is a matter of considerable doubt. When abscess forms, early nephrotomy gives great relief, and certainly prolongs life, but should nephrectomy be ever performed for this disease? In the early stages, before the kidney is much enlarged, the diagnosis is uncertain, even after examination by an exploratory incision, and it is scarcely ever be justifiable to remove the organ. In the later stages when both kidneys are affected, as is almost invariably the case in advanced cases, would evidently be useless, and probably fatal. The difficulties of the operation are also very great, as the kidney is usually firmly adherent to the

standing parts. On the whole, it seems advisable not to interfere with these cases except by nephrotomy.

Pyonephrosis from other causes than stone or tubercle is rare. It is occasionally met with as a sequel to gonorrhoea. In a case of this kind in University College Hospital the patient was completely cured by two aspirations, nearly a pint of pus being removed on each occasion. He died some years after, and the kidney was found to be reduced to a mere shrivelled mass of fibrous tissue.

Hydronephrosis may be congenital, arising from a malformation of the ureter, or may occur as the result of partial or complete obstruction of the ureter by an impacted calculus, or by the pressure of a tumor. The early stages have already been described as the result of increased urinary tension; in exceptional cases only does the dilatation continue to increase till a large tumor is formed. The symptoms are those of a renal tumor, fluctuating distinctly and accompanied by little pain and no hæmaturia. The diagnosis may be confirmed by aspiration and examination of the fluid withdrawn, which will be found to contain urea and uric acid.

Treatment.—Aspiration can evidently be only of temporary service; nephrectomy and drainage would probably be followed by an incurable urinary fistula. Nephrectomy by the abdominal incision has been practised successfully, but probably the best treatment would be antiseptic drainage and subsequent lumbar nephrectomy.

Tumors of the Kidney. Single cysts are not uncommon in the kidney, but they seldom reach such a size as to call for surgical interference. Hydatid cysts are occasionally met with and may be recognized by the character of the fluid drawn off by the aspirator. The disease known as *cystic kidney* is, however, an exception to this rule. In this disease the whole organ may be converted into little more than a mass of cysts, varying in size from a pea to an orange. The kidney may thus form an enormous tumor, taking a great part of the abdomen and extending down to the pelvis. It is not uncommonly double, but one side is usually more affected than the other. These tumors seem to cause but little trouble beyond that arising from their size, and are often discovered only on the post-mortem table.

Carcinoma and Sarcoma of the kidney are of moderately frequent occurrence. The sarcomata are frequently met with in infants and young children. They are usually spindle-celled, but striated muscular fibre has been met with in many of the congenital specimens. Carcinoma is usually soft and rapidly growing, and occurs after middle life. These tumors increase quickly, sometimes with little pain, in others with constant aching and uneasiness. The most important symptom is free hæmaturia, and in the absence of this we are never justified in making a diagnosis of renal cancer.

The **Diagnosis of Renal Tumors** is usually not accompanied by any great difficulty. In manipulative examination of a kidney, whether healthy or diseased, the patient must be placed on his back, with the knees drawn up and the shoulders supported. The surgeon then places one hand in the flank with the tips of the fingers immediately outside the mass of the erector spinae just below the last rib, and pushes firmly forwards, while with the other hand placed flat upon the abdomen, outside the edge of the rectus, he presses backwards. The kidney is thus grasped between the two hands, and in this way a healthy kidney can usually be distinctly felt, and in a diseased organ its size and form can be readily judged of. It is more difficult to estimate the degree of mobility in this way, as the parts to which the kidney adheres in this region are themselves movable. A tubercular or calculous kidney which is readily adherent to a mass of indurated fat can often be moved forwards and backwards for some inches. If the tumor be large, the hand must

next be passed below its border to ascertain by the absence of a pedicle passing into the pelvis that it is not ovarian. When the tumor is of such size that this cannot be done errors are very likely to occur, and numerous cases are on record in which the most accomplished ovariologists have been deceived, the nature of the case being ascertained only after opening the abdomen. The anterior border of the tumor must next be examined; all renal tumors are rounded in form, and lobulation is common. The movement during respiration must not be too much relied upon; renal tumors move less than those of the liver, but are not, as a rule, fixed. The outline of the tumor must next be ascertained by percussion; it will be found that all renal tumors form an angle with the costal margin, which is less than a right angle. The reverse is the case with splenic tumors and some of those of the liver. The flank will be found to be persistently dull in any position in which the patient may be placed. The most characteristic sign is the presence of the colon crossing the tumor. This may sometimes be recognized by manipulation, and after watching the case for a few days and examining repeatedly, so as to hit upon a time when the colon contains flatus, a line of resonance will often be found passing across the dull mass of the tumor. A retroperitoneal sarcoma close to the kidney may not only closely resemble a renal tumor, but may be indistinguishable from it. In these cases the presence of a rapidly growing soft tumor in the renal region without hæmaturia would lead to a suspicion that it did not implicate the kidney.

The presence of a renal tumor having been made out, it remains to determine its nature. When fluctuation is distinctly present, it is probably either hydronephrosis, pyonephrosis, or a cystic kidney. A very soft sarcoma may, however, yield a sense of elasticity, or even of fluctuation. The diagnosis is best effected by aspiration, during which the diagnosis may be still further cleared up by the needle impinging on a calculus.

If it be pyonephrosis, the pus has usually a peculiar sickly smell, especially if it be tubercular. In calculous pyelitis it is sometimes offensive from decomposition which has spread up from the bladder. This is far less common in tubercular pyelitis. All renal abscesses may acquire a fecal smell when they approach very near to the colon.

The lobulated form and great size of the cystic kidney and the absence of hæmaturia would probably serve to indicate its nature. Profuse hæmaturia following the examination is suggestive of malignant disease. In some cases of large accumulations of calculi grating has been felt during manipulation. The above taken in connection with the symptoms already described will usually enable the Surgeon to determine the nature of a renal tumor with sufficient accuracy.

The **Treatment of Carcinoma or Sarcoma** is necessarily limited to nephrectomy. This has been done both through the loin and by the abdomen. If the tumor exceed a moderate size, the latter is the only possible method. In small tumors the lumbar operation is practicable and has so far yielded the best results. The operation is not to be lightly undertaken. The disease is not usually a very painful one, and for that reason in the cases of it are seldom seen till the tumor is of considerable size. The immediate mortality is great and the prospect of permanent cure very small. If the disease be detected sufficiently early, the operation might, however, give the patient a chance of prolongation of life if not of cure.

Fistulous Communications between the ureter and the uterus or vagina are occasionally met with as the result of injury during labor or during ovariectomy. In these cases the kidney being healthy may be very safely excised by the lumbar incision.

Floating Kidney.—Three degrees of abnormal mobility of the kidney are met with. In the slightest form the organ can be moved upwards and downwards for about an inch beneath the peritoneum; this is very common. A further degree of movement in the same direction beneath the peritoneum is met with in rare cases, and still more rarely the peritoneum completely surrounds the gland, forming a meso-nephron. The first is recognized only by careful examination; the two more extreme degrees may give rise to constant and severe pain of a sickening character, occasionally accompanied by hæmaturia, which can sometimes be induced by handling. These conditions were formerly treated by the application of a padded elastic belt, and although this is seldom efficient, it should always be tried before suggesting other means. If it fails and the patient's life is scarcely endurable from the pain in the displaced kidney, operative interference becomes justifiable. Nephrectomy has been repeatedly performed for this condition, but it is a severe measure in a disease not attended by any danger to life; lately, however, Hahn, of Berlin, has suggested a simpler proceeding, which has been successfully carried out in several cases, and to which he has given the name of *nephrotomy*. It consists merely in exposing the kidney by the method to be presently described, and sewing the perinephritic areolar tissue to the margin of the wound, leaving it subsequently to heal by granulation. The operation is almost free from danger, and should be certainly preferred, if any such proceeding is necessary, to one so dangerous as nephrectomy.

OPERATIONS ON THE KIDNEY.

Exploration of the Kidney.—If the symptoms of renal calculus are well marked, before proceeding to any more severe measure the kidney may be explored, as suggested by A. E. Barker, by means of the aspirator, a long fine needle being used. This is preferable to making use of an acupuncture needle, as the escape of urine shows that the instrument has reached the pelvis. The situs of the kidney is situated about two inches from the middle line and opposite the first lumbar spine. If the needle be introduced immediately external to the erector spine at this level, and passed almost directly forwards it will probably enter the pelvis. Experience, however, has shown that owing to the thickness of the soft parts covering the kidney, the exploration carried out by this method must necessarily be very imperfect, and cannot be considered conclusive if yielding negative results. The only thorough method of exploration is fully to expose the kidney before using the needle.

Aspiration of the Kidney.—This operation is performed in the same way as in other parts. A good-sized needle should be used if pus is expected to be present, as it is often too thick to pass through a fine tube. The spot selected must vary with the case, but care should be taken to avoid any risk of puncturing either the colon or peritoneum. In all enlargements of the kidney these are carried forwards. If, therefore, the normal line of the colon, that is to say, a line drawn vertically upwards from midway between the anterior and posterior superior iliac spines, be taken, the needle is certain to pass behind the gut if there be any distinct enlargement of the kidney. If any part of the tumor be particularly prominent this may be punctured, but if it be in front of the line just mentioned a careful examination for the colon by palpation and percussion should be made. Aspiration, if carefully performed with a clean instrument, is perfectly free from danger.

Examination of the Kidney through an Open Wound, and Nephro-lithotomy.—Three incisions have been recommended for exposing the kidney in the loin: a vertical incision immediately external to the edge of the quad-

raise lumborum, a long oblique, and a transverse, or nearly transverse, incision. Of these the last is preferably, as being a safeguard against error, and more likely exposing the kidney. It is best made about an inch and a half long, immediately below the free extremity of the spine, and passing backwards to the edge of the erector spinae. It must be made parallel to the rib, but slightly less oblique, so that its posterior end is three-quarters of an inch or an inch below the rib. These precautions avoid the risk of wounding the pleura, which often extends below the rib posteriorly far from that its three-quarters of an inch. This incision may be enlarged forwards if necessary, care being taken to avoid wounding the psoas muscle, and should more room be required for any purpose it is continued by cutting from the first incision downwards towards the crest of the ilium, parallel to the outer border of the quadratus lumborum. The position of the patient and early stages of the operation are the same as in a craniotomy, except that the incision is passed higher up, and for the removal of the parts cut through, the reader is referred to the description of craniotomy, p. 822. The fat about the kidney being reached, the wound is made a little further open by copper statum, while an assistant presses the chest towards the wound by pressing on the abdomen. The fat is then cut through with fingers or forceps, keeping to the back part of the wound, and the quadratus. If the fat is much infiltrated by chronic perinephritis considerable difficulty may be found in exposing the capsule of the kidney, but in a case adapted to nephro-tytomy, in which the kidney is healthy, no difficulty is found in so doing. The sense of resistance offered by the solid mass of the kidney will serve as a guide to the direction in which it is to be sought. This part of the operation is accompanied by scarcely any bleeding. The kidney, being exposed fully, should now be methodically punctured with a smooth round needle. A common drawing needle and a pair of torsion forceps answer the purpose admirably. A piece of sterilized silk may be passed through the eye and tied round the forceps to prevent the needle from accidentally slipping out. If after a moderate examination carried out over the whole kidney, nothing is felt, the finger may be passed before and behind it, and the kidney pressed between them and the pelvis examined. Even after all this, experience has shown that a stone two-thirds of an inch in diameter may escape detection. If the patient suffering have been very great, and more especially if there is an increase of discharge of pus, it may be justifiable to cut through the cortex and open the pelvis with the finger, as even when no stone was present this procedure has been known in several cases to give great relief.

If a stone be felt, a scalpel may be passed down to it, guided by the needle. As the scalpel is withdrawn, a profuse gush of blood may follow, which is at first very alarming, but the pressure of a sponge for a few minutes arrests it. A pair of polypos-forceps may then be passed into the wound enlarged by opening the blades. This is accompanied by scarcely any bleeding. The finger may then be inserted, and the stone perhaps brought out by it; but if this cannot be done, a pair of forceps must be applied by the finger. It is better in all cases to cut through the cortex, and to try to open the pelvis. Wounds of the kidney-substance heal readily, but those of the pelvis are apt to leave a fistula. The stone having been removed, and all bleeding arrested by temporary pressure on the kidney with a sponge, the external wound may be closed by sutures, leaving an opening made for a large drainage tube. The urine will probably flow for some weeks, but in several of the recorded cases rapid healing has been taken place. The most extraordinary is that recorded by Wagner, May 1871.

He removed a stone weighing one ounce, and of extremely irregular

form, the wound completely healing in five weeks. The dressing should be strictly antiseptic, and while the urine is escaping it must be changed twice a day. Morris recommends finely powdered German moss-peat as the best absorbent material to place beneath the patient outside the dressing. The operation of removal of a stone from a healthy kidney has not been very frequently performed, but so far has been uniformly successful.

Nephrotomy.—This consists merely in making an incision into a kidney distended with pus. The incision must be in the same position as that just described, but need not be so extensive, as no exploration of the surface of the kidney is required. The surface of the enlarged kidney being exposed, it must be punctured by a broad-bladed scalpel, and the finger inserted at the puncture before the pus escapes. In this way the dilated calyces are easily examined, and should a stone be present it may be removed. After the operation a large drainage-tube is inserted, reaching well into the pelvis of the kidney; this must be gradually shortened as the cavity closes. The dressings should be antiseptic throughout. Nephrotomy for calculous pyelitis is often successful; for tubercular pyelitis scarcely ever so, although it gives relief and prolongs life. If a sinus remains, the drain from which is exhausting to the patient, the question of lumbar nephrectomy must be considered. The operation, far from being increased in difficulty, is actually facilitated by the previous drainage.

Nephrectomy.—By nephrectomy is meant the complete extirpation of the kidney, an operation that a few years since would have been considered as unsound in physiological principle as impracticable to surgical art.

Before proceeding to the removal of the kidney, it becomes necessary for the Surgeon to ascertain that a person could not only live, but that the health might be maintained after the removal of so very important an eliminatory organ. That this can be has been proved by the result of injury, by pathological research, and by physiological experiment.

There are cases on record in which, in consequence of a deep stab or slashing cut in the loin, one kidney has been wounded and forced out of the wound, whence it has been removed after ligation of its pedicle, the patients making a good recovery. Then, again, it has long been known to pathologists that a person may live with one kidney practically useless, either blocked by calculus, destroyed by suppuration, or converted into a mere sac in hydronephrosis. Simon, of Heidelberg, proved by numerous experiments on dogs that one kidney might be extirpated without danger of uremia, and that the animal not only recovered, but enjoyed perfect health afterwards.

The ground having thus been cleared, and the fact having been proved by the combined evidence of observation as to the result of injury, of the effect of pathological changes, and by experimental investigations, Gustav Simon was encouraged to undertake the operation for the extirpation of one kidney. This he did in 1869, in the case of a woman who, having had the ureter cut across in the operation of ovariectomy, was left with a urinary fistula otherwise incurable. The kidney, which was healthy, was removed by a lumbar incision. The patient made a good recovery, the fistula being cured. Seven years after the operation she was in perfect health. Since this time the operation has become an established one in surgery, and has frequently been performed.

The conditions under which nephrectomy is undertaken have been already described. It must always be borne in mind that the gravity of the operation is such that it should never be performed except for conditions threatening life. In all cases, before undertaking this operation, the condition of the other kidney must be ascertained if possible. Various means have

been suggested for doing this. Catheterism of the ureter, even in the female, cannot be carried out with sufficient certainty to be of any use. R. Davy has proposed pressure on the ureter leading from the aorta to the kidney by means of the same lever that he employs in compression of the iliac. It remains to be seen whether this is practicable. At present no means of cutting off the flow of urine from one kidney while examining that from the other can be said to be practically efficient. The sound kidney must be examined by manipulation for enlargement or tenderness. Severe vomiting should always lead to a grave suspicion of *double disease*. A marked deficiency in the quantity of urine excreted, or in the amount eliminated by the kidneys, is also a grave sign. In operating by the abdominal incision, the other kidney may be felt for from within the abdomen. In spite of all precautions, however, the only working kidney has been removed more than once.

The operation may be performed by the *lumbar* or the *abdominal* incision. If the lumbar method be adopted the transverse incision, with the vertical extension carried from it to the crest of the ilium is the best, as giving most room. The early steps of the operation are the same as in nephrectomy. When the capsule is reached this must be opened in cases of pyelitis. In other cases it should be preserved uninjured if possible. The kidney is then carefully enucleated with the fingers of one hand till it remains attached merely by its pedicle. In doing this care must be taken to keep close to the gland lest the peritoneum or colon be torn. The tumor may now be drawn forwards in the wound, and if the ureter can be isolated, this should be done and a double ligature passed round it. It may then be divided between the ligatures, its end being touched as it is cut with a solution of chloride of zinc lest septic matter pass from it into the wound. In cases of *pyelitis* it is usually impossible to separate the ureter from the rest of the pedicle. A strong carbolized silk ligature is now passed through the pedicle and it is tied in two pieces. If this be done carefully with a blunt aneurysm needle there is no fear of puncturing the renal vein. The pedicle at this stage must not be dragged on too forcibly, first, for fear of tearing it, and, secondly, lest on the right side the ligature be applied too close to the vena cava. The pedicle having been securely tied, the kidney is cut off with a pair of scissors, not too close to the ligature. All bleeding having been arrested, the ligatures are cut short and the wound is closed, a large drainage-tube being inserted, and the case treated as an ordinary wound in some other part of the body by some form of antiseptic dressing. The dangers during the operation are hemorrhage from the substance of the kidney in the case of a tumor, wound of the peritoneum, and wound of the colon in cases of *pyelitis*. These are avoided by keeping outside the capsule in the former case, and inside in the latter. The shock of the operation is great and often directly fatal.

Abdominal Nephrectomy is performed with all the precautions already laid down as being necessary in abdominal operations (p. 737). The section now adopted in all cases is that recommended by Langenbeck, a *linea semilunaris*. It has the great advantage over the median incision of more directly exposing the pedicle, and of enabling the intestines to be held more readily on one side during the operation. When the surface of the tumor is exposed, the peritoneum external to the colon must be carefully divided, all bleeding being immediately arrested by *cauterization*. The pedicle is then carefully exposed and the vessels ligatured *separately* or in the same way as in the lumbar operation. The ureter is then divided between two ligatures, care being taken that while so doing none of its contents pass into the abdominal cavity. The divided *ureter*

must be immediately disinfected with chloride of zinc (40 gr. to ℥j). The enucleation of the tumor can then be completed. Barwell has recommended that an aperture for the drainage-tube should now be made in the loin, and in cases in which the raw surface left after the removal of the tumor is very large it would undoubtedly be a wise precaution. The wound is closed in the ordinary way. The operation should be performed with all antiseptic precautions.

In the after-treatment of nephrectomy the patient must be covered up as warmly as possible to promote the action of the skin. Vomiting is almost always a troublesome symptom, and must be relieved by ice. Opium must be used sparingly, as the opposite kidney often becomes congested and somewhat disturbed in its functions for a few days.

The results of **Nephrectomy** were at first very discouraging, for out of the first 12 cases in which the operation was done but 2 recovered. But increased experience in the operation, a more just appreciation of its difficulties, and, above all, the great advances in abdominal surgery generally, have during the last ten years turned the balance in favor of the operation, so that the recoveries now exceed the deaths. For from the statistics of 100 cases of nephrectomy collected by Dr. Harris, of Philadelphia, all that have been published up to May, 1882, there were 49 recoveries against 45 deaths, the remaining 6 being still under treatment.

Dr. Harris states that 16 floating kidneys have been removed by nephrectomy with 10 recoveries. Two were by the lumbar method, 14 by abdominal section. The 2 lumbar cases recovered; of the 14 abdominal, 6 died. Of 18 cases of malignant disease 9 died. The remaining cases were as follows: Large cysts, 4 died, 1 recovered. Hydronephrosis, 4 died, 4 recovered. Calculous hydronephrosis, 2 died, 2 recovered. Hydronephrosis, with sarcoma, 1 died. Pyonephrosis, 3 died, 6 recovered. Calculous pyonephrosis, 2 died. Calculous pyelitis, 3 died, 1 recovered. Urethral fistula, 1 died, 6 recovered. Tuberculosis, 2 died, 2 recovered. Of 96 cases in which site of incision is mentioned, 46 were abdominal operations, with 23 deaths and 23 recoveries. Lumbar, 19 deaths, 27 recoveries, with 4 under treatment.

CHAPTER LXVIII.

URINARY CALCULUS AND LITHOTOMY.

URINARY DEPOSITS AND CALCULI.

The urine is liable to deposit various solid matters, which, when impalpable, are termed **Sediments**; when in fine gritty particles, **Gravel**; and when forming a large concrete mass, **Calculus or Stone**. These deposits may be the result of constitutional abnormality, and the conditions giving rise to them are then sometimes termed a **Diathesis**. Much importance was formerly ascribed to these so-called diatheses, as it was believed that there was some definite constitutional condition corresponding to each form of urinary deposit; but this view can no longer be maintained.

Uric or Lithic Acid Deposits.—These occur in two forms, as free uric acid and as urates. Free uric acid, in the form of crystals, is never met with in healthy urine. When it forms a deposit it appears as small red granules, which may be compared in general appearance to cayenne pepper. Under the microscope it is found to be crystalline. The form of the crystals varies considerably; most commonly they appear as smooth transparent rhombic plates, mixed with which may be diamond-shaped prismatic, or barrel-shaped crystals. Occasionally they are barrel-shaped (Fig. 824). As

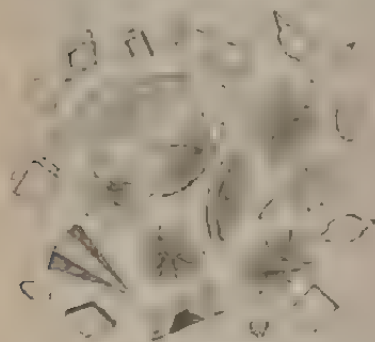

Fig. 824.—Uric Acid

Fig. 825.—Urates of Ammonia and Amorphous Urates.

rule, they are darkly stained with urinary pigment and present a reddish color, but the tint varies greatly in different cases. The crystals are readily soluble in dilute solutions of potash and soda.

Urates form the common pale yellow or reddish yellow deposit which is frequently observed to form as urine cools after being passed. This deposit, often termed *lithitons*, is amorphous, and has no very definite chemical composition, consisting of uric acid, combined with soda, potash, and ammonia, in varying proportions, with traces of lime and magnesia. The depth of color is proportional to the amount of pigment in the urine.

Urate of ammonia (Fig. 825), in the form of spoked globular masses, is occasionally met with alone or mixed with amorphous urates. The amorphous urates are readily recognized clinically by their completely dissolving when the urine is warmed. Free uric acid and urates are not uncommonly found together.

Uric acid is one of the products formed in the elimination of foreign organic material from the body. Under normal circumstances by a process of oxidation it becomes converted into urea and carbonic acid, the former being eliminated with the urine and the latter by the lungs. Such uric acid as remains unoxidized is excreted in the form of urates in such quantity as is, under normal conditions, readily soluble in the urine. The presence of an excess of uric acid is therefore due to imperfect oxidation. A deficiency of oxygen may be absolute, as when the patient is confined to an ill-ventilated room, and takes insufficient exercise in the open air, or when he suffers from some disease interfering with respiration, as pulmonary phthisis, or when, from the deficiency of red corpuscles, the blood is unable to take up the necessary quantity. In all these conditions deposits of lithates are habitually met with. In other cases the supply

oxygen is normal in amount, but the refuse products to be oxidized are excessive. This may arise from an excessive supply of nitrogenous food, or, in fact, of food of any kind, for there seems reason to believe that the carbohydrates, starch, sugar, etc., and alcohol, exert a sort of preference claim on the oxygen, and if supplied in excessive quantities leave an insufficient amount for the perfect oxidation of the refuse nitrogenous substances arising from the natural waste of the body. These deposits are therefore commonly met with in individuals of a robust habit of body and florid appearance who have lived too well. Copious deposits of urates occur also in all febrile conditions which are invariably associated with an increased waste of the tissues of the body. Violent and prolonged muscular exertion may produce the same effect.

Excess of uric acid in the blood, as was clearly demonstrated by Garrod, is an essential feature of gout. In this disease deposits of uric acid, either as lithates, or as pure uric acid, are always met with in the urine; and the gouty deposits in joints and other structures are composed of urate of soda.

Uric acid is frequently met with in unhealthy children of the poor and less commonly among the children of the rich, who are allowed more animal food than they can readily digest.

The mere deposit of the normal quantity of lithates on the cooling of the urine, concentrated by excessive sweating, may be regarded as a natural condition.

Calculi.—The calculi containing uric acid are of two kinds; the pure uric acid and the urate of ammonia. Uric acid in the form of minute concretions forms the most common variety of gravel. When a distinct calculus is formed it is usually of regular form, oval, somewhat compressed and flattened, smooth, or slightly nodular on the surface, and of a fawn color. On section it is seen to be laminated, and to present various shades of light brown or fawn tint. Fissures are occasionally met with in its structure, the origin of which it is difficult to explain, and in rare cases the whole stone has been known to break up spontaneously into small fragments. The urate of ammonia calculus is of very rare occurrence; it occurs chiefly in children, is composed of concentric rings, has a fine earthy appearance, and is clay-colored. The uric acid calculus may be distinguished from the urate of ammonia by heating a fragment in solution of caustic potash; both dissolve, but the urate of ammonia evolves ammonia in the process of solution.

Treatment. The treatment of uric acid deposits must be directed to the removal of the prime causes of this condition, viz., mal-assimilation, defective oxygenation, and the ingestion of too large a quantity of nitrogenous food. All these may be remedied by attention to ordinary hygienic measures; the patient must live sparsely, should avoid fermented liquors, especially red and effervescent wines, and abstain from sweets, pastry, etc. He should take plenty of out-door exercise, and keep the skin in healthy action by warm dry air or vapor bathing, and the use of horsehair gloves. The bowels also must be carefully regulated by means of saline and other aperients, with occasional alterative doses of blue pill, to which, if the constitution be peculiarly rheumatic or gouty, some colchicum may advantageously be added. Preferable to all medicines, perhaps, are the natural aperient saline waters of Pillna, Friedrichshall, or Carlsbad, taken fasting. The patient may also be directed to drink some of the natural

Fig. 820. Uric Acid Calculus.

alkaline waters, as those of Vichy, Vals, or Fachingen. The Vichy waters containing a large quantity of carbonate of soda, with free carbonic acid, are often extremely serviceable. If they cannot be procured, a very good alkaline drink consists of a scruple of bicarbonate of potash and two grains of nitre dissolved in a tumbler of cold or tepid water, to which about ten grains of citric acid or a tablespoonful of lemon juice may be added; this should be taken early in the morning or in the middle of the day. Tansparations of lithin are of essential service in removing uric acid gravel, and clearing the urine of urates. They may be given alone, or in combination with the citrate or carbonate of potash.

Deposits of Oxalate of Lime.—Oxalate of lime appears in two forms: octahedra (Fig. 827), and as dumb bells. The crystals are common, and nearly so. The dumb bells sometimes become agglomerated into small rounded masses, forming the so-called hemp seed calculus. The origin of oxalate of lime in the urine is a somewhat doubtful point. Oxalic acid is not present normally in the urine, and is supposed to be derived from uric acid by imperfect oxidation. It has been ascribed also to the imperfect oxidation of the carbohydrates taken as food. Certain articles of diet, as sorrel and rhubarb, which contain oxalates in considerable quantities, will cause their presence in the urine. It was formerly supposed to be associated with marked symptoms indicating the so-called oxalic diathesis, the patient being pale, hypochondriacal, dyspeptic, and suffering from acidity of the

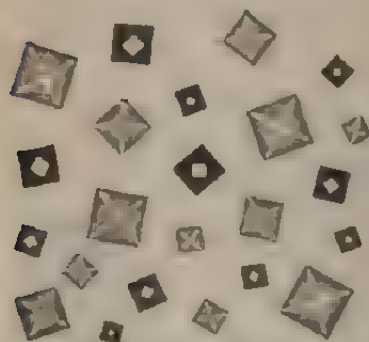

Fig. 827. Crystals of Oxalate of Lime.

Fig. 828. Very rough, irregular mass of Oxalate of Lime.

stomach, disturbed sleep, and loss of sexual power. W. Roberts has stated that oxaluria accompanies no constant train of symptoms, and that the presence of oxalates furnishes no definite indication for treatment. Urine containing oxalates is usually pale, abundant, and does not cause some sensation of heat and pain in its passage along the urethra. It forms no definite deposit, but is usually associated with a slight excess of mucus. The crystals adhere to the side of the glass in lines corresponding to any irregularity in the glass, or to marks left by the cloth used in wiping it out. There is strong reason to believe that in many cases the oxalate is produced during the early stages of decomposition after the uric acid has been passed.

Calculus.—The oxalate of lime or mulberry calculus is usually of a cast brown or even black color, rough, tuberculated, and sometimes almost covered with spines on the surface (Fig. 828). It is very heavy and hard. It sometimes reaches a great size, as the irritation it causes calls attention to it. Oxalic calculi of small size are not unfrequently passed as gravel.

Treatment.—When the patient habitually passes oxalates, and especially if they appear as gravel, he must be put upon a light and nourishing diet, especially fish, as recommended by Bird, cautioning him to avoid sweets and all fermented liquors, with the exception of a moderate quantity of weak spirits and water. Tonics, particularly the mineral acids, iron, zinc, and quinine, may be given and the residence should, if possible, be changed for a time to a warm climate. Distilled water only must be used for drinking purposes. When calculus is formed, there is, owing to its roughness, and the irritable state of the patient's nervous system, usually a good deal of pain in the region of the bladder, requiring the free administration of opiates.

Fig. 820.—Crystals of Ammonio-magnesian Phosphate.

Phosphatic Deposits.—The sediments and calculi containing phosphates occur in three distinct forms: 1. Triple or Ammonio-magnesian Phosphate; 2. Phosphate of Lime; and, 3. Mixed Phosphates, consisting of a mixture of the preceding varieties.

1. The *Triple or Ammonio-magnesian phosphate* is met with in all specimens of urine that are decomposing. It has no pathological significance, and is not associated with any special constitutional condition. It forms the chief part of the white crust which is deposited on all instruments tied into the bladder for any length of time, and on all stones which have given rise to severe cystitis.

2. The *Amorphous Phosphate of Lime* is deposited whenever the urine becomes alkaline, whether from the administration of alkaline drugs, from the presence of alkaline mucus in large quantities secreted from an inflamed bladder, or from the formation of carbonate of ammonia from decomposition. It very rarely forms a concretion alone. Excess of phosphates is met with in some forms of disease of the nervous system, but unless the urine be at the same time alkaline it does not form a deposit. Amorphous phosphates are very frequently passed a few hours after a meal, during the so-called "alkaline tide" in the urine, especially about eleven or twelve o'clock after a heavy late breakfast. This occurs more readily if the actual amount of phosphates be in excess. The causes of this condition are not very clear, but the alkalinity can easily be shown in many cases to be due to the presence of alkaline carbonates, the urine effervescing vigorously on the addition of any acid. It is frequently associated with late hours and overwork. The patient is often much alarmed by the appearance of the phosphates, as they usually come at the end of micturition, forming a white cloud in the stream which he may take for seminal fluid. If the phosphates are very abundant they often hang about in the urethra, and may cause severe smarting or burning pain after micturition. The condition is easily detected by examining the urine. The white heavy deposit looking almost like pus disappears immediately on the addition of a little acid.

3. *Mixed Phosphates* are usually met with in all cases of disease of the bladder with ammoniacal urine, as in the cystitis following an injury to the spine, or in advanced cases of prostate disease.

Calculi.—Pure phosphatic calculi are very rare, if we exclude those soft concretions that form in a foul bladder. They are commonly composed of mixed phosphates in varying proportions. If the proportion is about two

parts of the ammonio-magnesian to one part of the phosphate of lime fuses readily into a bead before the blowpipe, and has hence been a fusible calculus. This calculus is friable, laminated, and has a shaly or earthy look. The ammonio-magnesian calculus is less common. It is beautifully crystalline in structure. The phosphate of lime calculus is more rare, as the amorphous phosphates seem to show but little tendency to agglomerate into a concretion. The few that have been met with are laminated and harder than the other phosphatic stones.

Treatment.—The treatment of the deposit of phosphates is in most cases purely local, decomposition of the urine being prevented, and the bladder kept clean by those means that will be described in the chapter on Cystitis. The passage of amorphous phosphates may be treated by avoidance of overwork and late hours, and by exercise in the open air, a few days of such treatment will usually cause a complete disappearance of the symptoms. Tonics, especially nitric acid or nitro-hydrochloric acid and tincture of sulfuric acid, are often of use.

Cystine is one of the rarer forms of morbid product occasionally met with in the bladder. It differs from all other ingredients in containing a large quantity—about 26 per cent.—of sulphur. It is very rarely seen as a sediment in the urine; but when it occurs in this form it presents the microscopic characters seen in Fig. 830, being composed of hexagonal laminae. The causes which lead to its formation are uncertain, but the tendency to it is often hereditary. Calculi containing cystine have occasionally been met with. Golding Bird states that in Guy's Hospital Museum there are three

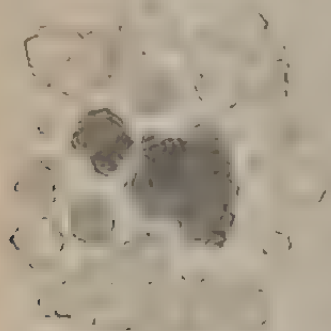

Fig. 830.—Crystals of Cystine.

composed of this peculiar substance, and in the Museum of University College we have some good specimens. Cystine in color has a peculiar yellowish color, becoming green after exposure to the air, and a waxy look, thus differing much from any other ingredient met with in urinary concretions. Friction applied to its cut surface causes it to emit a smell like that of garlic.

Xanthine, or Xanthic Oxide, was first noticed by Marcet, and has since been observed by Laugier, Langenbeck and others. It is of extremely rare occurrence, and has been found only in four recorded instances in the form of calculous concretions. These have generally been of small size, with the exception of the one removed by Langenbeck, which weighed 388 grains. For a detailed account of the characters and constituents of this substance, as well as of the materials of which calculi are formed, I must refer to the works of Golding Bird, etc.

Carbonate of Lime has occasionally been met with as an amorphous powder in alkaline or very faintly acid urine. Bird states that he has seen carbonate of lime as forming a distinct stratum in some phosphatic calculi, and Thudichum has examined prostatic concretions consisting almost entirely of this substance—the urinary origin of which, however, he doubts. In urinary vesical calculi composed of carbonate of lime are occasionally met with.

Chemical Examination.—For a complete account of the chemical examination of urinary calculi, I must refer the reader to works on medical chemistry by C. H. Raffe and others. The following rough tests may be

ever, be employed for the three chief varieties, the other forms being so rare that they may be practically excluded from consideration. Place a small fragment on a piece of platinum foil, and hold it in the flame of a spirit lamp. If it burns completely away, or at most leaves a scarcely appreciable residue, it is probably uric acid or urate of ammonia. If it blackens and then leaves a white residue of the same size as the original fragment, it is either oxalates or phosphates. Then place three very small fragments on three glass slides, and add, by means of a glass rod, a drop of dilute liquor potassæ to one, of acetic acid to another, and of dilute hydrochloric acid to the third. If it dissolves in the liquor potassæ it is either uric acid or urate of ammonia; if it dissolves in acetic acid and hydrochloric it is phosphates; if it dissolves in hydrochloric acid and not in acetic, it is oxalate of lime. If it dissolves in liquor potassæ, put a glass cover slip over it, and then run in beneath a drop of acetic or hydrochloric acid; as the acid meets the alkaline fluid a white cloud will appear; examine this under the microscope, and it will be found to be composed of diamond-shaped crystals of uric acid. As a confirmatory test for oxalate of lime, the white residue left after heating on the platinum foil may be placed on a glass slide, and a drop of acid added, when it will be seen to dissolve with effervescence, oxalic acid having been broken up by the heat, and carbonate of lime remaining.

STONE IN THE BLADDER.

STRUCTURE OF CALCULI.—Calculi, though sometimes composed throughout of the same deposit, are not unfrequently made up of layers or strata, differing in chemical composition from one another, and these usually go by the name of *alternating calculi* (Fig. 831). Most frequently, the nucleus consists of uric acid; next in the order of frequency comes the oxalate of lime; and then the concretion of a phosphatic character throughout. It is

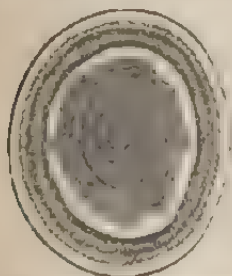

Fig. 831.—Section of an Alternating Calculus.

Fig. 832.—Section of Oxalate of Lime Calculus incrusted with Phosphates.

very seldom that the nucleus is absent; but concretions have occasionally been met with in which none could be detected, or in which it was even replaced by a cavity. The nucleus is usually as nearly as possible in the centre of the calculus, and is generally nearly regular in shape; occasionally, however, it is branched or curiously radiated, and then the concretion generally affects a corresponding outline. Calculi containing two or three nuclei have sometimes been found, consisting, probably, of an equal number of concretions agglomerated together. A foreign body occasionally takes the place of a nucleus.

The body of a calculus having the uric acid nucleus is usually composed

of the same substance, possibly mixed with some urates; but not infrequently these are incrustated by a deposit of phosphates. In other instances, the body may be wholly composed of some of the earthy phosphates, which more rarely alternate with the oxalate of lime or the triple phosphate.

An oxalate of lime nucleus usually has a body of the same composition, but in some cases it is incrustated by phosphates or urates. Fig. 842. When the interior is phosphatic, the concretion is always of the same composition.

The alterations in the composition of a calculus are due to varying conditions of the general health, and consequently of the character and constituents of the urine, and of the state of the lining membrane of the bladder. The uric acid and oxalate of lime nuclei and layers are undoubtedly due to constitutional causes. The phosphatic laminae, whether interposed between the uric acid or incrusting the calculus, are dependent on vesical irritation and decomposition of the urine, consequent on the presence in the body of the uric acid or oxalate of lime nucleus which has been previously formed.

ORIGIN.--Calculi may be formed either in the kidneys or in the bladder. Those that contain nuclei of the urates or oxalates are probably renal in their origin; whilst those that have a phosphatic nucleus are usually vesical. From the first, renal nuclei of this composition being rarely met with.

All renal calculi, all those vesical calculi that have a renal origin, and some of those even that appear to be primarily formed in the bladder, have a constitutional source; they arise from a morbid state of the urine, which in its turn probably depends upon mal-assimilation, the peculiar form of which determines the chemical composition of the stone. Those calculi that are formed by deposit from the urine upon and around some foreign body, as a pin or straw accidentally introduced into the bladder, and some with phosphatic concretions that appear to be the result of an unhealthy state of the mucous membrane, may be looked upon as being local in their origin.

The symptoms arising from a stone in the kidney, and during its passage to the bladder have been already described (p. 889). Though a vesical calculus often owes its origin to the descent of a stone from the kidney, frequently there is no evidence of its coming from such a source, but even appearance of its being deposited in the bladder; a nucleus being originally formed in this viscus by the aggregation of some sabulous matters, around and upon which fresh deposits take place, until a true calculus is formed. In some instances, vesical calculi have been found deposited upon and around foreign bodies, accidentally introduced into the bladder, such as a piece of straw, a pin, a bit of bougie, fragment of bone, etc.

NUMBER.--The number of calculi in the bladder varies considerably; most commonly only one is encountered; but in about one-fifth or even one-tenth of the cases operated upon, several will be found; from two to six, and more are by no means uncommonly met with. Occasionally several distinct calculi have been detected; and there are instances on record in which even hundreds of distinct and separate calculi have been found in one bladder. The most remarkable case of this kind is one in which Physick removed upwards of a thousand calculi varying in size from a partridge-shot to a bean, and each marked with a black spot. Several calculi may become matted together in one large concretion, as in the anatomical representation of a calculus (Fig. 833) that I removed from a soldier many years old; it was formed of eleven distinct uric acid calculi soldered together in this way, besides which, three others were loose in the bladder. Whether or more calculi occur, it is remarkable how uniform they often are in size, and weight, one being the exact counterpart of the other. This uniformity is remarkable when the calculi are very numerous, dozens of small stones of exactly the same size, shape, and weight, being met with.

large calculus is very rarely, if ever, found associated with numerous small ones.

When there are several calculi in the bladder, the attrition of one against the other usually causes the opposing surfaces to become smooth, thus constituting "facets" (Fig. 834). This is probably owing to the bladder being at one, always containing urine, and thus not compressing and grinding the calculi against one another. In some cases, however, when the calculi are numerous, there are no signs of attrition. In a patient of mine who had fifteen calculi in his bladder, all the stones were round, about the size and shape of marbles, without any facets. In other cases, again, there may be more facets on one calculus than companion calculi in the bladder. A

Fig. 833.—Uric Acid Calculi matted together.

Fig. 834.—Calculi with Facets.

second stone may occasion two or even three facets on the first, having rolled first to one and then to the other side of it.

Spontaneous Fracture of a calculus will sometimes occur within the bladder. This curious phenomenon, which has been met with only in uric acid calculi, may happen to a stone that is single, or to one among several. When it occurs, great irritability of the bladder is set up. There are several ways of explaining this fracture, or rather disintegration, of a calculus. Civiale supposes it to occur by the contraction of the hypertrophied coats of the bladder upon the stone. It is possible that, when there are several calculi in the bladder, the concussion of one against another may give rise to it; and for the breaking up of a calculus to happen, it would by no means be necessary that this pressure of the bladder or concussion should be sufficiently strong to resolve the stone at once into fragments. If a crack or fissure merely be formed in it, the infiltration of the urine into this may so soften and loosen its cohesion, that it becomes resolved, without further violence, into a number of pieces. In some instances these become agglomerated together, by the deposit of a quantity of phosphatic matter upon and around them. In other cases, the different fragments may each form the nucleus of a fresh calculus, so that the bladder may afterwards contain numerous concretions.

PHYSICAL CHARACTERS.—The **Size** of calculi varies from that of a hempen seed or pin's head to a concretion of immense magnitude. One of the largest with which I am acquainted, was a calculus removed by the high operation by Cuyterhoeven, of Brussels, which I saw some time ago in his possession, and of which he has been obliging enough to give me a cast. It is pyriform, and measures 19 inches in its longest circumference, and 12 inches round at its broadest part, being 6 inches long, and about 4 wide. In the celebrated case of Sir W. Ouzelvic, Cline attempted, but failed, to extract a calculus measuring 16 inches round one axis and 14 round the other. It weighed 44 ounces, and must have been about the size of Cuyterhoeven's. These enormous concretions are happily rarely met with at the present day; the usual

size of stones removed by operation being from about one to two inches in the longest diameter, somewhat narrow, and perhaps flattened.

The **Weight** of calculi varies from a few grains to several ounces; the commonest weight is from three drachms to about an ounce, reaching occasionally from three to six ounces; from this they may range upwards, and several pounds are reached. Thus, in China's case the stone weighed 11 ounces. Deschamps saw one of 51 ounces, and Morand one weighing 60; none of these admitted of removal. The largest calculi are generally composed of phosphates, in greater part if not in whole. Large and recent calculi are certainly less frequently met with now than formerly, owing to operations for stone being simpler and less dreaded since the introduction of anesthetics, and hence practised in an earlier stage of the disease.

The **Hardness** of calculi varies considerably; the oxalate of lime is the hardest; the lithates come next in consistence, and are often very hard though brittle; the phosphatic calculi are always comparatively soft and friable.

The **Shape** of calculi presents great variety; most commonly, however, they have an ovoid figure. Concretions of urate of ammonia and urea are generally pretty regularly ovoidal, smooth, and disk-like. Those composed of oxalate of lime are usually somewhat globular or square shape, and generally rough, nodulated, or spiculated upon the surface. The phosphatic calculi present usually the most irregular outline; most commonly, it is true, they are ovoid or globular, but are not unfrequently branched, as if deposited in the interior of a sacculated bladder, constricted, or of an hour glass shape. The cystine calculi are generally tolerably oval and regular in outline.

Position.—Most frequently calculi lie loose in the bladder; but sometimes they may be fixed, either by being encysted, and then lying in one of the sacculi that have already been described within the walls of the bladder (Figs. 835 and 836); or by being fixed in and embraced by one of the

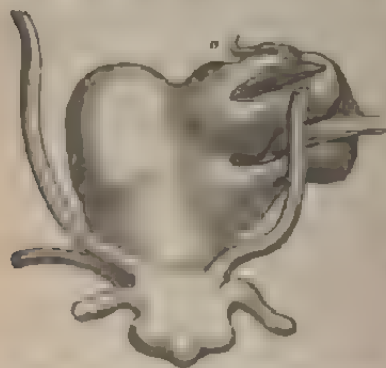

Fig. 835. External view of bladder, containing an Encysted Calculus at *a*.

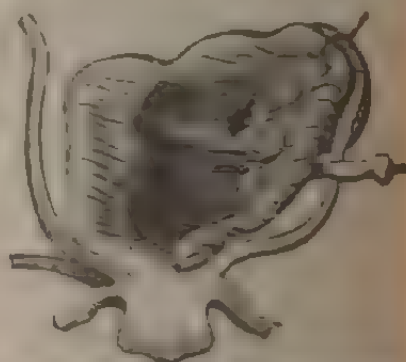

Fig. 836. Internal view of the same bladder, showing small Orifices leading into the cyst, at *a* and *b*.

ureters; or, in other cases, by being deposited upon, and partly inclosed by, villous or malignant growths.

Causes.—Whenever a foreign body of any kind, as a piece of catheter, etc., is introduced into the bladder, it will form the nucleus of a calculus, speedily becoming incrustated by calculeous phosphatic matter. But the causes of calculi occurring spontaneously are very obscure. There can be little doubt, it is true, that the different forms of concretion are connected

with the various general and local conditions that have already been described; and we may look upon the formation of a calculus as an indication of the existence, in a greater degree of intensity than usual of the causes which ordinarily give rise to sediments or gravel; but why, in particular cases, aggregation into a calculous mass takes place, it is impossible to say.

Age exercises considerable influence upon the production of calculi. Stone may occur in the bladder at all periods of life, and even, according to Stahl, be congenital. The greatest number of cases apparently occur during the first two decennial periods; thus, in the statistics collected by Sir Henry Thompson from the chief hospitals of this country, he shows that one-third of the entire number of cases occurred before seven years of age, and one-half before the thirteenth year is completed. Coulson has collected 2972 recorded cases of lithotomy from various sources; of these, 1466 occurred under the age of ten, 731 from eleven to twenty, 205 from twenty-one to thirty, 264 from thirty-one to fifty, and 306 from fifty-one upwards. These statistics refer entirely to hospital practice. The later statistics published by Thompson, derived from his own practice, public and private, show somewhat different results. Thus, of 812 patients upon whom he has operated, 595 were above fifty. This apparent discrepancy arises from two causes. First, the more extensive statistics are derived from cases operated on chiefly before the days of anesthetics, when numerous adults died unrelieved rather than face the horrors of lithotomy; whereas children had little choice in the matter. Diagnosis also was not so perfect at that time, and many small stones in old people escaped detection. Secondly, Thompson's own statistics are chiefly derived from private practice, and it is well known that the children of the rich very rarely suffer from stone; whereas that disease is very common among the poor. The cause of this is not very certain, but some attribute it to insufficiency of milk in the diet.

Sex influences materially the occurrence of stone, which is far more frequent in the male than in the female, in the proportion of about twenty to one of cases requiring operation. This, however, does not represent the exact ratio; as, owing to the shortness and large size of the urethra in females, many small calculi are voided by them that would be retained in the male.

It would appear that in some parts of the world calculus is a far more common disease than in others. It is generally more frequently met with in cold than in warm climates. The negro race is remarkably exempt from this affection. It is a singular fact that in some parts of the same country calculous disorders are of far more frequent occurrence than in others. Thus, it is well known that the inhabitants of the east coast of England and Scotland are peculiarly liable to these disorders; and that in Norfolk stone occurs with especial frequency, the mortality from calculus being much higher here in proportion to the population than in any other county of England (Cadge). In America also, it would appear that the inhabitants of certain States are peculiarly obnoxious to this affection; and I understand that in some districts of Germany the disease may be said to be almost unknown, whilst in others it is of common occurrence. The relative frequency of the kinds of calculus also varies in different countries. H. V. Carter, who has analyzed and described upwards of a hundred specimens contained in the Museum of the Grant Medical College, at Bombay, shows that the percentage of calculi with an uric acid or urate of ammonia nucleus is, in India, 56.39, in England, 71.79; while that of calculi with a nucleus of oxalate of lime is, in India, 43.60, in England, 16.87. The calculi composed purely of oxalate of lime also greatly exceed in number those which consist entirely of uric acid or urate of ammonia. To what these differences are owing it is impossible to

say. Peculiarity of race, of constitution, and of diet, with exposure to prevalent easterly winds, have all been assigned as reasons for them, but probably not on very sufficient grounds.

Symptoms.—The symptoms of stone in the bladder vary according as the calculus lies loose in the cavity of the viscus or is encysted. Their intensity will depend on the size and shape of the stone, the condition of the bladder, and the constitution of the patient. Most commonly, the severity of the symptoms is in proportion to the magnitude of the calculus. This, however, is not always the case. In a patient whom I once cut the most intense suffering and repeated attacks of cystitis had been occasioned by a small and sharp-pointed calculus, not weighing more than a drachm; and some years ago I saw a patient in whose bladder five calculi were found after death, some as large as chestnuts, though their presence had never been suspected during life by the different Surgeons under whose care he had been for stricture. A little distress had they occasioned. In some cases, the symptoms of stone suddenly declare themselves; and then the Surgeon finds on examination that the patient has a calculus of some size, which must have been a long time forming without attracting attention. Rough and angular calculi necessarily give rise to more severe symptoms than smooth ones, owing to their exciting a chronic form of cystitis; as phosphatic calculi are deposited almost invariably as the consequence of cystitis with foul urine, they are accompanied by much local suffering and constitutional disturbance.

The symptoms induced by stone are the result of the mechanical irritation produced by the presence of a foreign body in the bladder; these are *Pain, Increased Frequency in Micturition, occasional Stoppage of the Urine, and Various Morbid Conditions of that Fluid.*

The *Pain* in calculus is often the first symptom that attracts attention; it varies greatly in character and degree. It may not only be experienced in the region of the bladder and the perineum, but may radiate, when it is the course of the nerves of the lumbar and sacral plexuses, the patient complaining of a heavy and dragging sensation in the groins, extending down to outside or back of the thighs, and not uncommonly experienced in the sole of the feet. The penis is the seat of a good deal of uneasiness, frequently of a sharp and cutting pain at the end of the glans. This is especially noticed in children, in whom attention is often attracted to the complaint by their constantly squeezing and pulling the organ to relieve the distress they suffer in it. The pain is much increased by any movement by which the stone is jolted about in the bladder, as in driving, riding, or jumping, and is especially severe in those cases in which cystitis occurs. It is always most severe towards the termination of, or immediately after, micturition; and there is then a tendency for the calculus to roll forwards towards the neck of the bladder, where it comes into contact with and is grasped by the most sensitive part of that organ. Hence it is not unfrequent, in cases of calculus in children, to find that the little patient instinctively lies upon his back or side whilst passing urine, and thus escapes much of the agony that he would otherwise suffer. In adults in whom the prostate happens to be enlarged, the calculus usually lies in a depression behind this gland, and hence, being prevented from being squeezed by the neck of the bladder, the consequence of imperfect contraction, occasions less suffering than in other cases.

In consequence of the irritation set up in the bladder occasioning chronic inflammation of the mucous membrane, there is an *Increased Frequency of Micturition*, more by day than at night. The urine is passed frequently in small quantities at a time, usually contains some mucus or pus, and is occasionally tinged with blood, or loaded with thick vesical mucus. But a

many cases the urine remains remarkably clear, transparent, and free from marked admixtures throughout. Albumen from blood or pus is commonly present, and in the later stages when the kidney becomes affected, it may come from that source also. The presence of blood in the urine is often one of the earliest signs of stone in the bladder, and in children especially should lead to the suspicion of calculus. It may be in large quantities, and may continue for many weeks, especially in the earliest stages. The urine may then clear as the bladder becomes accustomed to the presence of the stone, and the blood may reappear only under the influence of active movement, or of any cause of increased irritation of the organ. But it is important to observe that the quantity of albumen, as shown by boiling the urine, will continue to be very great. It very rarely happens that a stone has existed for any time, without the urine becoming occasionally streaked or tinged by blood.

An occasional *Stoppage in the flow of Urine* before the bladder is emptied owing to the stone being impelled against its neck, and thus blocking up the urethra is a common symptom in children, but very rare in adults. On the patient lying on his back or on his side, the stream flows again, the situation of the calculus being changed.

As a result of the straining and general irritation about the genito-urinary organs, *Protrusion of the Anus*, accompanied by *Tenesmus*, is by no means uncommon, especially in children; and in some cases there is very troublesome *Pruræum*.

Stone in Elderly Men often gives rise to but feebly marked symptoms. This fact has been specially called attention to by Sir Henry Thompson. He states, as the result of his unrivalled experience, that possibly from diminished sensibility of the bladder in elderly men, partly from the frequency with which only a moderately enlarged prostate may mask the symptoms, many a man may and does carry a uric acid calculus for three or four years with little or no inconvenience, so that the presence of the stone may easily be overlooked till it attains such a size as to make its removal a serious and possibly a dangerous operation. In these cases the symptoms he regards as most characteristic, are slight pricking or smarting at and near the end of the penis, often but not invariably felt during and after the close of micturition; increased frequency of micturition, less felt at night, and more manifest in the day, especially during exercise; but if the patient lead a very quiet life this symptom may be wanting. Florid blood in small quantities may appear after more violent exercise, or jolting from any cause. The urine is acid and clear, and often deposits lithates. By sounding the patient when these slight symptoms are present, a small stone may often be detected and removed without appreciable risk.

Stone in Children.—The symptoms in children present few peculiarities, except that the patient is often unable clearly to describe what he feels. Pain on movement is indicated by the child's disinclination to play or run about. Screaming or crying after micturition is common; the irritation of the stone often leads to incontinence at night, and frequent wetting of the clothes during the day. Constant handling of the penis and pulling of the foreskin till it seems in some cases to be actually lengthened, are also important signs. With these, straining, with prolapsus of the rectum during micturition, is usually present, and sudden stoppage of the stream during micturition is not uncommon. Whenever a child presents these symptoms, he should be at once sounded. If no stone be found, the child must be examined for worms, the irritation of which may give rise to symptoms closely resembling those of stone. A tight phimosis will also cause symptoms distinguishable from stone only by sounding.

Encysted Calculus.—When a stone is *encysted*, those symptoms that depend upon its being loose and rolling about in the bladder, are generally absent; thus there is no stoppage of the urine, the fluid is seldom bloody, and the pain is not materially increased by jolts and rough movement, though there are weight and pain in the usual situations, and increased frequency of micturition from the pressure and irritation of the calculus.

Physical Diagnosis of Stone.—The existence of stone is finally determined by **Sounding the Bladder.**

A **Sound** is a solid steel instrument shaped like a catheter but shorter in the curve (Fig. 837), so that it may explore thoroughly all parts of the bladder, especially those behind the prostate. It should have a wide and

Fig. 837.—Sound for examining Bladder.

smooth steel handle, and be slightly bulbous. Sir H. Thompson prefers a hollow sound with a round handle. The operation of sounding is conducted as follows. The patient lies upon his back on a hard mattress with his buttocks well raised on a pillow; a full-sized sound, well-oiled and warmed, is passed into the bladder which should, if the patient can retain it to a point, contain three or four ounces of urine. The Surgeon then using his left hand, or crossing over to the patient's right side, whichever he finds most convenient, carefully directs the beak of the instrument towards the neck of the bladder, turning it from right to left over the whole of that region.

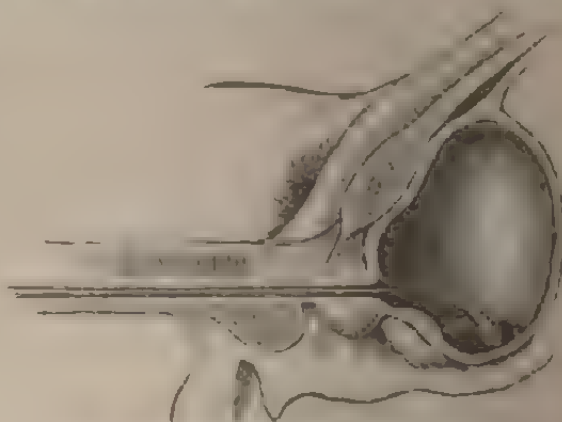

Fig. 838.—Sounding for Stone behind Prostate.

next draws it forward on one side as far as the neck, tapping as it goes gently with its beak; he repeats the same manoeuvre on the other side, and finally, directs the end of the instrument by raising its handle into the neck, which he carefully explores. Usually the stone is readily moved by these manoeuvres, and its position in the bladder will often be dependent upon, and may to a certain extent be taken as an approximate measure of, its size. Thus, when moderately large, it will usually be found lying on one side, most generally the right, of the neck of the bladder; when small it will be placed towards the fundus, near the orifice of one of the ureters. These then are the situations in which the Surgeon should first seek

for a stone, and in which he will generally find it when present. Should it not be met with here, the chances are, more especially if the patient be elderly, that it will be found in a pouch behind the prostate, where it may be detected by depressing the handle and so turning the beak of the sound downwards (Fig. 838). Should the Surgeon not detect the calculus in any of these situations, he depresses the handle between the thighs, and tilts up the beak so as to examine the pubic portion of the organ (Fig. 839). In the event of his not meeting with a stone, he may explore the bladder, first on one side, then on the other. Should the rational symptoms of stone be well marked, though no calculus be struck, the Surgeon must not give a decided opinion in the negative after the first exploration, but should examine the patient again a few days later, with the bladder in different state as to its

Fig. 839.—Sounding for Stone above Pubes.

contents. In making this second examination, I have found it of great service to use a hollow steel sound, by which the organ can be injected or emptied at pleasure (Fig. 840). The patient should on this occasion have his bladder injected through such an instrument as this, with four or six ounces of tepid water, so as to distend the organ slightly, and prevent the folds of mucous membrane from overlapping any concretion that may exist in it. Its interior is then carefully explored in the way already described; and, if the stone cannot then be detected, the contents of the bladder are gradually allowed to escape through the sound, and the patient is desired to stand up whilst

Fig. 840.—Hollow Sound.

the exploration is being proceeded with. In this way, by examining a patient in different positions and in different conditions of the bladder as to capacity, a calculus is sure to be detected if one exist. A lithotrite may occasionally be advantageously used as a sound for the detection of small calculi lying behind the prostate, a situation more readily reached by its short beak than by an instrument of larger curve. These examinations must not, however, be too protracted; the time occupied should not exceed five minutes, lest cystitis be induced. When a stone is struck by the sound, there is not only a char-

acteristic and distinct shock communicated to the instrument but a tolerably loud click is given, which can be heard by the bystanders, and frequently by the patient, as well as by the Surgeon.

Rough sounding is doubly injurious. It injures the bladder and fails to find the stone. The stone is often missed in sounding, especially when small, by being carried to and fro as the urine and the bladder are moved backwards and forwards by rough manipulation. It will be found, if the parts are allowed to become quiescent, that the stone falls to the bottom behind the prostate, where it will be found by a gentle tap of the sound first on one side then on the other.

By conducting the sounding properly, the Surgeon may usually ascertain not only the existence of a stone, but its size and hardness, whether it is single, if it be encysted, and the general state of the bladder; with all of which it is of importance that he should be acquainted before undertaking any operation. A good deal of this information may be elicited by the ordinary sound, but some of the points can be accurately determined only by sounding with the lithotrite.

The *hardness* of the stone may usually be judged of by the more or less clear ringing character of the click; a uric acid or oxalate of lime calculus giving a sharper sound than a phosphatic concretion.

A calculus may generally be known to be *encysted* if the sound strikes at times, but not at others (Fig. 841); if the stone always appears to be fixed in

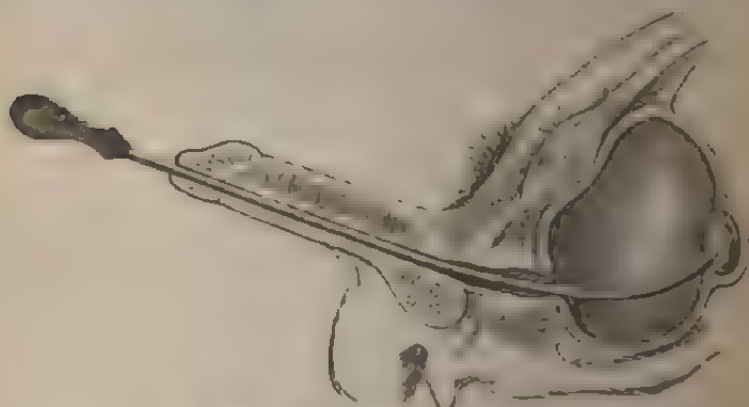

Fig. 841. - Sounding for Encysted Calculus.

one situation, and if the beak of the instrument cannot be made to pass round it, so as to isolate it, but a kind of tumor projecting through the way of the bladder is felt, around or on one side of the point where the calculus is struck.

The fasciculated, roughened, and sacculated condition of the bladder may generally be detected by the way in which the beak of the instrument grazes and rubs over the organ.

The size of the calculus is best determined by a lithotrite. It is true that a Surgeon may sometimes come to a decision as to the bulk of a calculus by observing the extent of surface along which the sound is in contact with the stone, as the instrument is being withdrawn. But a very rough guess can be made in this way; and I have frequently seen very experienced Surgeons deceived in their estimate of the size of a calculus, mistaking perhaps several small ones lying together for one large one. By introducing a litho-

trite and seizing the calculus gently between its blades, a correct estimate of its size may always be arrived at.

In order to determine that *several calculi* exist in the bladder, it is sometimes sufficient for the Surgeon to feel that the beak of the sound comes into contact with a stone on each side of the organ, or that it can be distinctly insinuated between two concretions. In some cases, however, these points cannot clearly be made out; and then the Surgeon, introducing a lithotrite and seizing the first calculus with which he meets, should hold this between the blades of the instrument, and whilst it is so fixed move it and the lithotrite from side to side; when, if a click be heard and felt, he may be sure of the existence of another stone.

Sounding is by no means destitute of danger, more especially if roughly done, or in patients who have chronic kidney disease. In the first case it may give rise to cystitis or profuse and continuous hemorrhage; in the second, to rigors and suppression of urine.

Errors in Sounding occasionally occur. The Surgeon may mistake a hardened and fasciculated bladder, having its ridges perhaps encrusted with phosphatic matter for a calculus; this is especially apt to happen in children. In these cases, however, the mistake may usually be guarded against by the absence of a distinct click, though a rough grating sensation be experienced, and by the Surgeon being unable to isolate a stone. Yet the difficulty in some cases is great; Velpeau stated that he was acquainted with four instances, and S. Cooper with seven, in which patients have been cut and no calculus found; and when we reflect that these accidents have happened to such men as Cheselden, who on three occasions cut a patient and found no stone, to Crosse, to Roux, and to Dupuytren, it is easy to understand that in some cases the difficulty of coming to a correct decision must be very great.

Examination of the Bladder by Manipulation can be easily carried out in children. The patient is fully anesthetized; the Surgeon then passes one finger into the rectum and presses firmly with the other hand above the pubes. If a stone be present, it can be clearly felt by the finger in the rectum and its size ascertained. In adults this mode of examination is of course impossible if there be much abdominal fat or any enlargement of the prostate, and even in the absence of these conditions it is very uncertain, as the finger does not reach far enough up to grasp the stone.

Stone in Women. In women the symptoms of stone closely resemble those met with in men, and the detection of the calculus is usually very easy, owing to the shortness of the canal and the facility with which the stone may be tilted up by introducing the fingers of the left hand into the vagina. The sound used in these cases should be shorter and less curved than that employed for the detection of calculus in the male bladder.

PATHOLOGICAL CHANGES INDUCED BY CALCULUS.—After a stone has existed for some time in the bladder, it induces serious pathological changes in the whole of the urinary apparatus. The *urethra* usually becomes slightly dilated; and the *prostate* not unfrequently somewhat enlarged and irritable, in consequence of which a kind of pouch is formed behind it, in which the calculus is apt to lodge. The most important changes, however, take place in the bladder and kidneys. The *bladder* becomes extremely sensitive, especially about its neck, and is consequently unable to contain as much urine as usual; hence it becomes contracted. In some rare instances, however, as will be more especially noticed when we come to speak of lithotrity, it falls into an atonic condition, and then is apt to become rather largely dilated. The mucous membrane is commonly a good deal inflamed and irritated by the presence of the calculus; and the muscular coat becomes thickened and hypertrophied, so as to give it a very fasciculated appearance. Sacci

occasionally form, containing sabulous matter and fetid pus or urine, and in some cases lodging a concretion, which then constitutes an encysted calculus lying altogether outside the cavity of the bladder, with which it merely communicates by a very narrow aperture, as in Figs. 835 and 836, representing a case that was under my care, and which is fully described in the Journals for March, 1853. The *kidneys* are often congested, frequently in a state of chronic or subacute interstitial inflammation, and ultimately become the seat of such structural changes as are incompatible with life. When death occurs as the consequence of stone, the patient usually sinks, worn out by protracted suffering and kidney disease.

LITHOTOMY.

It is not my intention to enter into the general history of lithotomy, an operation that has been practised from the earliest ages; nor to give a sketch of the gradual modifications that have at various times been introduced, from the rude attempts of the Greek and Roman Surgeons to the barbarous and unscientific procedures adopted by the itinerant operators after the revival of letters. For all this, I would refer the reader to the classical works of Deschamps and of John Bell. The operation, as now generally practised in this country, is essentially that introduced by Cheselden, and modified more or less according to the views of particular Surgeons. Though Surgeons generally are agreed upon the great principles involved in it, they differ in their modes of carrying these out; thus the direction and extent of the incisions and the instruments employed have been much varied to suit the tastes and views of particular operators. But, although I look upon Cheselden's operation, as modified and practised by Liston, as being on the whole the simplest and safest mode of cutting for stone as yet introduced, there can be no doubt that recourse may occasionally be had with advantage to other methods instead of it. Indeed, there is no operation that requires to be considered from so many and such different points of view as lithotomy. The size, shape, and position of the stone, the age and constitution of the patient, all render it desirable and indeed necessary, to modify the method of operating. Hence, a Surgeon should not be too exclusively wedded to one plan, but should adopt one or other of the methods about to be described, according to the exigencies of the particular case before him.

Instruments, etc.—The table for operating must be firm and of a convenient height, so that when the Surgeon sits on a rather low stool the patient's nates will be on a level with his breast; a few blankets doubled should be laid upon the table, and covered by a piece of mackintosh cloth hanging over the end; and a tray of sawdust placed under it on the floor. The instruments necessary are the following: a pair of lithotomy-tapes, a sharp and probe-pointed scalpel, a staff, forceps, and scoops of various sizes, and a tube. To these may be added a searcher, and a brass injecting syringe.

The *tapes* should be of coarse flannel, about three yards long, by three inches broad.

An infinite amount of ingenuity has been expended in giving variety to the shape of the *knives* used for opening the deeper portions of the urethra and neck of the bladder in lithotomy. Instruments of this kind, straight-edged and shouldered, beaked and probe-ended in every possible way, have been devised; and each has had its special advocate, but has seldom been adopted in practice by any except its inventor. All these modifications of the ordinary scalpel are, to say the least, useless; some, perhaps actually

dangerous. They simply seek to supply by mechanical means that safety in the deeper incisions which may as readily be secured by a broad-bladed, straight-backed scalpel, if properly guided by a hand that is ordinarily skilful.

The cutting gorget, formerly much in vogue, is all but universally discarded as a most dangerous tool by the modern lithotomist.

The *scalpel* for the adult may be of the size and the shape represented

Fig. 842.—Lithotomy Scalpel.

(Fig. 842); for children it may be made a little smaller. A *probe-pointed lithotomy knife* of the size and shape here represented should also be at hand (Fig. 843).

Fig. 843.—Probe-pointed Lithotomy knife.

The *staff* should have a deep groove on its left side, occupying nearly one-third of the instrument; it should be well curved, of as large a size as the urethra will admit, and have a roughened handle (Fig. 849).

The *forceps* must not be too heavy, but should be of a good length in the handles, and have the joint well set back; the inside of the blades, as recommended by Liston, should be lined with linen to prevent the stone from

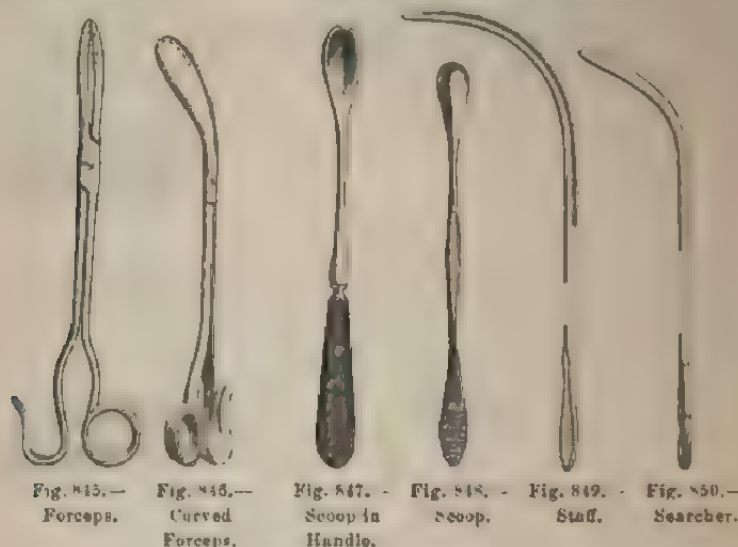

Fig. 844.—Open-bladed Lithotomy-forceps, lined with linen.

slipping (Fig. 845). Coxeter has made them with open blades, but lined with linen as heretofore (Fig. 844); in this way, as there is less metal, the weight is diminished, and the diameter of the instrument with a stone in its grasp is materially lessened. The ordinary forceps are straight, but it is advantageous to be provided with some that are curved (Fig. 846). The handles should be made with a loop on one side and a ring on the other; the ring for the reception of the thumb should be placed somewhat obliquely. The *scoops* of different sizes, and curved, can most conveniently be used when fixed in roughened handles (Figs. 847 and 848). The *tube* should be of silver or gum-elastic, well rounded at the end, and provided with silver rings, and may be petticoated. The *searcher* is a slightly curved sound, having a bulbous extremity (Fig. 850). The *syringe* should be provided with Gross's ball nozzle, which propels a reversed current.

In describing the operation of lithotomy, we shall first of all examine *seriatim* the different steps of an operation that presents no unusual compli-

cation or difficulty; we shall then consider the difficulties that may be met with, the accidents that may occur during the operation, and the principal sources of danger and the causes of death after its performance.

Preparation of the Patient.—Before subjecting a patient to operation, his general health must be properly attended to; and, indeed, if we find the constitution much broken by prolonged suffering, the bladder or kidneys seriously diseased, as indicated by the existence of pus or albumen in large quantity in his urine, and by the presence of the symptoms of interstitial nephritis (pp. 890-894), it will be wise to postpone the operation for a time, or perhaps even to abandon it altogether. There are few conditions in which a Surgeon is placed, that test his moral courage more severely than the refusal to operate on a patient for stone, and thus allowing him to die unrelieved. For a Surgeon to do this, unmoved by the entreaties of the patient and of his friends, requires no little self-reliance. Yet, when the patient is greatly emaciated, his constitution broken down, and his kidneys evidently much diseased, lithotomy would be attended by an inevitably and rapidly fatal result, and the performance of an operation would be a useless act of cruelty. Supposing, however, that the stone is of moderate size, that evidence of renal disease is absent or slight, that there is no visceral complication to prevent the performance of the operation, and that the patient's health is in a tolerably good state, it will be necessary to subject him only to proper preparative treatment for a short time, so as to allay or remove irritability of the urinary organs before proceeding with it. With this view, he should be kept as quiet as possible for about a week or ten days preceding the operation; his diet should be properly regulated, but not too low; the pain should be lessened by the administration of opiates or henbane, and the bowels properly relieved. On the day preceding the operation, a dose of castor oil or some other aperient should be administered; and, on the morning of the operation, the rectum must be emptied by means of an enema.

LATERAL OPERATION.—All the urine contained in the bladder having been drawn off, that organ should be filled by the injection of about six or

eight ounces of tepid water, in order to steady it and to facilitate the seizure and extraction of the stone. After chloroform has been administered, the Surgeon should introduce a full-sized staff, which he uses as a sound, in order to feel for the calculus. If he detects it, he proceeds with the operation; if he cannot detect it, it is usually recommended that he should withdraw the staff and introduce a sound, with which he examines the bladder; and, in the event of his still failing to discover the presence of the stone, the operation must be deferred, for it is an imperative rule in surgery that lithotomy should never be performed unless the stone can be felt at the time when the patient is actually on the table. It is, however, safer not to proceed with the operation unless the stone can be felt with the staff; lest the point of this, though apparently in the bladder, be actually engaged in a false passage. The stone, then, having been felt, the patient is to be firmly tied up. This is done by making a clove-hitch on the tape, and passing it round the wrist, after which the ends of the tape are passed round the instep and hand in a figure-of-8, as in Fig. 851. Some Surgeons prefer leather anklets, which

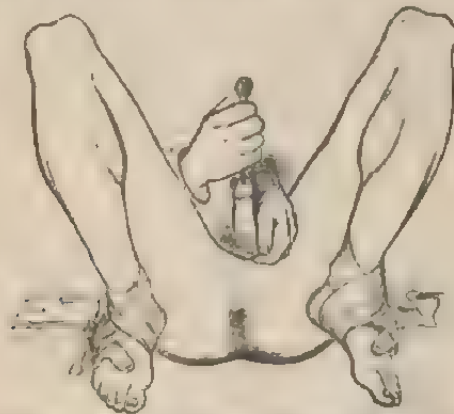

Fig. 851.—Position of Patient and Line of Incision in Lateral Lithotomy.

are attached to collars round the wrists by hooks; but these take longer to apply, and possess no particular advantage over the tapes. The patient is now brought to the end of the table, so that his nates project beyond it, where he is to be securely held on each side by an assistant, who grasps the foot in his hand, places the patient's knee under his arm, and draws the limb well aside, so that the perineum may be fairly exposed. It is desirable that the perineum be thus fully exposed to the Surgeon. In a patient, however, on whom I once operated, this could not be done, owing to the left hip being stiffened by chronic rheumatic arthritis; but I did not experience any particular difficulty in the operation, though somewhat inconvenienced by the position of the limb. The Surgeon then, seating himself before the patient, shaves the perineum—if this have not already been done—and introduces his finger into the rectum. This is done with three objects: first, to ascertain the depth of the perineum by feeling for the apex of the prostate; secondly, to make sure that the rectum is empty; and, thirdly, to cause a contraction of the gut, which will keep it out of the way during the first incision. He then gives the staff into the charge of a trusty assistant, who stands on the patient's left, and who raises and draws aside the scrotum with the left hand whilst he holds the staff in the right (Fig. 851).

The Surgeon then sees that the staff is held in the way in which he prefers

it. There are two ways in which it may be held; it may either be drawn well up into the arch of the pubes, or it may be pushed somewhat down, and slightly turned towards the left of the perineum. Liston always employed the first method, which I certainly think is the best, as it tends to increase the space between the urethra and the rectum, and consequently lessens the danger of wounding the gut, which more than counterbalances the advantage of the other method—that of approaching the membranous portion of the urethra to the surface.

The external incision is made by entering the knife in the raphe of the perineum, one inch and a half above the anus, and carrying it downwards and outwards, until it reaches a point that is just below the anus, but about one-third nearer to the tuberosity of the ischium than to the margin of the anal aperture (Fig. 851). It is useless to prolong the incision beyond this, as any freer division of the structures of the scrotum and on the nates cannot

Fig. 852.—Lateral Lithotomy: Finger nail in Groove of the Staff.

facilitate the extraction of the stone; but it must occupy the extent indicated, otherwise considerable difficulty may be experienced in the later steps of the operation. The depth to which this incision should be carried must vary according to the obesity of the subject; usually from about three-quarters of an inch to an inch, but not so deeply above as below. By this incision the skin, superficial fascia, subcutaneous fat, and inferior hemorrhoidal vessels, are divided. After it is completed, the knife is again introduced a little below the upper part of the wound, and the blade is run lightly downwards over any resisting structures; the left forefinger being placed at the middle of the wound, so as to protect the rectum. In this way the triangular space is opened between the accelerator urine, the erector penis, and the transversalis perinei muscles; and as the knife is carried downwards, the last-named muscle, the transversalis perinei artery and some areolar tissue are cut through. The lower border of the triangular ligament also is notched so as to open up the space between the two layers of the ligament, in which the membranous part of the urethra lies. The knife is then withdrawn, and the left index-finger is pushed deeply into this space until the edge of the nail

is lodged in the groove of the staff (Fig. 852), which can be felt just anterior to the prostate, thinly covered by the membranous portion of the urethra, the constrictor urethrae, and the deep transverse muscle. The point of the knife is then pushed through the urethra at its membranous part into the groove of the staff, above the index-finger, which protects and presses to the right the rectum lying beneath it (Figs. 853 and 854).

When the knife is felt to be well lodged in the groove, its handle is slightly depressed, so that the point may be raised; at the same time the blade should be somewhat lateralized so that its side lies parallel to the ramus of the ischium. If the edge be turned too directly downwards towards the mesial line, the rectum may be wounded; and if it be directed too much outwards the internal pudic artery will be endangered (Fig. 855); hence the mid course is the proper one.

The Surgeon, keeping the knife steadily in this position, and pressing the point firmly against the side of the groove of the staff, which he must never

Fig. 853. - Knife in Groove of Staff.

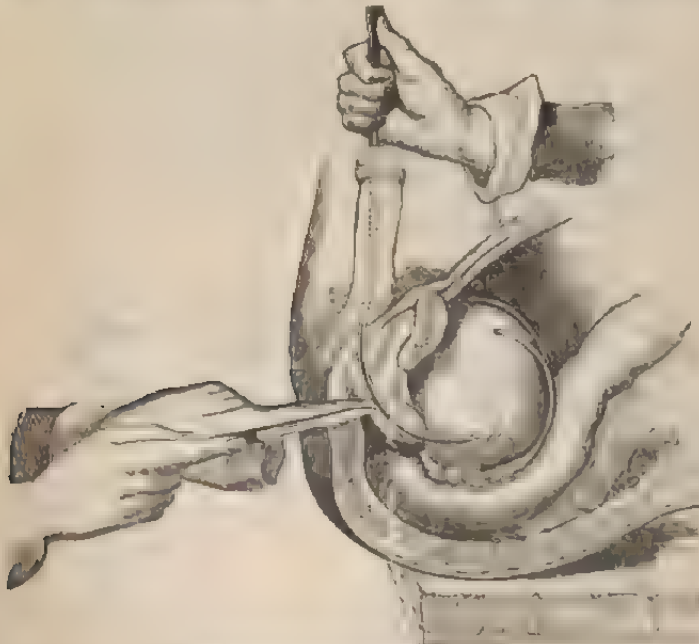

Fig. 854. - Second Stage of Lithotomy.

for a moment lose, pushes it forwards, dividing the membranous part of the urethra, the anterior part of the prostate gland and the sheath enclosing it, and a few fibres of the levator ani (levator prostatae), and thus makes an entry into the bladder (Fig. 854); he then withdraws the knife, keeping its back against the staff, so as not to enlarge the extent of the excision in the prostate.

Through this, and along the staff, he then pushes his left index-finger, and reaches the bladder, when he endeavors to feel the calculus with it. Should his finger be short, the perineum deep, or the prostate enlarged, he may be unable to reach the bladder in this way; and must then introduce

Fig. 855.—Arteries of Perineum and Deep Fascia.

a blunt gorget, as recommended by Cheselden and Martineau, in order to dilate the aperture in the prostate. If he use his finger for this purpose, he gives it a twist or two after passing it through the prostate, so as to enlarge the aperture through which it is entered. Having made sure that it is in the bladder, and having, if possible, felt the stone, he directs the assistant to withdraw the staff from the urethra.

Here let us pause, and state the principal points in these, the first and second stages of the operation. It will be observed that, in accordance with the best authorities upon the subject, and with my own experience, I have recommended the external incision to be free, the rectum to be protected by the left index-finger, the knife to be somewhat lateralized toward

and after the opening of the urethra, and the deep incision to be lateral.

1. The **Position of the Knife** must be carefully attended to, especially during the deep or second incision. At this stage of the operation the knife should be *lateralized*; that is, directed about midway between the transverse and perpendicular positions, so that the surface of the blade lies nearly parallel to the ramus of the ischium. The manner of holding the knife has

Fig. 856.—Position of Hand and Knife Ferguson.

Fig. 857.—Position of Hand and Knife Laston.

been much discussed, and necessarily and naturally varies with different Surgeons. I believe it signifies little how the handle of the instrument is held between the Surgeon's fingers, provided the edge be never turned upwards, but be always kept well lateralized, with the point steadily pressed into the groove of the staff.

If a Surgeon know what he is about, he may safely hold his knife as best suits his own convenience. In the first incision, most operators, I believe, hold the knife *under* the hand, as represented in Fig. 856, a position which that excellent lithotomist and accomplished Surgeon, Ferguson, preserved throughout the operation. Laston, in the early part of his career, appear-

to have held the knife, in the second stage of the operation, *above* the hand; and in all the representations, published as well as unpublished, that he has left of his operation, he has depicted the knife and hands in the position shown in Fig. 857; which, in the last edition of his *Practical Surgery*, he describes as a correct sketch of "the position of the hands and knife" at the commencement of the second stage of the operation. There can be no doubt, however, as Fergusson has pointed out, that in actual practice, at least after his first few years as an operator, he held the knife under the hand, with the index-finger upon the side or the back of the blade.

For my own part, I believe that every Surgeon will hold the knife in the way which he finds most convenient, and, as it were, natural to him. If any rules can be laid down on this point, I should say that, in operating on a child, or on an adult with a shallow perineum, the knife is most conveniently held as represented in Fig. 856.

But if the patient be fat, and the perineum deep, then I think that it is a question whether greater steadiness may not sometimes be secured by holding the knife somewhat in the manner of a gorget, with the index-finger perhaps a little more upon the side of the handle (Figs. 858 and 854; in this way the point is firmly pressed

Fig. 856. Position of Hand and Knife (Author's.)

into the groove of the staff, out of which it cannot slip, as it is secured and supported by the index-finger being somewhat under it. The section of the prostate is thus made by a steady push or thrust of the knife forwards, and not by any cutting movement downwards. No danger can result in the deep incision from pushing the point of the knife up into the groove of the staff; but there is great danger of missing the bladder, and entering the recto-vesical space, if it be at all depressed and the handle raised, though this cannot always be avoided if the staff be pushed deeply into the bladder. It may happen that the knife will not run readily along the groove, if its blade form too small an angle with the part of the staff with which it is in contact. The hand must then be slightly raised and depressed again as the knife glides along the curve of the staff into the bladder, so that the point may be kept well in the groove; and all risk of slipping out avoided.

2. The Incision into the Prostate must be at least of sufficient size to admit the tip of the forefinger readily. The extent to which it should be carried has been the subject of much discussion, and of wide diversity of opinion, John Bell advising that the incision should reach backwards to the bladder, and Scarpa, that it should not exceed five lines in adults and two in children. The danger, however, it must be borne in mind, does not consist in the section of the prostate itself—which is in reality a structure of but little importance—but in cutting beyond it to such an extent as to open up the loose areolar tissue surrounding the bladder, which would expose the patient to the danger of urinary extravasation and diffuse inflammation.

It was formerly supposed by some Surgeons that a stone of moderate size could be extracted through the prostate without tearing the fibrous capsule of the gland derived from the recto-vesical fascia, which was asserted to remain uninjured, and to prevent infiltration of urine into the surrounding parts. Experiment on the dead body, and the post mortem examination of those who died after lithotomy, clearly demonstrated the fallacy of these views. No stone of one inch in diameter can be removed through a healthy prostate without dividing the gland and its capsule for a considerable part

of their length, and if the calculus be of considerable size, the rectum is found to extend backwards in the floor of the bladder, some way toward the left ureter. The danger of urinary infiltration is not in the external parts of the wound, but in the loose subperitoneal tissue: and that distinguished anatomist, Ellis, taught many years ago that the separation between the cavity of the pelvis and the external parts in which a lithotomy wound can be safely made is not the sheath of the prostate but the lateral and anterior true ligaments of the bladder, or, in other words, the recto-vesical fascia. Hence the incision may be safely carried through the whole length of the lower and outer side of the prostate up to the very neck of the bladder, provided it do not pass beyond the attachment of the lateral ligament of the bladder, and so open up the loose subperitoneal tissue around this vessel.

There are, however, other dangers beside extravasation of urine that may arise from too free use of the knife in the deeper parts of the wound, especially hemorrhage from the venous plexus surrounding the prostate and wound of the rectum. For these reasons I prefer to incise the prostate to a moderate extent, enlarging the aperture by stretching with the forefinger.

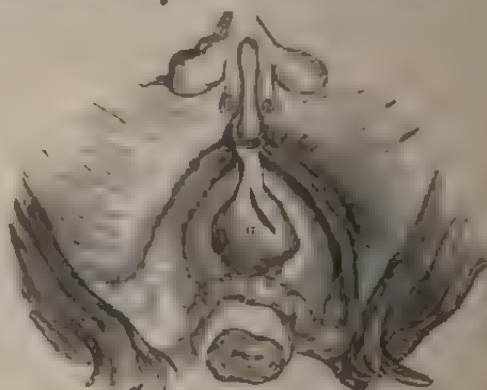

Fig. 859. - Incision in Prostate.

In the section of the prostate, then, two points have specially to be attended to: one is, that the knife in entering be not pushed forward at too great an angle with the staff, so as to cut widely, and the other is that, on its withdrawal the blade be kept steadily in contact with the staff. I believe that there is more danger of doing mischief in the withdrawal than in the entry of the knife; for, if it leave the staff for a moment, the guide is lost, and the edge may sweep downwards through the base of the prostate and the neck of the bladder. As the knife is withdrawn the index-finger is pushed forwards into the aperture in the prostate, which is then dilated by its pressure to a sufficient extent for the introduction of the forceps, which are slipped in as the finger is withdrawn, and for the extraction of the stone. This part of the operation may very conveniently be performed as was usually done by Liston, at the moment when the surgeon is stooping down, engaged in selecting his forceps. The dilatation of the prostate is readily effected; for this structure, though dense, is fragile, and breaks down easily under somewhat forcible pressure by the finger. In this way, by a mere stretching of the prostate, by a moderate section of its apex, followed by simple dilatation with the finger, sufficient space will be obtained for the extraction of all moderate sized calculi, without the employment of any violence, or the infliction of any bruising upon the tissues.

But another obstacle exists which will prevent the dilatation of the neck of the bladder to any very material extent, without an amount of bruising, or laceration, or even rupture that would probably prove fatal to the patient. This obstacle consists of a firm resisting tissue, which has been described by Tyrrell as "an elastic ring," surrounding the neck of the bladder; by Liston as "a fibrous or ligamentous band surrounding the orifice of the bladder, into which the muscular fibres of the organ are inserted." If this ring or band be ruptured, either by the finger or by the expansion of the forceps, fatal consequences will ensue; but if it be divided, the other tissues, as Liston observes, will yield to an inconceivable extent, without injury to the recto-vesical fascia. The division of this ring must be practised only to a very limited extent. I believe that it is always effected in the act of pushing the scalpel inwards into the bladder; a mere notching of the fibres of the ring, indeed, is sufficient to allow the requisite expansion to take place when pressure is applied.

In thus describing the mode of incising the prostate and neck of the bladder, I have, generally, used the term "dilatation;" and I believe that, by a simple process of dilatation or expansion of these parts, and without any violence whatever, small calculi under an inch in diameter may be extracted. In fact, for the removal of such stones, no force whatever is required, either in opening up the prostate or in withdrawing the calculus. But, in removing stones of greater magnitude than this, I believe that the process of expansion of the prostate and neck of the bladder, whether effected by the finger, by a blunt gorget, or by the opening up of the blades of the forceps, is a process of laceration rather than of dilatation, as I have frequently had occasion to observe in experiments on this point made on the dead subject. If this laceration be, however, confined to the substance of the prostate, and do not extend through the lateral ligament of the bladder, and into the subperitoneal tissue, no harm results. It is difficult, with ordinary force, to lacerate the dense ligament. This structure, therefore, remains as a firm unbroken barrier between the pelvic areolar tissue and the external wound, preventing the possibility of the infiltration of urine into the internal subperitoneal areolar tissue, and lessening materially the chance of diffuse inflammation. But if, in the withdrawal of the stone, or by an undue expansion of the blades of the forceps, the Surgeon feel a sudden giving way of a tense annular structure, he may be sure that the lateral ligament has been torn, and fatal mischief will probably ensue.

Extraction of the Stone.—A forceps of sufficient length, of a size proportioned to that of the calculus, and previously warmed by immersion in tepid water, must be slid along the index finger, which is kept in the wound, and by which the neck of the bladder should be drawn somewhat down so as to meet the instrument. In this way, also, the stone may often be fixed by the point of the finger, and its position thus accurately determined. The forceps having been introduced closed, the finger is withdrawn, when a gush of urine will usually take place through the wound, if that fluid have not already escaped at the time when the incision is made through the prostate. By this gush the calculus may, as Fergusson observes, sometimes be carried into the grasp of the instrument; most commonly, however, the stone requires to be felt for with the closed forceps. When its position has been ascertained, usually at the inferior fundus, the blades of the instrument are opened; and, by pushing one against the wall of the bladder, and giving it a slight shake, the calculus generally drops between them; though occasionally it is somewhat troublesome to seize, and this, indeed, often constitutes the most tedious and annoying part of the operation. Fergusson advised holding the forceps

transversely, opening them as widely as possible, then giving a rotation so as to make the lower blade scoop along the floor of the bladder, when closing the forceps the stone will usually be caught. The blades, having the stone in their grasp, are then closed, and the stone is drawn down

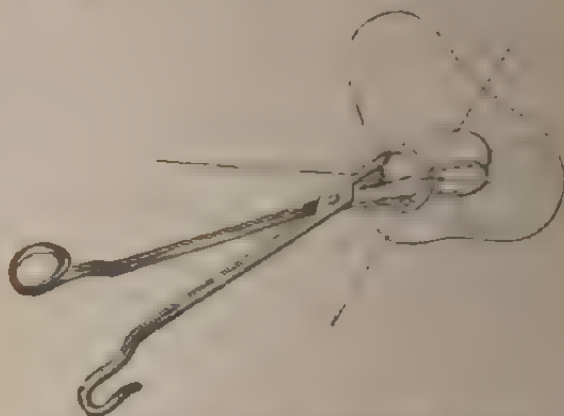

Fig. 852.—Direction of Forceps in Extraction of Stone.

through the wound. If it be small, it may be extracted at once without difficulty; if it be of moderate size, the finger should be introduced along the blades, in order to feel whether it is in a proper position for extraction.

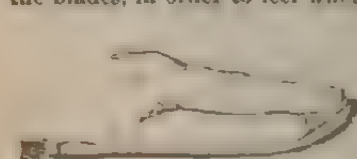

Fig. 861.—Position of Finger and Scoop in Extracting Stone.

If its long axis lie across the wound, it must be changed; and it must then be withdrawn by a kind of to-and-fro movement in the direction of the axis of the pelvis (Fig. 860). Should the stone unfortunately be broken, or should there be several small calculi, the fragments of the small calculi may generally be removed by means of the scoop (Fig. 861).

In the event of fracture occurring, it will be necessary to wash out the wound freely and repeatedly with tepid water, injected by means of a tube introduced through a tube introduced by the wound.

If the perineum be very deep, and the prostate enlarged, it may happen that the neck of the bladder is so far removed from the surface that the finger cannot reach its interior. In these circumstances the Surgeon must be careful in passing the forceps, that the instrument do not slip to the side of the incision, the guide and support of the index finger being lost. In two or three cases of this kind that have occurred to me, in which, owing to the anatomical reasons above stated, I could not reach the bladder with the tip of my forefinger, I have directed the assistant who held the staff not to draw it, but, using it as a guide, have slipped the forceps along its groove and over its concavity, in this way making it enter the bladder with the greatest ease and certainty. This manœuvre I would strongly recommend in the cases alluded to.

It is of the first importance to extract the stone whole without breaking it, or even chipping fragments from it with the blades of the forceps. No effort consistent with the safety of the patient should be spared in obtaining this desirable result; not for the sake of any vain display of manual skill, but from a regard to the well-being of the patient. If the stone be too

broken by the attempt at extraction, what happens? The Surgeon is obliged to introduce repeatedly the forceps and the scoop in his attempts to clear the bladder; the mucous membrane of which, falling upon and enveloping the fragments, is liable to be pricked, bruised, and excoriated in the endeavor to seize them. The bladder requires to be frequently washed out with copious injections of tepid water, and the operation thus becomes greatly and dangerously prolonged. Even after much time and labor have been spent in these efforts, fragments are apt to be left behind which may occasion great present irritation, and, if retained, will form the nuclei of future calculi.

In children, and indeed in most cases in which the perineum is not very deep, so that after the introduction of the finger the stone can be felt and hooked forwards, the scoop is a most convenient instrument for its extraction; and in these cases I have often employed it in preference to the forceps.

After the calculus has been removed, it must be examined for facets, and the finger must be passed into the bladder and its cavity explored while firm pressure is made above the pubes. In this way the whole interior of the bladder is easily explored except in those cases in which the perineum is unusually deep. The interior of the bladder may be further explored by means of a *searcher*; and if other stones be found, they must be dealt with in the same way as the first.

If the urine has been foul before the operation, it is well to sponge the surface of the wound over with chloride of zinc (gr. 40 to \mathfrak{z} j.), and to insert a little ichthorm.

The *gum-elastic tube* may then be introduced, and secured with tapes to a band round the patient's abdomen. This tube must be kept free from coagula by the introduction into it, from time to time, of the feather of a pen. The tube is of great service in preventing the wound from becoming blocked up by coagula, by which the free escape of the urine would be interfered with. By means of this tube a ready outlet is given to the urine, the chance of infiltration is lessened, and if there be hemorrhage the wound may readily be plugged round it.

Lithotome for Lateral Lithotomy.—Surgeons have, at various times, expended much ingenuity on the construction of instruments calculated to facilitate the operation of lithotomy, and to enable the operator to make his incision with absolute precision. Most Surgeons prefer to rely on their own skill to accomplish this, and mechanical contrivances have very generally and perhaps somewhat unjustly been discarded. Of all the instruments of the kind referred to, that which is the invention of N. R. Smith, of Baltimore, is the most ingenious and practically useful.

The instrument consists of a staff with appliances, and a peculiarly shaped bent cutting-georget. It was first described and figured by Smith in 1831. It has undergone many modifications at the hands of its inventor, and is now given to the profession with all its improvements, as seen in Figs. 862 and 863.

The staff consists of three parts. 1. A rectangular tubular staff, with a wide slit making a quarter turn, so as to fit it for lateral lithotomy. 2. Attached to the staff by a hinge close under the handle, is an "arm-piece," or "conductor." This ends in a knife-blade, set at right angles to the shaft and deeply grooved at its under part. 3. An "indicator" consists of a slender rod traversing the handle of the staff and terminating in a cup sliding in the tubular staff.

The mode of action of the instrument is as follows: The conductor being drawn back on its hinge, the rectangular staff is passed in the usual way into the bladder, the angle being brought just in front of the prostate and

resting on the membranous part of the urethra. When the Surgeon is satisfied himself that the staff is in proper position, he draws down the "conductor," and, pressing upon it, pushes its terminal knife through the skin of the perineum until it enters the slit in the staff. The groove in the "conductor" outside the perineum is now continuous with that in the staff which is in the urethra. The "indicator" is now drawn up so that its cup is immediately under the groove of the "conductor." The superficial incision having been made in the usual way, the urethra is opened on the groove in the "conductor," the beak of the knife is then engaged in the cup of the "indicator," and as the Surgeon advances the rod of the indicator deeper but ceases to move if the blade departs from the proper route by slipping out of the groove in the staff and stops when the end of the groove is reached. The knife, or *gorget*

Fig. 862. — Smith's Lithotomy Staff and Conductor.

Fig. 863. (to right) — Smith's Gorget

Fig. 863, ends in a blunt beak, and its handle is set at an angle to the blade so as to enable the Surgeon to watch more accurately its attitude and position.

Professor Johnson, of Baltimore, has used this instrument many times, and speaks highly of its utility.

After-treatment of Lithotomy. — After the operation, the patient must be removed to a bed, which should be properly arranged by having a large square of white cloth put across it. On this a bed sheet should be laid, which must be placed upon the further side, so that as it becomes wetted by the escape of urine, it may be drawn across from under the patient. This must be changed frequently, to keep him clean and dry. A full dose of tincture of opium in barley-water should then be given; a warm flannel laid over the abdomen; plenty of barley-water

water allowed for drink, and nothing but rice-milk or light pudding for food during the first three or four days. After this, some broth may be allowed, and the quality of the food gradually improved. Occasionally, however, it may be necessary to depart from this routine system of dieting the patient after lithotomy; and I have, with great advantage, allowed wine, and even brandy, a day or two after the operation.

At the end of thirty-six or forty-eight hours the tube may be removed from the sides of the incision by that time having become glazed over, and without danger of infiltration existing. The patient, who up to this time has been lying on his back, should then be directed to change his posture, first on one side and then to the other. The buttocks and hips should be well oiled and smeared with vaseline, so as to prevent the irritating effects of the constant drainage. The urine continues to flow entirely through the wound for the first four or five days. About this time it frequently suddenly ceases to flow, so, escaping by the urethra. This is owing to the prostate becoming turgid from inflammatory swelling, and thus blocking up the aperture in it. As this swelling goes down, in the course of a day or two, the urine again

escapes by the wound again, and continues to do so in gradually decreasing quantities until the aperture is finally closed, which happens usually at about the end of fourteen or eighteen days; though in patients who have suffered from phosphatic calculus it sometimes takes a longer period, owing to the broken state of the general health. Should the wound fall into a sloughy state, the patient must be put on a very generous diet, even a free allowance of stimulants; and the tincture of benzoin may be daily applied. When slow in healing, it may be stimulated with nitrate of silver applied to the bottom; and, should a fistulous aperture be left, that may be touched with the electric cautery. After the operation, appropriate constitutional treatment should be continued for some time, in order to prevent a recurrence of the disease.

Lateral Lithotomy in Boys under the age of puberty is, perhaps, the most successful of all the great operations in Surgery. It is performed much in the same way as in the male adult; there are, however, some points of modification or of difference in the operation when practised on young subjects. The following are worthy of note, and should be remembered by the Surgeon in proceeding to operate on children.

1. The urethra in boys will commonly be found larger than would, perhaps, at first be expected from their age, readily admitting a No. 8 or 9 staff.
2. The perineum is usually proportionately more vascular in boys, in consequence of the straining produced by the irritation of the calculus.
3. There is often from the same cause a tendency to prolapsus of the rectum.
4. As the prostate is a rudimentary organ in the boy, the deep incision necessarily passes beyond its limits into the neck of the bladder.
5. In boys the tissues are more yielding, and more readily lacerable under the finger.
6. The most important point, however, is, that in the boy the bladder lies high, being rather in the abdomen than in the pelvis; hence, it is of importance to raise the point of the knife somewhat more than in the adult in making the deep incision, and to be careful that it do not slip into the tissues between the rectum and the bladder, which may happen unless this precaution be taken. I have known this to occur in several instances to Hospital Surgeons of skill and experience, the forceps being passed into this space under the supposition of its being the bladder; and in every case the patient died unrelieved. This accident is the more likely to happen, because in boys the parts are very yielding, and readily admit of being pushed before the knife or finger; and the finger may thus pass between the neck of the bladder and the pubes, or into the loose areolar tissue between the rectum and the bladder. The urethra being opened, urine escapes; and the Surgeon introduces his finger into a distinct cavity, which he believes to be the interior of the bladder, but which is not so, but the recto-vesical space. The liability to the occurrence of this distressing and fatal accident is materially lessened by injecting the bladder fully with tepid water, by which it is steadied and brought lower down. But in young boys lithotomy is from this cause always an anxious operation. It falls to the lot of but few Surgeons of experience in lithotomy to pass through an active professional life without meeting with difficulty and anxiety in operating on boys; and when such an untoward accident occurs, those will be the most charitable in their judgment of others, who have themselves had the most experience in the operation, and have had most frequently to encounter its intrinsic difficulties.

In order, then, to obviate the special dangers that have just been mentioned as likely to occur in the lateral lithotomy of boys, the following points should be attended to.

1. The bladder should be injected with two or three ounces of tepid water.

2. The knife should not be too narrow, as it has to make an opening of sufficient size to admit the forefinger of the operator in the child as in the adult. Its point, when it has entered the groove of the staff, should be kept very firmly pressed against its side, and carried somewhat upwards instead of straight forwards.

3. When the knife is laid aside and the Surgeon proceeds to pass his finger into the bladder, he will find the following manœuvre to facilitate this step of the operation very greatly, and lessen materially the danger of pushing the neck of the bladder before him. Placing the nail of the left index in the groove of the staff, he should not carry it along the convexity of this instrument, but, sliding it over to the concave side, gently but steadily work his way along this into the bladder. In doing so, he passes the finger between the roof of the urethra, which is a fixed part of the canal, and the staff, instead of between this and the floor of the urethra, which is mobile and yielding. There is the additional advantage that, by pressing down the staff as the finger goes above it, the urethra and neck of the bladder are somewhat dilated.

C. Heath recommends the following plan, which will be found most efficient: as soon as the knife is withdrawn he inserts a strong director with a handle like that of a staff set at a convenient angle. This is passed along the groove of the staff like the conductor in median lithotomy. The staff is then withdrawn and the finger passed above the director, which is at the same time pressed downwards.

4. So soon as the finger enters the bladder and the staff is withdrawn, the calculus should be fixed with its point against the floor of the bladder, where it may then be seized easily by the forceps.

DIFFICULTIES DURING LITHOTOMY.—The difficulties before and during the operation are threefold: 1, in Finding the Stone; 2, in Entering the Bladder; and, 3, in Seizing and Extracting the Calculus.

1. **Difficulty in Finding the Stone**, either by the staff or the sound, may exist before commencing the operation; and sometimes it is impossible to find the stone, although its presence may have been distinctly and incontestably ascertained a few days previously. In these circumstances, the Surgeon must on no account be tempted to proceed with the operation; but, after a carefully conducted exploration has failed to elicit the actual presence of the stone, all further proceedings must be deferred to another opportunity. The stone may escape detection in three ways. 1. It may have been passed by the urethra, between the first examination and the time fixed for the operation. A small calculus, especially if elongated and spindle shaped, may give a very distinct click against the sound, and yet be not too large to pass through the urethra. 2. The stone may have become encysted. 3. It may have become enveloped in folds of the mucous membrane of the collapsed bladder, and so may escape contact with the sound. All these events, except the presence of an encysted calculus, are more likely to happen in children than in the adult, and it is in them that, for want of attention to these precautions, the unfortunate accident of cutting into the bladder and finding no stone has most frequently occurred.

2. **Difficulty in Entering the Bladder.**—This is rarely experienced in adults. It may, however, arise in consequence of the Surgeon neglecting to keep the point of the knife well lodged in the groove of the staff, and thus letting it slip between the rectum and the bladder; the tissue of which, being broken up, leaves a kind of cavity that he mistakes for the interior of the

bladder. If the perineum be very deep and the prostate enlarged, he may also experience some difficulty in reaching the bladder; but he can scarcely fail to do so if he push the knife well on in the groove of the staff, and dilate the incision in the prostate with a blunt gorget, if his finger fail to reach the cavity beyond it.

Perhaps the most serious obstacle to entering the bladder consists in the presence of large tumors in the prostate. The combination of a deep perineum, an enlarged prostate, and a tumor, certainly constitutes a formidable series of obstacles. In these cases, the finger when slipped along the staff does not enter the bladder, but becomes involved in the smooth and irregular sinuosities that wind between the prostatic tumors (Fig. 864). In such cases it is well to practise the manœuvre that has already been described, viz., of using the staff as a guide into the bladder, slipping the forceps along the side and concavity of this instrument before it is withdrawn.

Fig. 864.—Tumor of Prostate, natural size, removed during Lithotomy from a man aged 64.

In boys, great and sometimes insuperable difficulty has been experienced in reaching the bladder. This difficulty arises in consequence of the small size of the urethra, the mobility of the bladder, and the ready lacerability of the tissues. If, after the groove in the staff has been exposed, care be not taken to insinuate, as it were, the nail into the opening in the urethra thus made, the membranous portion may be torn across; and the neck of the bladder, receding before the finger, may easily be pushed away from the surface, so that the Surgeon may fail in reaching the cavity of the organ. When the road is once lost in this way, there is the very greatest difficulty in finding it again. The course that should be pursued is, I think, as follows. If the staff have not been withdrawn, the Surgeon must again place the knife in its groove, and carefully push it on towards the neck of the bladder, notching that structure and passing the finger cautiously along the groove, and hooking down the parts with his nail until he reach the inside of the bladder. Should the staff have been withdrawn the Surgeon must endeavor to pass it again; if he succeed in this, he may act as just stated; but if he cannot succeed in introducing the staff fairly into the bladder, he must on *no account whatever* endeavor to open that viscous, or continue his attempts at the extraction of the calculus, but must at once abandon the operation until the parts have healed, when he can repeat it. The great danger in these cases arises from the Surgeon losing his presence of mind, and endeavoring to enter the bladder without a guide—a procedure which must be unsuccessful, and can end only in the destruction of the patient.

In adults, the difficulty is to get out the stone; in children, to get into the bladder.

3. **Difficulty in Seizing and Extracting the Stone** is far more frequently met with than in reaching the bladder. This may be owing to a variety of causes. It is likely to happen in all those cases in which, either from the depth at which the bladder lies from the surface, or from the peculiar position of the calculus, the stone cannot be felt with the finger after the incisions have been made into the neck of the bladder.

Difficulty from the Position of the Stone.—The calculus may be lodged in the lower fundus. This is especially apt to happen if the patient be old and fat,

and have a deep perineum, perhaps with enlarged prostate, behind which the stone may be lodged. This constitutes the greatest difficulty. Hence the best plan is to use a much-curved pair of forceps, and to tilt the bladder by introducing the finger into the rectum, so as to bring the stone within reach.

When the stone is situated in the upper fundus of the bladder above the pubes, it is altogether out of the axis of the incision, and in such a case can be extracted only with great difficulty. Aston Key recommends that in such cases the abdomen should be compressed, and the calculus thus pushed down into reach. This suggestion is a very useful one; and it was only by employing this manœuvre and using a very curved scoop, that I could remove a calculus lodged above the pubes, in the first patient whom I cut at the Hospital many years ago.

Difficulty in consequence of the Stone being Fixed to or retained in the Bladder.—A small calculus may be enveloped by the folds of the mucous membrane, and in this way elude the grasp of the forceps. In these circumstances there is nothing for the Surgeon to do, but patiently to try to disentangle and remove the calculus by means of the finger and scoop, if it can be so reached; or, by expanding the forceps in the bladder, to try to push aside the mucous membrane that surrounds the stone.

In consequence of *spasm of the bladder*, it is said to have occasionally happened that a calculus has been so firmly fixed as not to admit of the application of the forceps, the blades of which could not be introduced between the walls of the viscus without using an improper degree of force, and giving rise to the danger of rupturing the neck of the bladder. I am disposed to think that this "spasm of the bladder" is purely imaginary, and that the real difficulty has arisen from some other cause, as perhaps a contracted and rickety pelvis. But, whatever may be the real cause of a difficulty that has undoubtedly been encountered, I think it would be safer for the Surgeon to desist from the operation, and in the course of a few days or weeks endeavor to complete the extraction, and thus perform the operation "*a deux temps*" of Deschamps.

The stone may be so fixed between hypertrophied *semiculi* in the interior of the bladder, as to be detached with considerable difficulty. In such cases the scoop will be found to be the most useful instrument for its removal.

When the calculus is *encysted*, its extraction will probably be more difficult, or attended with most dangerous consequences. Hence, it is expedient not to operate in cases of encysted calculus that are known to be such. If, however, the Surgeon have been unfortunate enough to cut into a cyst containing an encysted calculus, he must be guided in the course he shall adopt by the condition in which he finds the stone. If the aperture leading into the cyst be very small, as in Fig. 836, the better plan will be to proceed no further with the operation, as it will be clearly impossible to remove the stone. If, on the other hand, the aperture into the cyst be large, he might be disposed to make an effort to extract the calculus. With this in view he might adopt the plan pursued by Sir B. Brodie in such a case, and endeavor to enlarge the orifice of the cyst by means of a probe-pointed bistoury cautiously applied, and then finish the extraction by means of a scoop. Such a proceeding, however, is in the highest degree hazardous, on account of the readiness with which the section may extend into the peritoneal cavity, as well as difficult in execution, from the depth at which the parts are lying.

I believe that a calculus may occasionally become encysted, or rather encapsuled, in another way,—by being covered in by a kind of false membrane whilst lying on the floor of the bladder. This condition I found in a boy who was operated for stone some years ago. After removing a calculus of

about the size of a pea, I felt, with the end of the finger, a hard irregular body, covered apparently by mucous membrane, lying at the inferior fundus of the bladder. On scraping through the membrane covering this with the point of my nail and a curved scoop, I exposed the calculus (Fig. 833), and removed it, with a cyst attached to it. On examining the structure of this cyst, which was of about the thickness of ordinary writing paper, of a reddish color, and resembling a piece of mucous membrane, it was found to be a false membrane, composed of organized fibro-cellular tissue. The patient made a good recovery, with the exception of a slight attack of secondary hemorrhage, which occurred on the eighth day after the operation.

Fibroid Tumors in the Prostate constitute sometimes rather a serious difficulty in lithotomy. They may do this in two ways: first, by elongating the prostatic part of the urethra to so great an extent as to carry the neck of the bladder far from the surface; and, secondly, by being in the way during extraction of the stone. A tumor of this kind, an inch or more in diameter, necessarily fills up to a very serious extent the space in the wound through which the stone has to pass; it jams up the orifice and prevents the free play of the forceps. These tumors, however, when caught between the blades or shanks of the forceps, soon shell out, and, rolling out of the wound, allow the easy exit of the calculus after them (Fig. 864).

Rickets of the Pelvic Bones may constitute a serious or even an insuperable obstacle to the extraction of a calculus. This condition may act in two ways. It may narrow the brim of the pelvis in its antero-posterior diameter, to so great an extent as to prevent the passage of the stone downwards after it has been seized by the forceps. This condition is more to be feared in children, in whom the bladder, being an abdominal organ and lying high, is altogether above the brim of the pelvis in these cases. Or there may be difficulty in the extraction of the stone through the inferior outlet, owing to the approximation of the rami on each side. The first cause of difficulty once occurred to me, in operating on a very rickety boy, four years and a half old. Of the second I have had no experience. The rickety condition of the pelvis may be suspected in cases in which the lower limbs are much distorted. Its existence may be ascertained by digital exploration of the rectum, and by external measurements. If it be found to exist to an extreme degree, it would probably be safer to perform the suprapubic operation.

In old men the outlet of the pelvis may be greatly narrowed as a consequence of senile osteomalacia. This is recognized by the approximation of the ischial tuberosities.

Difficulty depending upon the Shape and Size of the Stone.—If the stone be very round, it is usually more difficult to seize than when flat or elongated. Flat, disk-shaped calculi, however, occasionally fall into the fundus of the bladder behind the prostate, and then cannot be readily reached by the forceps, which pass over them. In these circumstances they are best extracted by the curved scoop. Very flat broad calculi, and those that are round, egg-shaped, or branched, are the most difficult to remove, even though their size be not very great. As a general rule, however, it may be stated that, the larger the calculus, the more difficult is its extraction. This arises not so much from the outlet of the pelvis being too narrow, as from the necessity of making the internal incisions through the prostate very limited. There will always be considerable difficulty in extracting calculi weighing six or eight ounces and upwards; though cases are recorded by Cheselden, Klein, and others, in which calculi from twelve to fifteen ounces in weight have been extracted by the lateral operation. Any calculus above one inch and a half in its shorter diameter will be hard to extract through an incision of the ordinary length (not exceeding eight lines) in the prostate, even

though this be considerably dilated by the pressure of the fingers: and I think it may be safely said, that a calculus two inches and upwards in diameter can scarcely be removed by the ordinary lateral operation with any degree of force which it is safe to employ. The practice adopted in such a case, more than a century ago, by Gooch, of Norwich, is probably the best that can be pursued. It consists in drawing the stone well down with the forceps, and then letting an assistant carefully divide the tissues that resist. In this way, by a process of traction, twisting, and division, the stone may be brought out with safety. In the facility with which the calculus is extracted, however, much will depend upon the make of the forceps. As Liston most truly observes, "There can be no more fatal error than to attempt the extraction of a large stone with short and shabby forceps." In these cases the open-bladed forceps (Fig. 844) will be found useful, the absence of metal in the most convex part of the blade lessening materially the bulk of the instrument when grasping a stone.

In the event of the calculus being too large for extraction by the ordinary lateral operation, what course should the Surgeon pursue? Three are open to him: 1. Division of the Right Side of the Prostate from the interior of the wound; 2. Crushing the Calculus in the Bladder, and then removing it; and, 3. The performance of the Recto-vesical Operation.

The Incision of the Right Side of the Prostate gives considerable additional space, and is sufficient for most ordinary purposes; very large calculi being fortunately seldom met with. This section may be made by introducing into the wound a probe-pointed scalpel (Fig. 842), guided by the index-finger, and very cautiously dividing the right side of the prostate downwards and outwards, in the same direction that the section of the left has been made. This procedure must be cautiously done. The parts, being put well on the stretch as the stone is drawn forwards, are carefully notched, and thus yield to the traction. In two cases I have seen Liston do this. In one the patient recovered, in the other he died of diffuse inflammation of the areolar tissue of the pelvis. I have practised it once on a patient at the Hospital, who made an excellent recovery.

The second plan, that of **Crushing the Calculus in the Bladder** through the wound in the perineum, would certainly be a hazardous procedure. The irritation that would necessarily be set up by the large lithotrite or crusher (Fig. 865) that has been invented for this purpose, by the presence of the fragments of stone, and by the necessary difficulty and delay of clearing them out of the viscus, would be a serious and possibly fatal complication of the operation. In the event of its being impossible to extract the calculus through the perineum, I think it would be safer to adopt the third course, and to perform the *recto-vesical operation*, which will presently be described. Should, however, the unusually large

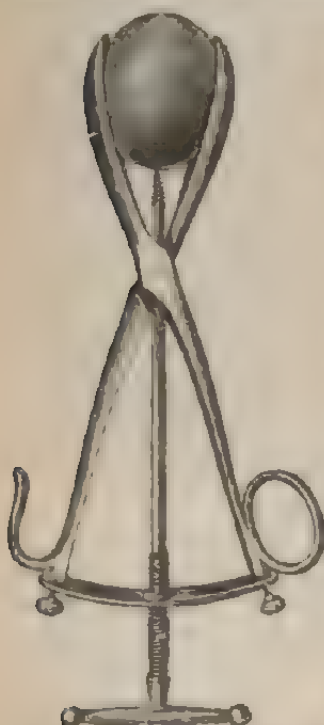

Fig. 865. Lithotomy Crusher and Drill for Large Calculi.

for this purpose, by the presence of the fragments of stone, and by the necessary difficulty and delay of clearing them out of the viscus, would be a serious and possibly fatal complication of the operation. In the event of its being impossible to extract the calculus through the perineum, I think it would be safer to adopt the third course, and to perform the *recto-vesical operation*, which will presently be described. Should, however, the unusually large

size of the stone have been recognized before the commencement of the operation, it might be thought more safe to practise at once the high than the lateral operation.

Difficulty from Fracture of the Calculus. The difficulty of extraction is greatly increased if the stone be broken. Fracture of a calculus is of two kinds. In the one case the stone is simply broken into several fragments, or splinters, so to speak, are detached from it. This accident may happen to hard as well as to soft calculi, and is generally owing to the Surgeon employing too much pressure on the blades of the forceps, fearing that the stone may escape from between them; or it may arise from the large size of the calculus requiring some force to be exercised in its extraction, when the Surgeon is very apt to compress the forceps as he draws the stone down. When this accident is found to have occurred, the Surgeon must remove with small forceps or the scoop the fragments that have been detached. He should then wash out the bladder by copious injections of tepid water, and very carefully examine its interior for any loose pieces. It is seldom that any worse consequence results from this occurrence, than delay in the completion of the operation.

The second mode of fracture consists in the crumbling down of the calculus so soon as it is seized by the forceps, into a soft mortary mass; the stone is not broken into large pieces, but, having naturally little cohesion, disintegrates into a mass of softish fragments, none of which probably exceed a cherry-stone in size, and which indeed resemble a wet sabulous aggregation, rather than distinct pieces of calculus. This crumbling down can occur only in phosphatic calculi. It is in no way the fault of the Surgeon, but arises from want of cohesion in the calculus, so that the blades of the forceps bite, as it were, through it. It is an unpleasant accident to occur, as it becomes extremely difficult, if not impossible, to clear away the whole of the soft mortary detritus from the interior of the bladder, to the lining membrane of which it tenaciously adheres, small masses lying under the folds into which the contracted organ is thrown. As much as possible should be removed by the scoop, and the remainder washed away, as far as practicable, by copious injections; with all care, however, some will be left, and may be discharged through the wound some days, or even two or three weeks, after the operation. When this happens, the bladder should be thoroughly washed out every day, or every second day, by warm water injections thrown in through a catheter passed down the urethra, and allowed to regurgitate through the wound; and this plan must be persevered in so long as any foreign body escapes. Should the wound have healed, the detritus must be treated as in lithiarity; and the bladder must be washed out every second or third day by a large eyed catheter, until all is removed.

ACCIDENTS DURING LITHOTOMY.—The principal accidents that may occur during the performance of the lateral operation of lithotomy are Hemorrhage; Cutting the Bulb; Missing the Membranous Portion of the Urethra; Wound of the Rectum; or Wound of the Posterior Part of the Bladder.

Hemorrhage during lithotomy may occur from three sources: 1. The Superficial Arteries of the Perineum; 2. The Deep Arteries of this region; and, 3. The Prostatic and other Veins. When excessive, from whatever source it proceeds, it is always a very serious complication; for, even if it do not prove fatal by the induction of syncope, etc., which I believe to be very rarely the case, it is apt to lead to a fatal termination indirectly at a later period, by predisposing to the occurrence of infective processes either local or general. I believe that patients who lose a large quantity of blood at the operation seldom recover.

1. Hemorrhage from the Division of the Superficial or the Transverse Artery

of the *Perineum* is seldom very dangerous, though occasionally, if these vessels be larger than usual, they may furnish a serious quantity of blood; in such circumstances their ligature would be required, and might be practised either before or after the extraction of the calculus. It is better, if possible, to wait until the completion of the operation, lest the ligature be pulled off during the extraction of the stone.

2. The *Division of the Deep Arteries* of the perineum, that of the bulb and the internal pudic, would be attended by far more serious, perhaps even by fatal consequences: as, from the depth at which the vessels are seated, it would be almost impossible to apply a ligature to them, unless the patient were very thin, and the perineum proportionately shallow. The facility of ligaturing any of these arteries, especially that of the bulb, when wounded, is greatly increased by enlarging the incision upwards. In the event of a ligature not being applicable, the Surgeon would have to trust to plugging the wound round the tube, as described further on, or to the pressure of an assistant's fingers continued for a considerable time, or to the application of forcipressure forceps. The pressure of the fingers of relays of assistants, kept up for a considerable length of time, although it seems to have been an efficient mode of treatment, is painful to the patient, and is difficult to carry out. The pressure must be kept up for many hours; thus South relates a case in which it was maintained for fourteen hours; and Brodie one in which, after twenty-four hours, it succeeded. The assistants should not be changed more frequently than necessary, each keeping up pressure for two or three hours, and removing his fingers as cautiously as possible. It is, doubtless, very rare for these arteries to be wounded when they follow their usual course; though such accidents have happened in the hands of some of the most skilful lithotomists, such as Home, Bell, Roux, and Desault. It was the opinion of Aston Key that the artery of the bulb was generally cut during lithotomy; but in this he was mistaken, so far as its trunk is concerned, though doubtless in many cases the bulb itself may be wounded, and the mesh of twigs, in which the vessel terminates, divided; this, however, would not yield an alarming hemorrhage. The trunk of the artery of the bulb would, however, be endangered by opening the urethra too high up, and lateralizing the knife too early, and if wounded bleeds very freely.

It may happen that on pulling the wound widely open the bleeding point may be seen, but at such a depth that it is impossible to apply a ligature. It may then be seized in torsion or forcipressure forceps and immediately twisted, or if this does not succeed the forceps may be left hanging on the vessel for a few hours. For this purpose the forcipressure forceps are the best, as they more efficiently crush and obliterate the vessel.

The internal pudic artery, bound down by a strong fascia, and under cover of the ramus of the ischium, runs but little risk unless the knife be lateralized too much, and the incision be carried too far outwards. In children in whom the ramus of the ischium is to a great extent cartilaginous, this accident could more easily happen. It is in some of the anomalous distributions of these vessels that the greatest danger would be occasioned. The artery of the bulb, the inferior hemorrhoidal, the dorsal artery of the penis, or the internal pudic, may take such an anomalous course that their division is inevitable; and, as the Surgeon has no possible means of knowing beforehand whether the distribution of the arteries is regular or not, and as his incisions are all planned on the supposition that they are, he is not to blame in the event of a vessel being accidentally divided, when it takes an abnormal direction, with which it is impossible to be acquainted until after the accident has occurred.

If the incision be commenced too high up, and especially if the upper part

of the first incision be made by pushing the knife in too deeply, the corpus spongiosum and its vessels may be wounded.

It may be stated as a general rule, that serious hemorrhage is usually best avoided by making the incisions low; and, indeed, I believe that the great secret of success in the lateral operation of lithotomy consists in making all the deep incisions as low as practicable; the knife entering the groove of the staff from below upwards, rather than from above downwards.

3. *Venous Hemorrhage* may occur from two sources—the superficial or the prostatic veins. It is very seldom that any trouble arises from superficial veins; but, in one case, I have seen very considerable loss of blood occur from a large vein, running transversely near the upper angle of the wound, lying almost immediately under the skin, which had been incompletely divided. From the prostatic plexus, hemorrhage is most likely to occur in old people, in whom the veins in this situation are often enlarged—almost hemorrhoidal.

Whether the venous bleeding take place from a superficial or from a deep source, it is very apt to find its way back into the bladder, to mix with the urine, and thus to escape through the tube rather than from the wound itself; or the blood may probably coagulate in the interior of the bladder, distending that organ and producing a feeling of dysuria. Should it proceed from a superficial source, it may be necessary, as was done in the case just alluded to, to pass a ligature under the vessel, and thus arrest it. If it occur from the prostatic veins, the better plan will be to plug the wound. This is done by passing long strips of lint, either dry or soaked in a solution of perchloride of iron or of alum, along the side of the tube, which must be left in the wound and kept pervious; or the lithotomy-tube may have a "petticoat" of thick muslin tied around it, into which the slips of lint are stuffed. The advantage of this arrangement is, that the whole apparatus may very easily be removed together at the end of forty-eight hours.

A far more efficient means of applying pressure is by means of the "Air Tampon," invented by Buckston Browne. It consists of an ordinary gum-elastic lithotomy-tube, surrounded by an India-rubber bag, which can be distended with air from a syringe by means of a tube fitted with a stop-cock. This is inserted into the wound, so that the India-rubber bag fills its whole length. On distending the bag, firm uniform pressure of any desired force can be applied. After from twelve to twenty-four hours, a little air can be let out so as to reduce the pressure, and this is repeated at intervals till the tube can be removed.

Hemorrhage from any of the above-named sources, but more especially from the deep arteries and veins, may take place into the bladder. When this occurs, the urine that escapes will be seen to be deeply mixed with blood; and coagula will form in the interior of the viscus, which becomes distended and rises above the pubes, with dulness on percussion in the hypogastric region. The patient will become pale, faint, and cold. In such circumstances, the coagula must be washed out of the bladder with cold water, the source of hemorrhage ascertained by an examination of the wound, the further flow of blood arrested by plugging or ligature, restoratives administered, the pelvis placed high, and the patient kept cool.

Wound of the Bulb is not of very uncommon occurrence in lithotomy; and, I believe, is of no consequence beyond furnishing a small additional quantity of blood. Indeed, the bulb is so situated, in many cases overlapping that membranous portion of the urethra, that this can scarcely be opened without wounding it.

Missing the Urethra altogether, and opening up the bladder through or even altogether beyond the prostate, is an accident that may happen if the

Surgeon miscalculate the depth of the perineum, and, keeping the incisions too low, thrust the knife too deeply. It is, I believe, an inevitably fatal accident, as in it the base of the bladder and the recto-vesical fascia are opened, and the patient is thus exposed to the occurrence of diffuse inflammation of, and infiltration into, the pelvic areolar tissue. I was present, many years ago, at the post-mortem examination of a fatal case of lithotomy, in which, perhaps, the most skilful operator of that day had opened the bladder beyond the prostate, leaving the urethra untouched; the patient died from the cause just stated.

Wound of the Rectum occurs more frequently than is generally supposed. It may happen either in consequence of the staff being too much depressed, of the edge of the knife turned too directly downwards, or of the rectum being distended and overlapping the sides of the prostate. I have also known the lower part of the rectum perforated by the Surgeon's finger, whilst depressing the gut so as to keep it out of the way of the knife. The *Treatment* of this accident will vary according to the size and situation of the aperture. If it be of but moderate extent and low down, just above the anus, it will probably close as the wound granulates and the urine resumes its passage through the urethra. If the incision be more extensive and higher up, the patient will incur the risk of the miserable infirmity of recto-vesical fistula being induced. In such circumstances, the proper treatment is to divide the sphincter ani from the opening downwards, and thus to lay the gut and wound into one cavity, which will probably fill by granulation, and thus close the urinary passages.

Wound of the Posterior Part of the Bladder is very rare; yet it has happened in consequence of the knife being thrust too deeply along the groove of the staff, more particularly in operations on children, and would be specially apt to happen in such cases if the bladder did not contain sufficient urine at the time. This is an additional reason for injecting the bladder before operating.

In *children*, the lateral operation of lithotomy presents certain special difficulties which have already been adverted to. These are: 1, the Surgeon missing the bladder and opening up the recto-vesical space (p. 929); 2, not opening the urethra and neck of the bladder sufficiently with the knife, but pushing these parts before the finger, and so tearing across the urethra, and thus necessarily being unable to complete the operation (p. 931); and, 3, running the knife too far along the groove of the staff into the bladder, and thus wounding the posterior part of that organ.

SOURCES OF DANGER AND CAUSES OF DEATH AFTER LITHOTOMY.—Lithotomy, even in healthy subjects, is always a dangerous operation; and, though the rate of mortality doubtless depends greatly upon the dexterity and skill of the operator, more is, I believe, due to the constitution and age of the patient, and especially to the state of his kidneys. Sir B. Brodie most justly says: "Success in lithotomy most undoubtedly depends in a great degree on the manual skill of the Surgeon, and on the mode in which the operation is performed; but it depends still more on the condition of the patient with respect to his general health, especially on the existence or non-existence of organic disease." That the mere cutting into the bladder is not a very dangerous proceeding, provided that viscera and the kidneys be healthy, is evident from the fact that, in those cases in which Surgeons have had to extract bullets, bits of catheter, etc., from this organ, bad consequences have rarely occurred, though the operations have often been tedious. In lithotomy the case is different; for here the bladder is not only usually in a state of chronic irritation, but the kidneys are frequently diseased, and these conditions influence the result of the operation more materially than any other

circumstances. Hence an operator may have a run of unsuccessful cases; or, by a fortunate concurrence of favorable cases, more particularly in children, it has occasionally happened that a Surgeon has cut 20 or 30 patients in succession without losing a single one; but several deaths then occurring, though the operation was performed in the same way and with the same care as before, his average has fallen to about the usual level. Green, at St. Thomas's, cut 40 patients in succession, and lost only one. Lynn cut 25 patients for stone without losing one, and he said that he thought he had at last discovered the secret of performing lithotomy with success; but, he added, the Almighty punished him for his presumption, for he lost the next 14 cases that he cut. Bransby Cooper, of Guy's, cut 30 patients in succession without a death, but then lost several, thus reducing the rate of mortality to the usual standard. Liston, during a period of six years, in which he operated 24 times, lost no patient from lithotomy at University College Hospital; but out of the whole 37 cases which he cut during the period of his connection with that institution, there were 5 deaths; reducing the average to 1 in 7.2. This success was, however, very great when it is taken into consideration that most of these cases occurred in adults, and that many of them were of a very serious character. I find on reference to the Hospital records, that only seven of the patients were under 10 years of age, whilst 14 were above 50; of these two were 80 years of age, of whom 1 died and the other recovered. I believe that Liston lost only one patient under 60 years of age, and that was a lad of 18, in whom he found it necessary to divide the right side of the prostate as well as the left, and who died of infiltration of urine. Thirty-eight patients successively operated on at the Norwich Hospital, recovered, but the average rate of mortality in that Institution, calculated from 871 cases, has been 1 in 7.50.

The accompanying Table gives much valuable information on the rate of mortality after lateral lithotomy at different ages. It may be taken as a fair example of successful English practice in this operation.

OF PATIENTS ON WHOM LATERAL LITHOTOMY WAS PERFORMED AT THE NORFOLK AND NORWICH HOSPITALS FROM JANUARY, 1772, TO DECEMBER, 1869. BY CHARLES WILLIAMS, F.R.C.S., ASSISTANT SURGEON TO THE HOSPITAL.

Age.	No. of Cases.	Percentage of the whole number.	Recoveries.	Percentage of Recoveries.	Deaths.	Percentage fatal.	Proportion fatal.	No. of Cases.	Percentage of the whole number.	Recoveries.	Percentage of Recoveries.	Deaths.	Percentage fatal.	Proportion fatal.

Cheselden lost only 1 in every 10; and, according to South, at St. Thomas's the mortality has not amounted to more than 1 in 9; but a good many of these patients were probably children. Sir B. Brodie states, that

of the 59 cases operated on in all the London Hospitals in the year 1854, 10 died; making the mortality as nearly as possible 1 in 6. But the more recent and extended statistics collected by Thompson, show that the average mortality in the London Hospitals is 1 in 71. According to Coulson the average mortality in England, deduced from 1743 cases of the lateral operation, is 1 in 6.93 cases; whilst in France it is 1 in 5.7; and for Europe generally 1 in 5.14. The more recent statistics of Sir H. Thompson show a more favorable result for lateral lithotomy in England. He finds that out of 1227 recorded cases there were 229 deaths, or nearly as possible 1 in 8. Klein states that, of 4486 cases of lateral lithotomy, in Moscow, there were 552 deaths; the mortality thus being nearly the same as in England.

The percentage of deaths after lithotomy in the adult will doubtless be found gradually to increase with the increasing use of lithotomy. This must not be referred to any defect in the method, or to want of skill in the performance of lithotomy, but to the fact that, instead of, as heretofore, being the general method of removing calculus, it has now become the exceptional one. Almost all cases of small and moderate sized calculi in men with otherwise healthy urinary organs are now subjected to lithotomy, whilst those cases in which the stone is too large, or the kidneys, bladder, prostate, or urethra too diseased, to admit of this mode of operating, are reserved for lithotomy; and as the mortality after this operation increases in the exact proportion to the size of the stone and the disease in the urinary organs, we must expect that, when its performance is confined to persons with large calculi, irritable bladders, enlarged prostates, diseased kidneys, or strictured urethrae, a higher percentage of deaths will follow it than was the case when all favorable cases, and not the unfavorable ones only, were subjected to it.

Age exercises a more marked influence on the result of lithotomy than any other condition. Lithotomy may be looked upon as one of the most successful operations in surgery at early periods of life, a hazardous one in middle age, and an extremely dangerous one in advanced age. At the Norwich Hospital, lithotomy has been found to be four times as fatal in men as in boys. Coulson finds, on analyzing 2972 cases of lithotomy, that the mortality at each successive decennial period is as follows. Below 10 years it is 1 in 13, and thence gradually augments from 10 to 80 years to 1 in 9, 1 in 6, 1 in 5, 1 in 4, 1 in 3.65, 1 in 3.23, and 1 in 2.71.

The reason of the small mortality after lithotomy in boys, as compared with adults, is most probably that the urinary organs, more especially the kidneys, are healthier than in the adult. Hence when boys die after lithotomy, they do not usually perish from the same causes that prove fatal in the adult, viz., kidney disease and diffuse pelvic inflammation and infiltration, but the fatal result is generally the consequence of some accident having occurred or violence been inflicted during the operation, such as by mistaking the recto-vesical space for the interior of the bladder, the tearing across of the urethra and non-extraction of the stone, wounding of the recto-vesical fold of peritoneum, or perforation of the back of the bladder by the point of the scalpel. It is by these accidents usually that death happens in boys that are cut for stone, and not from unavoidable circumstances that may follow the most skilfully performed operation.

The Shock of the Operation occasionally proves fatal, though probably much less frequently since the introduction of chloroform than was formerly the case. Yet, even now, patients occasionally die from this cause, induced either by a very much prolonged operation, or by the system being weakened, and having lost its resisting power in consequence of disease of the kidneys, perhaps of a latent character.

The **State of the Kidneys** influences the result of lithotomy in the adult more directly than any other condition. If these organs be sound, the patient will usually recover; hence in children, in whom the complication of renal disease rarely exists, lithotomy is very successful, even though the operation is proportionately far more severe in them than in adults. If, on the other hand, the kidneys be extensively diseased, the patient will commonly die, even though he have been operated upon with the utmost care and skill. The condition of the kidneys that is especially fatal has been fully described in Chapter LXVII.

A **Prolonged Operation**, even under anæsthetics, is dangerous; and, although it is certainly not well to operate against time, yet it is undoubtedly advantageous to finish the operation with as little delay as is consistent with the safety of the patient, even though he be unanæsthetized.

Hæmorrhage does not so often prove fatal, either shortly after the operation, or at a later period, as might be expected from the great vascularity of the parts incised. Secondary hæmorrhage, of a dangerous or even fatal character, may, however, come on six, eight, or ten days after the operation. I have known it as late as the fourteenth day. It must be borne in mind that, when hæmorrhage takes place after the operation, the blood may find its way into the bladder rather than escape externally, distending the viscus with æmula, but not giving any external evidence of the mischief that has occurred. Secondary hæmorrhage will usually cease on plugging the wound with sponge or lint soaked in alum solution. Should it prove serious, however, the actual cautery may be advantageously employed. In a case that occurred to me, the bleeding on the ninth day was stopped by wiping out the wound with the actual cautery, a practice which, I have been informed by A. Dalrymple, was occasionally successfully practised by that excellent lithotomist, his father.

Cystitis is, in my experience, a rare sequence of lithotomy. I have, however, seen it occur, attended by the secretion of large quantities of viscid,ropy mucus from the bladder, coming away two or three days after the operation, with tenderness in the suprapubic region. It may exist before the operation, or may be produced by long continued or rough manipulations with the forceps in searching for the stone, or by the irritation of the tube. The symptoms are apt to simulate those of pelvic peritonitis. The *Treatment* consists of fomentations above the pubes, abundant diluents, and washing out the bladder with tepid water injected through the wound.

Diffuse Inflammation of the Areolar Tissue of the Pelvis, especially of the layers around the neck of the bladder, between it and the rectum, which extend thence under the peritonæum, is the most frequent cause of death after lithotomy. This inflammation, which is always diffuse, followed by rapid sloughing of the textures that it invades, may arise from two causes: 1. From the urine being *infiltrated into the areolar tissue*, in consequence of the incision extending beyond the limits of the prostate, into the loose layers of tissue that lie behind the recto-vesical fascia and around the bladder; 2. In consequence of the *hemising and laceration* to which the neck of the bladder, the prostate, and the textures between it and the rectum, are subjected, in prolonged attempts to extract a large calculus through too small an incision.

1. The danger of *Cutting beyond the Lateral Ligament of the Bladder* in the adult has already been adverted to. In the extraction of calculi of ordinary size, there can be no necessity to extend the internal incision; but when the calculus is of considerable magnitude, the Surgeon, wishing to get as much space as possible, may inadvertently carry his knife beyond the prostate; or, if he make a cut into the right side of this gland, he may, perhaps, prolong

it a little too far, and thus open the loose areolar tissue or fascia which lies beyond it, and which is continuous with the subperitoneal plane of areolar tissue. By dilating the incision in the prostate downwards and outwards, either with the finger or with a blunt gorget, injury to this tissue is prevented.

If the incision extend beyond the prostate, the urine, as it escapes through the wound, soaks into the meshes of the loose areolar tissue over which it flows, and thus gives rise to infiltration, followed by rapidly extending inflammation and sloughing, which speedily involve the whole of the neighboring textures. This mischief generally occurs within the first forty-eight hours; indeed, I have never seen it come on after the third day. It is indicated by the patient being seized with rigors, followed by dry heat of skin, a quick pulse, which, after a time, may become intermittent, and a dry and brown tongue. At the same time, he will complain of some tenderness about the lower part of the abdomen and in the groins; the belly becomes tympanitic, the body covered with a profuse sweat; hiccups comes on, the pulse becomes more weak and fluttering, and death usually occurs about the fourth or fifth day after the operation. In some cases, there are more decided signs of peritoneal inflammation; but, as Brodie very truly remarks, this is not the primary disease, but is only induced secondarily by the inflammation and sloughing of the areolar tissue of the pelvis spreading to the contiguous serous membrane.

The *Treatment* of such cases must be conducted on the ordinary principles that guide us in the management of diffuse inflammation. It is only by administering ammonia, with such a quantity of wine or brandy as the state of the system may indicate, together with such nourishment as the patient can take, that life can be preserved. The disease is a depressing one, and requires a stimulating plan of treatment. Brodie has recommended that in these cases a free incision should be made through the sloughy tissues about the wound into the rectum, in accordance with the general principles that guide us in the management of similar affections elsewhere. In one case of that kind that occurred under his care, he saved the patient by passing a curved probe-pointed bistoury into the wound to its furthest extremity, to the left side of the neck of the bladder; he then pushed it through the tunics of the rectum, and, drawing it downwards, divided the lower part of the gut together with the sphincter; thus laying the wound and the rectum into one. The relief was immediate, and the patient recovered. This plan of treatment certainly seems rational, and worthy of trial in similar cases.

2. Diffuse inflammation of the areolar tissue around the neck of the bladder and prostate arising from *Bruising and Over-distention* of the parts during the extraction of a large calculus is, I believe, a more frequent occurrence than infiltration of urine, and fully as fatal. This sequence of lithotomy is especially apt to occur in those cases in which, in consequence of diseased kidneys, or the existence of other organic mischief, the patient is more than usually liable to the supervention of diffuse inflammation.

In the extraction of large calculi, considerable traction is required, and force must be exerted; hence undue bruising and laceration are very apt to be inflicted upon the parts that constitute the line of incision. It is in this way that the danger of lithotomy increases almost in exact proportion to the size of the calculus: for here the Surgeon is often placed between the horns of a dilemma. He must either cut beyond the limits of the prostate, and thus incur the risk of inducing urinary infiltration into, and diffuse inflammation of the pelvic fascia: or else, by limiting his incision to the gland, and thus, having an aperture of insufficient size, he may inflict severe injury by the bruising and laceration of parts during forcible and possibly pro-

longed efforts at extraction. It must, however, be borne in mind that, the larger the stone, the more probability is there of the existence of old-standing disease of the bladder or kidneys, and of an unfavorable result from this cause. Crosse has drawn up a table that shows very strikingly the influence of the weight or, in other words, of the size of a calculus on the results of lithotomy. He found that when the stone was one ounce and under in weight, the deaths were in the proportion of 1 in 11.25 cases. When it was from 1 to 2 ounces in weight, there was 1 death in 6.61 cases: when from 2 to 3 ounces, 1 death in 2.18 cases: when from 3 to 4 ounces, 1 death in 1.57 cases: when from 4 to 5 ounces, 1 death in 1.66 cases. This table, which has been constructed on the results of 703 cases, illustrates very clearly these facts, that the operation for the removal of a large calculus is far more dangerous than that for the extraction of a small one, and that the danger increases in the direct ratio of the size of the stone.

The symptoms of diffuse inflammation of the areolar tissue arising from this cause very closely resemble those from infiltration of urine, and the treatment must be conducted on precisely similar principles.

Peritonitis may occur after lithotomy, as a consequence of the extension of inflammation from the bladder or the pelvic areolar tissue to the serous membrane, from wound of the posterior part of the bladder, or from extension of inflammation from a sacculus of the bladder to its immediate investment of peritoneum. To one or other of these conditions, more especially inflammation of the pelvic fascia, it will always be found to be secondary.

Sloughing.—In feeble and cachectic persons, especially in those who are the subjects of phosphatic calculi, the wound will often assume a sloughy condition, and heal slowly, and its surface may become coated by phosphates. In such cases a liberal allowance of stimulants will be required, together with the local application of compound tincture of benzoin; and, in order to facilitate healing at a more remote period, a solution of nitrate of silver may be applied to the wound. The phosphates may be removed by injection of the dilute nitric acid lotion.

Pyæmia and Septicæmia are not uncommon causes of death after lithotomy. Acute septicæmia is usually the immediate cause of death in diffuse pelvic cellulitis, the patient perishing from general blood-poisoning rather than from the local condition. Pyæmia, when it occurs, usually sets in after the first week. The secondary abscesses are not uncommonly confined to the joints and subcutaneous areolar tissue, and the disease may assume a chronic form. The treatment presents nothing special.

OTHER METHODS OF PERFORMING LITHOTOMY.—Having finished the consideration of the ordinary lateral operation, we shall now proceed to that of other methods for extracting the stone by cutting procedures. These are the *Median*, the *Bilateral*, the *Medio lateral*, the *Recto-vesical*, and the *Suprapubic* operations; each of which has its advocates, to the exclusion of the others, and each of which undoubtedly possesses certain special advantages. In addition to these, there are various modifications of these different operations which the ingenuity of Surgeons has devised, but which have usually little to recommend them in the opinions of any except their originators.

MEDIAN LITHOTOMY.—The *median operation* of lithotomy is that procedure by which a stone is extracted through an incision in the raphe of the perineum extending into the urethra behind the bulb.

History.—The history of the median operation affords an illustration of the mutability of professional practice, and makes it appear as if there were a cycle of opinion in surgery, as in fashion, politics, and philosophy. The median operation was introduced three or four hundred years ago, and con-

tinued to be practised up to the middle of the last century, when its tediousness, its painful character, and the excessive mortality following it, caused it to fall into disuse as soon as the safer and simpler method of Cheselden was introduced. Of late years, however, it has been revived under a somewhat modified form; and it is this modern median operation, and its supposed advantages over the lateral, that we must here consider.

The old median operation—called also the "Marian," from Sanctus Marianus, who wrote on it though it did not originate with him, and the "operation of the apparatus major," from the number of instruments used in it—was performed in the following manner, according to John Bell. A grooved staff was introduced into the bladder, and the patient tied up in the usual way; the lithotomist then, kneeling or sitting before him, made an incision in the perineum, not exactly in the raphe, which was thought to be dangerous, but very slightly to the left side, and terminating just above the anus. The knife was then carried on to the membranous part of the urethra, which was opened on the groove of the staff; and, the knife being kept firmly pressed against the staff, a long probe was introduced into the bladder by its side. The knife and the staff were now withdrawn, nothing but the probe being left in the bladder, to serve as a guide into this cavity. Along this probe, two iron rods, called "conductors," were now passed, and with these the operator dilated the prostate and neck of the bladder, by separating the handles; at least, it was said that he dilated them, but, as John Bell pithily observes, "he dilated, or in plain language, tore open, the prostate gland." These conductors being held aside, "dilators" were introduced so as to enlarge the opening, the forceps was then pushed into the bladder, and the stone extracted as it best could be.

The principles of this operation were—a limited incision in the membranous part of the urethra above the anus; dilatation, and not incision, of the prostate and neck of the bladder; or, to use the words of Le Cat, "small incision; much dilatation."

Its results were, however, so unsuccessful, that it fell into entire disuse here, and almost so on the continent, merely appearing from time to time under various modifications at one or other of the continental schools. This condition of things prevailed until a new form of median operation was devised by Allarton, who with great perseverance and equal ability urged it upon the attention of Surgeons in this country, by whom it has now been extensively practised.

Operation.—This operation, for the introduction of which into modern surgery the greatest credit is due to Allarton, is performed as follows. A staff, grooved along its convexity, having been inserted into the bladder, the patient is tied up in the usual manner; the Surgeon then, sitting in front, introduces his left index finger into the rectum, and feels for the apex of the prostate, against which he keeps it lodged, in order to judge of the distance of the prostate from the surface, to act as a guide to the knife, and prevent the rectum from being wounded. A straight-backed bistoury is now entered half an inch above the anal aperture, and pushed straight forwards, to a depth of about an inch and a half in the mesial line, so as to enter, if possible, the groove of the staff at the apex of the prostate. A small incision upwards is then made in the groove of the staff, and, as the knife is withdrawn, the incision in the skin is also extended upwards; the knife is then laid aside, and a long ball-pointed probe is introduced into the bladder along the groove of the staff, which is then withdrawn. The probe is now the only guide to the bladder; and up to this point, therefore, there is but little, if any, difference between the modern median and the old Marian operations, except that the incision is exactly in, instead of a little to one side of, the

middle line. The forefinger is now introduced along the probe, and by working it forwards the prostate is dilated, and the finger enters the bladder, when, the probe being removed, the forceps is introduced, and the stone extracted. Thus, it will be seen that the only real point of difference between this and the old Marian operation, is that in the modern median the finger is used as the dilator, whilst in the Marian the prostate and neck of the bladder were forcibly expanded or torn open by the use of instruments; a difference, however, of no slight moment.

I have found it advantageous to modify this operation in one or two points. The first, which I think of some utility, is to use, instead of the ordinary

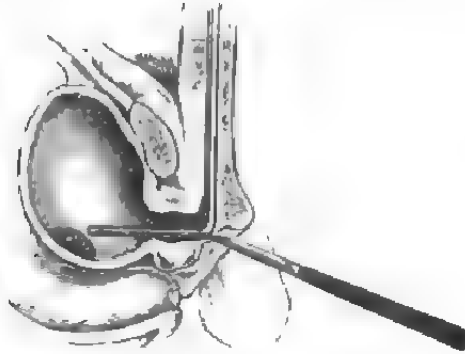

Fig. 866.—Median Operation with Rectangular Staff.

curved staff, a rectangular one grooved from about one inch above the elbow nearly to the point, resembling the staff introduced by Buchanan, of Glasgow (Fig. 866). Its use and advantages are that, when in the bladder, the angle rests against the apex of the prostate, and can be felt in the perineum, and the Surgeon can judge of the exact point where to enter the knife (directing it so as to open the groove just below the angle), which he cannot do with the curved staff; the incision upwards also is limited, and there is, besides, less danger of wounding the rectum, the urethra being drawn upwards away from it, and not pushed down against it, as with the ordinary staff. The knife should be straight-backed, having the back not more than two inches long; so that the Surgeon can tell to what depth he has entered it. I have found it advantageous in practice to carry a beaked director, shaped like a large hernia-director, along the groove, after the incision has been made in the urethra, so as to open up the canal and thus to clear the passage for the finger. And having opened the urethra, I think it better to dilate the prostate before withdrawing the staff; by pushing the finger slowly, with a rotatory movement, along its side, the bladder is entered with more ease and certainty; whereas, if only the probe be used, it may not be stiff enough, and the Surgeon is apt to push the bladder before him. It has been proposed to employ mechanical means of dilatation, instead of the finger, to open up the prostate and neck of the bladder; and I had some dilators for this purpose constructed by Coxeter on the principle of the two-bladed dilator of the female urethra. I tried them on the dead subject; but I have not ventured to use them on the living, lest, by the employment of screw-power, the same deep lacerations of the neck of the bladder should result that were so fatal in the old Marian operation. Indeed, I believe that their use would be fraught with danger from their liability to occasion rupture of the neck of the bladder; and, if persisted in, I cannot but fear that they will bring discredit on the operation, reducing it to the condition of an old Marian, and

repeating the dangers of that procedure. No safe dilatation can be effected except by the finger, with which no harm can be done, whilst it appears to me that the greatest possible mischief may be done with screw-dilators.

COMPARISON BETWEEN THE MEDIAN AND THE LATERAL OPERATIONS.—The two operations, the lateral and the median, cannot with propriety be compared as a whole, as we have as yet no sufficient statistics to enable us to determine whether the mortality after the median has been less than that which has followed the lateral. We may, however, compare the modern median operation with the lateral, and endeavor to determine in what respects the median is superior, in what inferior, to the lateral, and in what cases it might be employed instead of the latter. For in this, as in lithotomy, the Surgeon should not be too exclusive; it is his duty to learn and to practise different methods of attaining the same end, and to make use of one or the other according to the requirements of the actual case before him, and to endeavor to select what is good and to reject what is doubtful in every method brought before him. It would be in the highest degree unsurgical to crush only, or to cut only, every patient with stone coming under care; and I believe that there is a choice as to the cutting operation to be performed. In fact, there are no operations in Surgery that require to be so frequently modified, according to the necessities of the particular case, as those for stone; the age of the patient, the size and number of the calculi, and the condition of the urinary organs, all exercise very important modifying influences, and prevent the Surgeon from confining himself to one method exclusively.

In order to make a proper comparison between these two operations—the median and the lateral—we must take them *seriatim*. The difficulties and dangers of the lateral operation are: 1, the difficulty in some cases of entering the bladder; 2, hemorrhage; 3, the risk of wounding the bulb; 4, of wounding the rectum; 5, too extensive an incision in the prostate, and opening up the pelvic fascia; 6, the difficulty in extracting the stone.

1. General Ease and Simplicity of the Operation.—There is no doubt that the Surgeon will be more skilful in that operation which he has more often performed; but, so far as ease and simplicity are concerned, there is no great difference between them. In the lateral operation there is very seldom any difficulty in entering the bladder, though Surgeons have sometimes been foiled in this; but Surgeons of the greatest skill have also had great difficulty in entering the bladder in the median operation. The bladder tends to be pushed upwards and backwards before the finger, especially in boys, in whom the prostate is not developed; and, unless the neck of the bladder be well opened, there appears to be great danger of tearing across the membranous part of the urethra, and of pushing backwards the separated bladder. In boys, the parts are so very small and undeveloped, and the space to work in is so very narrow, that an ordinary finger can only with great difficulty be got through the neck of the bladder unless this have been freely incised. But, by doing this, we depart entirely from the guiding principle laid down by the advocates of the median operation, viz, dilatation and not incision. So far as facility of entering the bladder is concerned, the two operations are probably on a par in the adult; but, in the boy, the result of recent experience would show that the difficulties in this respect are far greater in the median than in the lateral; so great, in fact, that the operation should never be performed.

2. Hemorrhage.—In this respect, the median operation has decidedly the advantage. If the incision be made in the middle line, without wounding the bulb, although there may be tolerably free bleeding at the time, yet there is no vessel that can furnish dangerous consecutive hemorrhage; whilst in

the lateral operation there are the dangers of arterial and of profuse venous hemorrhage, the knife coming into close relation with the artery of the bulb and others of some size. If the object were, therefore, simply to save blood, the median is so far better than the lateral. But, after all, it must in fairness be said that the danger of excessive hemorrhage in the lateral operation is small. With care, it will rarely happen that the patient loses a dangerous amount of blood.

3. **Wound of the Bulb.**—This may occur in both, but is more difficult to avoid, and, indeed, is very likely to happen, in the median, as the bulb sometimes so overlaps the membranous part of the urethra, that it is difficult not to cut it; whilst in the lateral operation, by cutting low down, and entering the groove of the staff well back, and from below upwards, this may usually be avoided. It is true that division of the bulb in the mesial line seldom gives rise to much hemorrhage; but cases have occurred to my knowledge, though not in my practice, in which patients have died from this cause after perineal section, the blood regurgitating into the bladder, and filling that viscus.

4. **Wound of the Rectum.**—This gut is not in much danger in the lateral operation, unless it be distended. In the median, on the other hand, the rectum is in considerable danger. If this operation be performed on the dead body, it will be found that the back of the bistoury comes very—I may say uncomfortably—close to the finger in the rectum; and, if another finger be placed in the wound, they will come into very close apposition just anterior to the prostate. In the old Marian operation, the rectum used to be very frequently cut, gas and feces issuing from the wound.

5. **Treatment of the Prostate.** As to the difference in this respect—i. e., dilatation in the median, section in the lateral operation—I believe it to be more imaginary than real. I think that it is very nearly the same in both operations when properly performed. All are agreed that in the lateral operation but a limited incision should be made in the prostate and neck of the bladder, the opening being dilated with the finger, so as to avoid opening up the pelvic fascia. The difference between an incision that opens the capsule of the prostate, and dilating this structure by the finger, is very great. The great object in lateral lithotomy is not to open up the pelvic fascia with the knife; and it is difficult, if not impossible, to tear this with the finger. If we take an aponeurosis out of the body, it will be found to be very difficult to tear; but, if touched ever so lightly with the knife, it separates at once. So, in the median operation, the prostate may be dilated to a considerable extent without opening its capsule. I have used the word "dilate," but dilatation appears to me to be an erroneous term. I believe that the prostate is not simply dilated, but lacerated; that there is an actual laceration of the substance of the prostate, but not extending into or through its capsule. I have often examined the prostate in the dead subject, after it has been subjected to this process of "dilatation," and have always found its substance more or less torn. A laceration of the substance of the prostate, however, is of no consequence, and becomes dangerous only when it extends so far backwards as to tear the lateral ligament of the bladder, when it exposes the patient to the fatal accident of extravasation of urine and diffuse inflammation of the pelvic fascia. Now, in the lateral operation, in running the knife down the groove of the staff, the Surgeon may readily, unless care be taken, and very often, I believe, does actually and almost unavoidably go beyond the limits of the prostate, and thus exposes the patient to all these dangers. In the median this cannot be done, if the knife be not used after the urethra is opened, the prostate being dilated solely with the finger. So far as this point, then, is concerned, the median may be regarded as safer

than the lateral operation, it being *impossible* to open up the recto-vesical fascia with the finger in the median, whilst it *may* be opened by the knife in the lateral.

In fact, the neck of the bladder and the prostatic portion of the urethra are, in the median operation, placed very much in the position of the female urethra when that is dilated for the extraction of a calculus; being dilated to a great extent, and somewhat lacerated, but not torn through so as to admit urine into the subperitoneal cellular tissue of the pelvis; and in this I believe the great and essential superiority of the median over the lateral operation to consist.

6. **Manipulation of the Forceps and Extraction of the Stone.**—In the adult, the main difficulty of lithotomy does not lie in entering the bladder, but in the completion of the operation—the removal of the stone. And the difficulty and danger increase in proportion to the size of the calculus; the tissues between the neck of the bladder and the perineal integuments must either be widely cut or extensively torn and bruised to allow the passage of a large stone. No amount of simple dilatation of which these tissues are susceptible can make a passage through them that will allow the extraction of a stone $1\frac{1}{2}$ inch in diameter; such a stone must either be cut or torn out. Now, what space have we in the median operation for the introduction of the forceps and the extraction of a large stone? Here, I think, is the weak point of the median operation. In it the incision is made and all the manipulation is practised, towards the apex of the narrow triangle formed by the rami of the pubic bones. The base of this triangle is represented by a horizontal line corresponding to the level of the membranous portion of the urethra, and consequently does not occupy the widest part of the perineum; it is formed by the lower portion of the deep perineal fascia or triangular ligament, the space behind it being filled up by the rectum and its muscles, and the ischio-rectal fat. The ligament forms a barrier stretching across the perineum, which cannot be depressed, and requires to be divided laterally into the ischio-rectal fossa before a stone of any considerable magnitude can be removed. It was in consequence of the extensive bruising and laceration of these structures, and the difficulty experienced in bringing the stone through them that the old Marian operation fell into disuse.

In performing the median operation there are three points, or rather planes, of obstruction, between the surface and the interior of the bladder. The first is occasioned by the muscles of the perineum, and, perhaps, also by the under portion of the deep perineal fascia. In the lateral operation we cut across this plane, and lay open the ischio-rectal fossa, giving abundance of room for the manipulation of the forceps and the extraction of the stone, along the base of the triangle formed by the rami of the ischium and pubes. But in the median we have to extract towards the summit of this space, at the apex of a narrow triangle, having the muscular structures forming a tense bar along its base, and offering a material obstacle to the introduction of the forceps and the extraction of the stone.

The second obstacle lies in the prostate; but, as it is easily removable by dilatation, it cannot be considered a serious one.

The third, the deepest and most important, is situated at the neck of the bladder. We find here a narrow tense ring beyond the prostate; and this bar remains intact in spite of the dilatation and laceration to which the prostate has been subjected. On introducing the finger, we shall feel it grasped tightly by this ring. I have found, by experiments on the dead subject, that this inner ring of the neck of the bladder cannot be expanded to a size more than sufficient for the extraction of a calculus of one inch in diameter without laceration or incision; and its laceration or rupture is well

known to be one of the most dangerous and fatal accidents in lithotomy. It is in consequence of the obstacle offered by this, that the median operation is not available for the extraction of large calculi. A calculus over one and a half inch in diameter cannot be extracted by the median operation without the employment of great violence. But, though much force is usually required in order to extract a calculus of even moderate size through this tense ring at the neck of the bladder, it is an undeniable fact that serious consequences seldom follow the violence so used, and that a degree of force, which would be fatal in lateral lithotomy, may be employed without danger in the extraction of a calculus by the median operation. In this respect the extraction of a calculus by the median operation resembles the removal of one through the dilated urethra of the female; the great point in favor of the median over the lateral procedure, and the cause of its comparative safety, being that the lateral true ligament of the bladder is not incised, nor otherwise opened. But, it may be said, what is easier, when the finger is in the bladder, than to push a probe-pointed bistoury along it, and cut downwards and outwards through these structures into the ischio-rectal fossa, if the stone be large, and thus get plenty of space? Nothing could be easier or more simple; but what would be the consequence? We at once reduce the median to the conditions of the lateral operation. A free incision in the neck of the bladder and prostate increases the tendency to hemorrhage, opens up the fascia, and exposes the patient, in fact, to all the dangers of an ill-contrived lateral operation, destroying at once and altogether the principle of the median operation, viz., dilatation, and not incision; and, if we do not gain space by incision, but attempt to extract a moderately large stone by dilatation of the parts, we shall certainly not succeed; but our dilatation will end in a laceration, not only of the substance of the prostate, which is safe, but of the neck, and perhaps of the base of the bladder, which will be fatal. Urinary fistula was common after the old Marian operation. It remains to be seen whether it will be so after the modern median.

In conclusion, then, it appears to me, that the median operation, when performed in suitable cases, has the advantages over the lateral of being attended by less risk of arterial hemorrhage, and less danger of injury to the lateral ligament of the bladder; but that, in consequence of the very small size of the opening that can be made in the bladder by it, *provided these advantages are maintained*, it is applicable only to stones of at most a medium size, and that it cannot in all cases be substituted for lateral lithotomy, as the general operation for stone, where lithotomy is not admissible.

Indications for the Median Operation.—The median operation may, with propriety, be performed in the following classes of cases: 1. In cases where foreign bodies, such as pieces of bougie, of tobacco-pipe, etc., are lodged in the bladder, the median is preferable, the body being small, elongated, and easily extracted. 2. It may be employed to remove stones not exceeding one inch in their smallest diameter. But then, it may be said, calculi of this size can generally be safely subjected to lithotomy. That is true; but, in certain of these cases, lithotomy is not admissible; so that the median operation is indicated in cases of small calculi in which lithotomy cannot be practised in consequence of inflammation of the bladder, or some other complication. If a small calculus be lodged just behind the prostate, in a pouch which occasionally forms at a lower fundus of the bladder, we may come down on it at once by the median incision. 3. When there are numerous small calculi, lithotomy is not desirable, and then the median operation appears to be preferable. 4. In cases in which lithotomy has been performed, and the patient is unable to expel the fragments, we may perform the median operation, and readily extract the detritus by the scoop, as it lies behind the

prostate. 5. In the case, also, of calculi which are too large to be successfully subjected to lithotripsy, but which, if removed by the lateral operation, are attended by a frightful rate of mortality, it seems to me that the median operation might possibly be advantageously combined with lithotripsy. The stone having been broken up at one sitting, the fragments might at once be extracted through a limited incision in the mesial line of the perineum. 6. In cases in which the patient is so anæmic that the loss of an additional ounce or two of blood might turn the scale against him, median is preferable to lateral lithotomy. For, although it is by no means a bloodless operation, as is supposed by some, yet there is less hemorrhage during the performance, or rather, perhaps, less continuous oozing after its completion, than in the lateral, and there is certainly not the danger of the profuse bleeding that is sometimes seen in the latter operation. Where we have to do with a stone of large size, the median is not, in my opinion, safe; such an amount of traction must be used as will infallibly bruise and lacerate the neck and base of the bladder, and expose the patient to infiltration of urine and deep pelvic inflammation—to all the dangers, in fact, of the old Marian operation; dangers which were so great, that more than half the patients subjected to it perished, and which caused it to be abandoned for the lateral.

The median operation is not adapted to children. The space in them between the rectum and the pubes is too small, and, moreover, "dilatation" of the prostate would be impossible, as it is not large enough to allow the finger to pass through, and any attempt to do so without free incision would probably be attended by transverse laceration of the urethra. Moreover, the lateral operation in boys is so successful that there is no reason for adopting any other.

BILATERAL LITHOTOMY.—The bilateral operation introduced by Dupuytren is a modification of the old median. In it a curved transverse incision

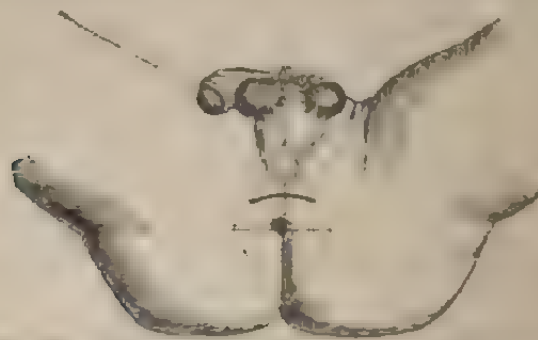

Fig. 867.—Line of incision in Bilateral Lithotomy (Dupuytren)

is made across the perineum half an inch above the anus, towards which its concavity looks, the horns of the incision extending to two-thirds of the distance between the anus and the tuber ischii on each side (Fig. 867). The dissection is carefully carried down to the central point of the perineum, and the membranous portion of the urethra is opened on a grooved median staff previously introduced; along this the double *lithotome cuche* (Fig. 868) is passed with its concavity turned upwards. The Surgeon, having well assured himself that the instrument is fairly in the bladder, turns it so that its concavity looks down towards the rectum; the spring in the handle is then pressed, and the blades expanded to a proper distance previously regulated, and both lateral lobes of the prostate divided to a corresponding extent

downwards and outwards in withdrawing the instrument (Fig. 869). The extraction of the stone is then effected in the usual way. This operation appears to me not to have received the attention that it deserves from Surgeons in this country. By being careful to introduce the lithotome into the membranous portion of the canal, the arteries of the bulb are not endangered, and indeed the transverse and superficial arteries of the perineum are also above and beyond the line of incision. The prostate is divided equally

Fig. 868.—Dupuytren's Lithotome Caché, Opened.

on both sides in its greatest diameter; if the expansion of the lithotome be carefully guarded, there is no danger of going beyond the limits of that organ, or of wounding the internal pudic arteries (Fig. 870); and the interior of the bladder is reached by the most direct and readiest passage. In withdrawing the lithotome, the handle must be well depressed, and great care must be taken that the instrument be kept securely in the mesial line, so that the section may not be made more feely in one side than the other.

Fig. 869.—Bilateral Section of Prostate.

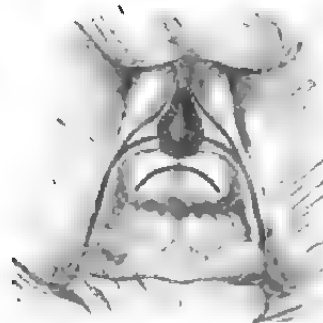

Fig. 870.—Line of Incision in the Prostate in Bilateral Lithotomy, showing its relation to the Bulb and the Internal Pudic Artery.

The operation has not been performed with sufficient frequency in this country for any reliable statistics as to the results; but Eve, of Nashville, has done it in 78 cases of all ages, with only 8 deaths.

MEDIO-BILATERAL OPERATION.—Civiale has recommended a combination of the median and the bilateral operations of lithotomy, by which the chief objections to both are got rid of. This operation is easy of execution, and has been performed for the extraction of large stones from the bladder; for those calculi, in fact, which cannot be removed by the ordinary median operation without too great an amount of force, and consequent bruising or laceration of the parts.

The operation may be performed in the following manner. The patient having been tied up, and a deeply grooved rectangular staff passed into the bladder, the urethra is opened at the membranous part with the edge of the knife turned upwards, as described in the median operation (p. 944); the

double lithotome is then slid along the staff into the bladder, its concavity turned downwards, the blades expanded to but a limited extent, and the prostate, or the bilateral gorget (Fig. 871), invented by J. Wood, of New York, may be pushed along the staff, and the soft structures between it and the surface incised as it is withdrawn. If the stone be not very large, the incision may be confined to one side only, and made with a probe-pointed bistoury. It will be found that sufficient space is obtained by the perpendicular incision of the skin; whilst the limited internal transverse cut removes that tension and resistance of the deeper structures, which in the

ordinary median operation interfere seriously with the manipulation of the forceps and the extraction of the stone; and, by the division of both sides of the prostate to a limited extent, abundance of space is obtained. Experience has shown, however, that the advantages are rather theoretical than practical, and that its performance in this country has been attended by unsatisfactory results; two of the principal dangers being wound of the rectum, and tearing through the sphincter.

Many other modifications of the median and the bilateral operations have been practised by varying the direction of the external incision, and by making the internal one on one or both sides of the prostate, or by notching this structure in various directions.

Fig. 871.—Wood's
Bilateral gorget.

RECTO-VESICAL LITHOTOMY.—This operation was suggested by Sanson in 1847, as a means of removing large stones and avoiding the dangers of hemorrhage, but the results have not been such as to justify its performance in preference to other methods. It is thus performed. A staff grooved on its convexity is passed into the bladder, the finger is then passed into the rectum, and the part of the staff lying in the membranous portion of the urethra felt for; a knife, with its edge directed forwards, is then passed along the finger into the groove of the staff and withdrawn, dividing the internal and external sphincters and the skin at the margin of the anus; it is then reintroduced with its edge directed downwards, and run along the groove of the staff, dividing the prostate and notching the neck of the bladder, and the stone is then extracted in the usual way.

HIGH OR SUPRAPUBIC OPERATION.—Although the median and lateral operations for lithotomy are, perhaps, the safest for the extraction of stones of small or moderate size, yet there can be no doubt that their results are extremely unfavorable when the calculus exceeds a certain magnitude; and in these circumstances it may be deemed expedient to perform "high operation" in preference to them. It is fortunate, however, that large calculi are comparatively rarely met with, and will doubtless become more rare, as the diagnosis of stone can now be made at a very early period of the existence of the calculus, and as the treatment is now generally preventive. Thus, of the 703 Norwich cases, that form the basis of Crosse's tables, and, indeed, of our chief information on these points, 529 were under 1 ounce in weight; 119 weighed from 1 to 2 ounces; 35 from 2 to 3; 11 from 3 to 4; 5 from 4 to 5; and only 4 were above this size. Hence, if we confine the high operation to those instances in which the calculus is above such a size as will readily admit of extraction through the perineum, we shall seldom have occasion to perform it; yet instances occasionally occur in which no other method of extracting the calculus presents itself. Thus, by this method, Uytterhoeven succeeded in extracting a calculus, of which he has kindly given me a cast, which

measured $16\frac{1}{2}$ inches in one circumference, and $12\frac{1}{2}$ in the other. It was perfectly moulded to the shape of the inside of the bladder, and clearly could not have been removed by any incisions through the perineum, as the outlet would have been insufficient for its extraction. The patient survived the operation eight days.

But not only may the high operation be required on account of the size of the calculus; it may be rendered necessary by other conditions, such as the existence of so much rigidity about the hips in consequence of rheumatic disease, as would prevent the proper exposure of the perineum; or by that region being the seat of disease which would interfere with any operation being practised through it; or the pelvic outlets may be so contracted by rickets as to prevent the possibility of the extraction of a stone through them by any of the perineal operations.

Operation.—The high operation consists in making an incision through the abdominal wall, above the pubes, and opening the anterior part of the bladder below the reflection of the peritoneum that passes upwards from its summit.

In performing this operation, it is necessary that means should be taken to raise up the summit of the bladder, so that it may project well above the pubes, and thus admit of being safely opened. To do this it must be distended with fluid as the first step in the operation. The fluid used should be some unirritating antiseptic solution; perhaps the best is a concentrated cold solution of boracic acid, warmed to the proper temperature before being used. Thymol, salicylic acid, and permanganate of potash have also been recommended. Whatever solution be used, the bladder should be thoroughly washed out with it two or three times if the urine be foul. If it be acid and healthy, this may be dispensed with. About twelve to sixteen ounces are then injected, and an India-rubber ring put round the penis to prevent the fluid from escaping. This part of the operation may be performed through a metal catheter, which can be securely plugged and left in to serve subsequently as a guide to the bladder. Many Surgeons, however, prefer withdrawing it. Too much force must not be used in injecting the bladder, as several cases have been recorded in which rupture has resulted from so doing. The bladder having been distended, Petersen, of Kiel, recommends that an India rubber bag of a pyriform shape, capable of holding about sixteen ounces, and stiff enough to retain its form, should be introduced into the rectum and distended with water through a tube fixed to its apex, and provided with a stopcock. In this way the bladder is steadied and pushed forwards, so that it can be felt clearly through the abdominal walls.

The incision is then made accurately in the middle line. It should be about two to three inches in length, and should extend slightly over the pubes at its lower end. The pyramidules being drawn on one side, and slightly notched if necessary, the linea alba is exposed, cautiously opened near the pubes, and divided upwards for about two inches. The fat above the pubes is then pushed upwards, and the distended bladder felt for with the finger. If an instrument have been retained, its handle must be depressed, so as to make its point project, pushing the bladder before it. The part of the bladder uncovered by peritoneum may be recognized in adults by its muscular fibres; in children, Dufour states that its bluish-gray color is characteristic. The bladder having been fully exposed, must now be secured by a tenaculum passed completely through its coats. Some Surgeons prefer two tenacula, between which the opening may be made. The object of thus securing the bladder is to prevent its being lost behind the pubes as soon as its contents are let out. The incision into it must be made with the edge of the knife directed towards the pubes. The finger is then introduced, followed by the forceps, and the stone withdrawn. In doing this no force must be used, lest

the rent should extend to the peritoneal surface. Should the original opening be too small, it must be enlarged towards the pubes with a probe-pointed bistoury till the calculus can be drawn out without violence.

The stone being removed, three courses are open to the Surgeon: he may close the bladder and the external wound with sutures; he may sew up the bladder and leave the external wound open; or he may leave both open and insert a large drainage-tube. Further experience is yet required before it can be definitely stated which of these is the best. It was hoped that by adopting the first method, and at the same time performing the operation with antiseptic precautions, that complete union by the first intention might be obtained, but at present the results of this mode of treatment have not been very satisfactory, and it is now generally agreed that if sutures are applied at all, it is better in all cases to leave the external wound open, as it is a great safeguard against infiltration of urine, and the delay of a few days while it heals by granulation is a matter of little consequence. If sutures are applied, they should be of catgut, and should include the muscular coat only, missing the mucous membrane. If the opening be very large, the lower part of it, when the bladder is collapsed, will be so far behind the pubes that great difficulty would be found in inserting stitches accurately. If the wound in the bladder be sewn up, a catheter must be passed every few hours to draw off the urine, or it may be tied in and the bladder drained by an India-rubber tube attached to the end of the instrument. Most Surgeons prefer leaving both the wound in the bladder and that in the external parts open. If this be done, a drainage-tube of good size should be passed to the fundus of the bladder, and retained for a week or ten days. A gum-elastic catheter may at the same time be tied into the urethra, but this is not necessary if the drainage from the wound be efficient. The best dressing is to smear the external parts with iodo-vaseline ointment, and to apply a large sponge squeezed as dry as possible out of a 1 in 40 solution of carbolic acid. This must be changed every hour.

In order to prevent the risk of urinary infiltration, the older Surgeons kept the bladder empty by making incisions through the perineum into the membranous portion of the urethra or neck of the bladder, thus seriously and needlessly complicating the operation. Vidal recommended that the bladder should be exposed, and the wound left open for a few days to granulate before making the incision for the removal of the stone, but this would fail in its object, as all the adhesions would be broken down during the extraction of the calculus.

Another cause of danger in the operation is wounding the peritoneum. This may occur when the bladder is so contracted and hypertrophied that it cannot be sufficiently distended to make it rise above the pubes. If the stone be very large, the wound may extend back during extraction of the stone, and thus implicate the peritoneum. If the peritoneum be accidentally wounded before the bladder is opened, the operation must be, for the time at least, abandoned.

Dalles finds that the suprapubic is far less favorable than the lateral in its results for calculi below 5j in weight. For those between 5j and 3j, there is little difference, whilst for calculi above 3j, it is far more favorable. He states that, of a gross total of 465 cases of the suprapubic operation, in both sexes there had been 135 deaths, or a mortality of 1 in 3.44; the mortality being about 1 in 3 in males, against 1 in 8.2 in females. This high rate of mortality may to a certain extent be accounted for by the fact that the patients subjected to suprapubic lithotomy were on an average one-third older, and the stones four and a half times heavier, than in the cases subjected to the lateral operation. Dalles gives a table of 43 cases operated on by

American Surgeons, of which 14 died, or as nearly as possible 1 in 3. This agrees with the statistics previously published by Humphry, who collected 104 cases in which this operation had been performed; of these 31 proved fatal, chiefly from peritonitis and urinary infiltration—the mortality amounted consequently to 1 in 34; and Souberbille, one of the greatest modern advocates of this operation, lost 1 patient in 3. The general result, therefore, is not very satisfactory; though, as in many instances the operation was performed in cases in which the lateral method was not applicable on account of the size of the stone, we cannot with justice compare the two procedures in regard to the mortality attending them.

CHAPTER LXIX.

URINARY CALCULUS (*continued*).

LITHOTRITY.

THE operation of **Lithotrity**, by which the stone is crushed in the bladder and the pulverized fragments are expelled or extracted through the urethra, is of modern, and, indeed, of very recent invention; for, notwithstanding that various rude and incomplete attempts may at different times have been made with this view, it was not until about the year 1818 or 1820 that the subject began to attract serious attention: and to the French Surgeons is undoubtedly due the great merit of having not only introduced but perfected this operation. About this time Civiale, followed by Amussat, Leroy, and others, began constructing instruments, which, though very imperfect, yet were sufficient to break down a calculus in the bladder. This was publicly done by Civiale in 1822. From this period the system made rapid progress; and the successive improvements made by the Surgeons whose names have just been mentioned, together with the ingenious mechanical adaptations introduced by Charrière and Weiss, enabled Surgeons to attack the stone with certainty and effect.

The importance of lithotrity was urged upon the profession by the writings, and its applicability demonstrated by the practice of Civiale, Amussat, and Heurteloup, in France, and of Brodie and Costello in this country. The practice thus commenced and established by these Surgeons has from time to time been improved by the ingenuity and skill of others, amongst whom Sir William Fergusson, William Coulson, and Sir Henry Thompson, were conspicuous. To Thompson especially, the profession is indebted for having laid down with precision those rules by which the operation may be performed with as much simplicity as safety. Up to the year 1878, the operation of lithotrity continually improved by the combined labors of these distinguished Surgeons, aided materially by the skill and ingenuity of the surgical mechanician, had been practised on the lines originally laid down by Civiale and Brodie. In that year, however, a new principle in the operation was introduced by Bigelow, of Boston, by which its practice was materially modified, if not completely revolutionized, old rules were discarded, new methods introduced, and instruments of novel and ingenious construction

devised. In treating of the subject of Lithotrity, therefore, the operation will be described, first as practised antecedently and up to 1878; and, secondly, as done since Bigelow's operation, to which he has given the somewhat quaint name of "Litholapaxy," has been generally adopted by Surgeons.

Lithotrity as practised before 1878.—The invention of lithotrity was surmounted by difficulties of all kinds—anatomical, pathological, and mechanical—and too much credit cannot be given to those Surgeons and Mechanics by whose unceasing labors, practical skill, and inventive genius, these grave difficulties have been successfully overcome. But now that they have been surmounted, the mere practice of lithotrity is extremely simple, and the operation is easy of execution.

For the safe and proper performance then of the operation, the Surgeon must not only be acquainted with the general principles on which it is undertaken, but he must be thoroughly conversant with the more minute details in the construction and the manipulation of the instruments employed, as well as with the state of every part of the urinary organs. It is impossible for any Surgeon who wishes to practise lithotrity successfully, to devote too much time and attention to points of detail, which may often at first appear trivial.

INSTRUMENTS.—The instruments required for lithotrity are the following:

An ordinary *sound* with a short beak is required to examine the condition of the bladder. The steel sound should be hollow, so that the bladder may, if necessary, be injected through it after or during sounding, without the

Fig. 872.—Lithometer Sound for Measuring Stone. It is hollow, so that the bladder can be emptied and injected through it.

necessity of changing the instrument (Fig. 872). This will be found of much service in the later stages of the operation for detecting small fragments.

A *brass syringe*, with rings, having a large piston rod so that it may work easily, and admitting of adaptation to the hollow sound, should be at hand.

The Surgeon should be provided also with *silver catheters* of three different kinds: one with large lateral eyes, another with a large eye in the convexity,

Fig. 873.—Weiss's Old Thumb-screw Lithotrite for Breaking the Stone.

and a third with a large eye in the concavity near the point (Figs. 886, 887, 888; all having an elastic gum bougie fitted to the interior, instead of a stylet, to clear out the fragments (Fig. 889). These also should fit to the syringe.

The instrument for breaking the stone is called a *lithotrite*. This instrument has undergone various modifications and improvements at the hands of Mechanics and Surgeons. To Weiss, in this country, and to Charriere,

in France, we are especially indebted for having brought it to its present state of perfection. In the earlier days of lithotrity the thumb-screw lithotrite was generally used. Sir W. Fergusson invented a rack and pinion instrument, which, however, found little favor with Surgeons. Civiale's very ingenious and beautiful instruments, having the double action of screw and hand pressure, were those to which many gave the preference until the invention of the cylindrical handle by Thompson. This instrument, having the same double action as Civiale's, is that which is now commonly used.

The lithotrite must be made of well-tempered steel; and should be tested by being made to crush a piece of sandstone grit, of about the size of a walnut. It should be of as full a size as the urethra will readily admit; it must have the male blade well serrated, and the female or under blade pierced at the beak by an oval aperture, through which the detritus of the crushed stone is forced, and thus any entanglement of it between the blades is prevented (Fig. 873).

The object of this open-bladed lithotrite is to break the larger and harder stones into pieces; but it is not intended to pulverize smaller calculi and fragments.

The lithotrite should be cut out of a bar of solid steel, and not, as is the case with some instruments, made of a plate of this metal, turned up at the edges; as such a one possesses too little strength to be used with safety on large and hard calculi. Those cut out of a bar of metal have an external blade, having a grooved shape, as in Fig. 875. In this, the male or internal branch, cut to fit accurately (Fig. 877), slides smoothly, the whole

Fig. 874.

Fig. 875.

Fig. 876.

Fig. 877.

Sections of Lithotrites.

instrument possessing an amount of strength and power that no calculus can resist. The bent-up instrument is composed of an outer tube of metal, as represented in its transverse section (Fig. 874), in which the internal blade fits less accurately (Fig. 876), and which possesses less strength, especially at the elbow, than the lithotrite cut out of solid steel. The scoop, however, may without danger be constructed of bent metal.

Civiale's lithotrite, such as is represented in Fig. 878, has a most ingeni-

Fig. 878. -Civiale's Lithotrite for Crushing Fragments.

ous double action, enabling the Surgeon to work it either by the pressure of the hand or by a screw. In this instrument, there is no fenestra in the female blade. It is of two kinds. In one, the male blade is much narrower than the female; in the other, it is nearly as broad. The first kind is useful in crushing through moderate-sized stones; and the second kind, with the broad male blade, is used in completely crushing and removing the

detritus of small calculi, and the large fragments into which a stone has been broken by the open-bladed lithotrite.

Thompson's lithotrite (Fig. 879) somewhat resembles Civiale's in its action but is more handy. It is made with a fenestrated female blade for levating the stone, or with a scoop for crushing fragments.

Fig. 879.—Thompson's Improved Lithotrite

PREPARATION OF THE PATIENT.—Before proceeding to the operation of lithotritry, it is necessary that the patient's constitution should be carefully attended to; the bowels should be freely opened, and the condition of the digestive organs regulated, and, more especially, all local irritations of the urinary organs should be subdued by ordinary medical treatment. This is even of much greater importance in lithotritry than in lithotomy. In lithotritry, we must always expect that any existing irritation or inflammation of the bladder will be increased by the necessary introduction of instruments, and by the presence of sharp fragments of calculus in the bladder, and the passage along the urethra; but in lithotomy all source of irritation is at once removed by the extraction of the stone. The condition of the urinary organs must be very carefully examined; and, if these be diseased, and probably be requisite to abandon the operation.

In a subsequent part of this chapter, when we come to the comparison of lithotomy and lithotritry, we shall examine the conditions which either indicate or negative the performance of the latter operation. At present we will suppose a case in which the Surgeon may have recourse to lithotritry with every prospect of readily and permanently freeing the patient of his calculus; one in which the calculus is of moderate size, single, and not too hard; the urinary organs healthy; and the patient an adult, but not aged. In performing the operation in such a case, but little preparation or treatment is required; though it is well to keep the patient quiet for a few days, and to regulate his bowels before anything is done. Should the patient be nervous about the use of instruments, or should the urethra be irritable, a large sound may be passed every second day, so as to accustom the patient and the parts to the use and contact of instruments.

USE OF ANESTHETICS.—Much difference of opinion existed formerly as to the advisability of employing anesthetics in lithotritry. It has been objected to their use that the sensations of the patient are a useful guide to the Surgeon in his manipulations, and that, if these be annihilated by anesthetics, injury may be done by the lithotrite nipping or otherwise irritating the mucous membrane. But this objection is not tenable. It is the sensations of the Surgeon, and not those of the patient, that constitute a valuable guide. Although in the majority of cases lithotritry, when properly performed, is almost a painless procedure, yet cases not unfrequently occur in which the patient can with difficulty support the necessary manipulations, and in which, either from nervousness or from irritability of the bladder, he expects his urine on the introduction of the lithotrite, or even does not expect his bladder to be duly distended by injection. In such cases anesthetics are of inestimable service; and many patients when anesthetized can be subjected to lithotritry, who could not suffer the operation under other circumstances.

As lithotritry was done by the old method of short sittings the

administration of anesthetics remained to some extent an open question; but in modern lithotripsy, as practised since 1878, by complete evacuation of the fragments at one prolonged sitting, anesthetics are indispensable, and are now invariably used.

OPERATION. The operation of lithotripsy may be divided into three stages: 1. The Introduction of the Instrument. 2. The Search for and Seizure of the Stone. 3. The Crushing of the Stone.

1. Introduction of the Lithotrite.—Lithotripsy may most conveniently be performed with the patient lying on his back, either upon a hard mattress or on a couch or table. The pelvis must be raised by a hard pillow, so as to allow the stone to roll up on the posterior surface of the bladder. The Surgeon, standing on the right side of the patient, carefully introduces the hollow sound, or catheter, and draws off the urine; he then slowly and very

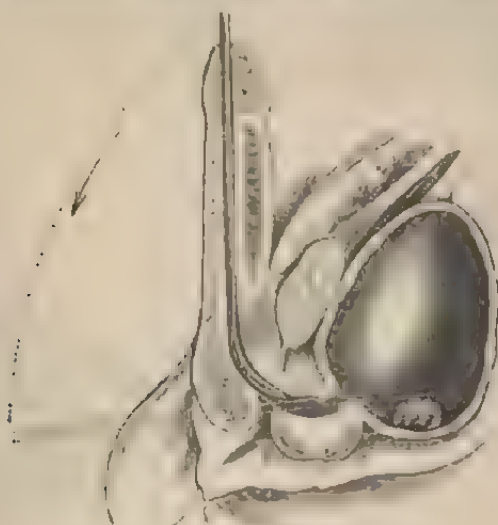

Fig. 880.—Introduction of the Lithotrite.

cautiously injects the bladder, by means of the brass syringe, with from four to six ounces of tepid water; or some antiseptic solution, such as boracic acid lotion, or Condy's fluid and water. Carbolic acid (1 in 50) has been used, but it is too irritating. The use of drawing off the urine is to make sure of the bladder holding the proper quantity of fluid when it is afterwards injected; and the object in injecting it, is to distend it to such an extent as to prevent the mucous membrane from being seized in the grasp of the lithotrite, or injured by the splintering of the stone. The instrument is then withdrawn, after the situation of the stone has been detected by it, and the lithotrite is introduced. Should the patient be able to hold enough urine, viz., from three to four ounces, to protect his bladder from the action of the lithotrite or the fragments, the injection may be dispensed with, and the lithotrite may at once be used. As this is straight, with a sharp elbow near the beak, some little skill is required in passing it. In doing this, the Surgeon must keep his eye upon the short curved beak of the instrument, the direction and position of which must be constantly observed, or, rather, judged of; and especial care must be taken, in carrying it under the pubes, not to injure the urethra by pushing the beak of the lithotrite forwards too suddenly, instead

of winding it, as it were, under the arch of that bone. The instrument should first be introduced nearly parallel to the abdomen, the point being held between the fore and middle fingers, and drawn over it. As the lithotrite passes down, it must be gradually raised to the perpendicular position, and as its curve passes under the pubes, the handle should be placed between the thighs (Fig. 880). The direction of the curve is the one to bear in mind; and the position of the handle must be varied in accordance with the course which this takes. The lithotrite should be well greased, and carbolized oil, so that the blades and screw may work smoothly. Iodo-ointment should not be used for this purpose, as it is apt to clog and entangle gritty bits of calculus.

2. Seizure of the Stone.—The next point is to seize the stone, which will generally be found in the situation where its presence was detected by the sounding of the bladder. If large, the stone will probably be caught at the neck of the bladder; if small, it is most frequently met with at the right side, or at the inferior fundus. Should it be situated in a depressed or deep region, it may most readily be seized by introducing a finger into the rectum,

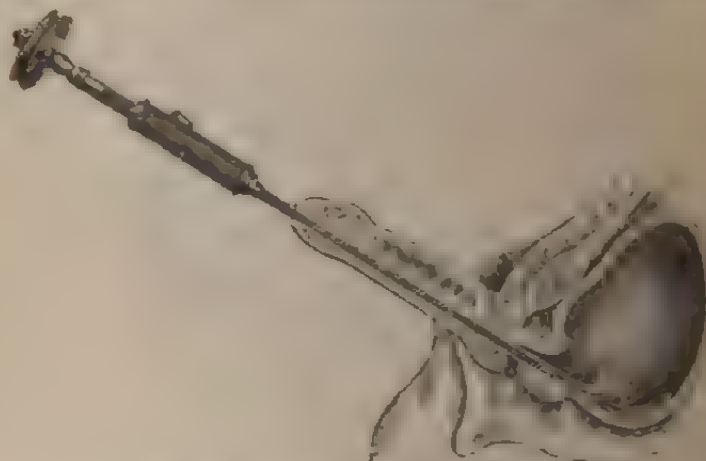

Fig. 881.—Brodie's Method of Seizing the Stone.

and raising up the lower part of the bladder. Brodie strongly advises that the lithotrite should never be used as a sound to ascertain the position of the stone; if this be done, the patient suffers pain, the bladder is irritated, the urine expelled, and the stone not readily seized. There is no objection, however, to doing so while the patient is under the influence of an anæsthetic. In seizing the calculus, a good deal of tact is required. The rule is to seize the stone. Brodie recommends that it should be done by pressing the female blade of the lithotrite against the inferior fundus of the bladder, pressing gently down with it so as to make a conical depression in the bladder wall, and then inclining the beak towards the stone, drawing back the female blade with the thumb (Fig. 881); with a slight shake or jerk, the stone then tries to get the calculus between the blades, at the same time the male branch is being pushed forwards to seize it. In this manoeuvre the female blade should be moved as little as possible, but the stone could be seized by pressing the thumb upon the half circle of steel fixed on the female branch. In this way, the stone may often be seized at the first attempt; in other cases it is not grasped until after several attempts have been made.

to fix it; the calculus, especially if round, slipping away from between the blades of the instrument, and being merely scraped by them. Civiale adopted another procedure (Fig. 882). In passing the lithotrite, he felt

Fig. 882.—Civiale's Method of Seizing the Stone behind the Prostate.

where the stone lay; he then very gently turned the beak of the instrument towards the opposite side of the bladder, opened the blades, and then, turning them over towards the stone, seized it between the open blades. In these manoeuvres, all rough handling must be most carefully avoided, and the instrument should be turned about as little as possible. It is far safer to desist from the operation, if there be any difficulty in seizing the stone, than to persevere in repeated and fruitless attempts, by which the bladder may be severely injured. Rather than do this, the patient should be allowed, if not under the influence of an anæsthetic, to get up and move about for a few minutes, when the position of the stone may be so far altered that it will admit of being seized.

3. Breaking the Stone.—When the stone has been seized, it is gently raised in the grasp of the lithotrite, so as to be placed about the middle of the bladder, and it is then crushed. This important step of the operation, like all the others, requires to be deliberately and carefully done (Fig. 883). If Civiale's or Thompson's improved lithotrite be used, the stone, if small, may often readily be crushed by the pressure of the hand alone without the action of the screw (Fig. 884). If the ordinary lithotrite be employed, the breaking should not be effected by suddenly and forcibly screwing up the instrument, but the screw should be gradually worked by a series of short and sharp turns, so as to constitute almost percussive movements (Fig. 885). In this way the calculus is generally made to crumble down, rather than to fly asunder; and, as it yields, the screw must be worked tightly home. The blades of the instrument may then be opened again, a fragment of the broken calculus seized and crushed in the same way as before; and thus the complete disintegration of the stone is gradually effected.

Before withdrawing the lithotrite, the Surgeon must be careful to see, by the scale on the handle, that the male blade is well home. If this be not the case, and the instrument be enlarged by any fragments or detritus entangled between the blades, laceration of the neck of the bladder or urethra might occur in attempting to withdraw it.

It was formerly considered of the greatest moment that too much time should not be consumed at one sitting. The rule enforced before 1878 was

that the shorter the sittings, the more likely was the case to do well. The first sitting was not to exceed four minutes, and the subsequent ones were to be as short as possible. In the repetition of the sittings, the Surgeon was guided by the effect produced on the stone and on the bladder. The stone was often entirely destroyed in one sitting, but most commonly from three to

Fig. 887. — Position of Lithotrite in Crushing the Stone.

Fig. 881. — Position of Hand in using Cistale Lithotrite.

Fig. 885. — Position of Hands in using Thumb-screw Lithotrite.

five or six were required; these were, if possible, conducted at intervals of three or four days, though this depended upon the amount of irritation induced by them.

At the first sitting, it was considered sufficient to break up the stone, the fragments being left to be dealt with subsequently. This sitting was by far the most important of all; it was not permitted to occupy more than a very few minutes. After the stone had been broken up, the patient was made to lie in bed on his back for about twenty-four hours, was kept warm, and plentifully supplied with diluents. He was not allowed to pass water in a usual, nor to stand up or lean forward, lest the fragments should fall against or become fixed in the neck of the bladder, where they might produce great irritation and distress. Much of the success of lithotomy formerly depended upon the gentleness with which the proceedings were conducted during the first sitting, and the care with which the patient was managed for a day or two subsequently.

After the stone had been broken, little detritus usually escaped during the

first twenty-four hours; but after this it was expelled, in some cases in considerable quantity, each time the urine was passed. In others, it did not escape so readily; and then the Surgeon was often called upon to use Civiale's instrument (Fig. 878), by which he could seize the smaller fragments, crush them, and, screwing the instrument home, extract the beak filled with detritus. In using this instrument, however, it was necessary not to get hold of too large a fragment; for in breaking this up, the beak was easily clogged with detritus in such a way that it could not close, and then there was considerable difficulty in withdrawing it. If this accident occurred, the scoop was emptied by passing its beak back into the bladder, tapping sharply upon the instrument, and moving the male branch to and fro. In crushing fragments behind the prostate, Civiale turned the concave part of the beak downwards, and seized the fragment in this position (Fig. 882). In doing this, however, great care must be taken not to nip the mucous membrane of the bladder.

Lithotripsy Catheters.

Fig. 886.—Eyes at Extremity.

Fig. 887.—Eye in Concavity.

Fig. 888.—Eye in Convexity.

Before 1878 much difference existed in the practice of Surgeons with respect to washing out the bladder, but the majority abstained from so doing, especially at the first sitting. The objection to this practice arose from the fear of setting up or aggravating cystitis, as it was not then fully recognized that the mechanical injury is a less powerful cause of cystitis than the accumulation of a quantity of foul and decomposing mucus. The instruments used for washing out the bladder before the invention of those to be presently described were chiefly catheters of the form represented in Figs. 886-888.

Clover, however, had invented more than twenty years ago an ingenious and simple instrument which may be considered the parent of all the "evacuators" now in use. It was intended not only to wash out mucus and detritus, but to remove the smaller fragments after each sitting. The instrument (Fig. 889) however, did not meet with the amount of favor it deserved.

Under the old plan the interval between the sittings varied according to the effect produced. If all went well, the second sitting usually took place about five or six days after the first, and they were then repeated at intervals of from three to four days, each sitting not exceeding five to eight minutes. When the Surgeon believed that the bladder had been emptied of all fragments and detritus, a *final exploration* was made. This last act of the operation both formerly and now is necessarily one of the greatest importance, as on the precision with which it is conducted depends in a great degree the future immunity of the patient from a recurrence of the disease; any fragment, however minute, that is left behind necessarily constituting the nucleus of a further calculus.

The exploration is best conducted by means of a small lithotrite, the bladder containing but a moderate quantity of urine. The whole of the interior, but especially the part behind the prostate, should be carefully explored; and if any fragment be found it must be crushed, and the detritus extracted. Civiale employed the "trilobe," allowing the urine slowly to

trickle out through the shaft of the instrument, at the time when he drew and closed the blades over the floor of the bladder, by pushing the tubular shank over them. As a measure of additional safety, the exploration should be repeated after the lapse of a week or two, and the bladder be well washed out after each procedure.

During the whole of the treatment, it is necessary to adopt means to allay irritation. With this view the patient should be kept in bed, or on a couch; a moderate diet only should be allowed, plenty of demulcent drinks given, such as barley-water, soda-water, or milk; and opiates or henbane, if necessary, should be administered.

Fig. 689.—Clover's Lithotrity Injection-apparatus. 1. Elastic Stylet for Lithotrity Catheter. 2, 3, 4, 5. Lithotrity Catheters with large eyes at end or in different sides, to be used with or without the Injection apparatus.

The amount of irritation of the bladder developed after lithotrity in several sittings varied greatly in different cases. In some, in which the stone, when unbroken, had excited much pain and irritability of the organ, the sufferings were at once lessened by its being broken up. It is difficult to account for this, except on the supposition that the fragments, being spread over a wider surface than the unbroken calculus, pressed less directly on any one part, and so produced less local irritation. More frequently, however, the crushed stone produced much greater irritation than the unbroken one. In this respect, however, much depended upon the care that was taken after the operation. If the patient was kept lying on his back, if diluents

were freely given, and opiates and belladonna rectal injections used, the irritation from this source was materially lessened. But if the patient was allowed to walk about, and to pass urine standing up or leaning forwards, some of the fragments might be driven into the neck of the bladder, or even the deeper part of the urethra, producing the most intense and painful strangury. When this unfortunate accident occurred, the patient passed urine every half-hour or oftener, squeezing out a few drops, writhing, and perhaps screaming with the agony he suffered, as the vesical neck contracted on the rugged fragments: his pulse became quick, his skin hot and perspiring, his tongue dry, the urine scanty, high-colored, and perhaps more irritating; and unless relief were speedily given, nervous exhaustion set in, and death ensued. In such unfavorable circumstances no time was to be lost. The patient had to be anesthetized, the bladder injected with weak belladonna-solution, the lithotripsy-scoop introduced, the fragments broken up as completely as possible, and detritus taken away or washed out. No means other than this or lithotomy, would save the patient.

Lithotripsy subsequently to 1878.—Lithotripsy, as practised by the best masters of the art, had gradually been improved in simplicity and in safety since the days of Civiale. It had been applied in various conditions of stone, of prostate, and of bladder, to which it had not previously been thought applicable; and thus many cases had been brought under the influence of this operation, for which lithotomy had heretofore been the only remedy.

The principles on which it was formerly conducted, and to which it owed its success, were those of extreme care and gentleness in the employment of the lithotrite, brevity in the sittings, and care that the bladder and urethra be not injured by the instruments, or irritated by the fragments of stone. The great principle that guided lithotritists was the avoidance of the prolonged use of instruments in the bladder. Prolonged instrumentation was looked upon as one of the chief dangers in the operation, as occasioning cystitis at the time, and leading to irritability and atony of the bladder subsequently. The Surgeon was especially enjoined not to allow a longer time than from two to four minutes for each sitting; to break up the stone in the first instance; to pulverize it at subsequent sittings; to allow the detritus to escape during the act of micturition; and not even to assist its removal by washing out the bladder, or at least to be very careful in doing this, using Clover's aspirator for the purpose. It is true that occasionally a small calculus was broken up, pulverized, and removed at one sitting; but in the vast majority of cases several sittings were required, often as many as five or six. These were repeated at intervals of from four to six days.

This state of things, the details of which have been described in the preceding pages, continued up to the year 1878, when a complete change came over the practice of lithotripsy. For in that year Bigelow, of Boston, U.S.A., published under the title of "*Litholapaxy*," or "*Rapid Lithotripsy with Evacuation*," a method of operating, by which calculi—of larger size than had previously been subjected to this operation—could be broken up and safely removed at one sitting, often of a very prolonged character.

The essential principle of Bigelow's operation consists in this, that danger does not arise so much from the prolonged use of instruments, as from the irritation produced by fragments left in the bladder. "It is probable," he says, "that injury from the use of instruments has been confounded with that resulting from the presence of fragments in the bladder." Bigelow not only entirely discarded, but acted in direct opposition to the principles laid down by all previous lithotritists. He used heavy and large instruments. He broke up the stone so thoroughly—comminuted, but did not pulverize it—by

repeated applications of the lithotrite, that all the fragments could be evacuated through a full-sized catheter tube; and he prolonged the sitting indefinitely until this was accomplished. In one of his earlier cases, the operation

Fig. 890.—Shut. Fig. 891.—Open.
Handles of Bigelow's Lithotrite, reduced size.

Fig. 892.—Shut.

Fig. 893.—Open.
Jaws of Bigelow's Lithotrite, full size.

lasted three hours and three-quarters, the object being to evacuate the whole of the fragments before the operation was discontinued. The patient is of

Fig. 894.—Removal of fragments of Stone by Bigelow's Extractor. Below, point of one of Bigelow's catheters.

necessity etherized during the whole period. Increased familiarity with, and improved skill in, this operation have enabled Surgeons materially to shorten the time occupied in its performance.

For the purposes of his operation, Bigelow has modified the older lithotrite and the evacuating catheters, and has invented aspirators of various kinds.

The peculiarities of his lithotrite are as follows. It is larger, heavier, and altogether more powerful than any previously in use. The handles are large and massive, and oval in form to fit the hand. The blades are somewhat longer, and the female blade has a long blunted point, curved towards the floor of the urethra, so as to protect the membranous part, against the roof of which the point of the instrument is directed as it passes through. These massive instruments are used only for breaking up a large stone. The fragments are crushed by smaller instruments, more like those already described. Before choosing the instrument, whether the lithotrite or the evacuating catheter, Bigelow carefully measures the urethra. The size of the catheter he generally uses is 20 French (18 English), but smaller sizes are often necessary. In Bigelow's method of operating, the stone is seized and broken up in the way already described. When from the size of the fragments it is evident that the stone is fairly broken into several pieces, the large fenestrated instrument is withdrawn, and a smaller instrument passed in its place. When the stone is thoroughly broken up, the evacuating catheter is passed. These catheters are of various forms and sizes, with a large eye situated in the concave side of the instrument, close to its extremity. In some cases Bigelow employs a straight instrument. The instrument should be of the largest size that the urethra will safely admit, and must be passed

Bigelow's Catheters, full size.

Fig. 895.—Bigelow's Straight Catheter.

Fig. 896.—Bigelow's Curved Catheter.

carefully with steady pressure, but no undue force. It is better to use a smaller size than to run the risk of injuring the urethra by attempting to force in a larger instrument than it can safely take. If the obstruction is at the orifice, this must be divided with a probe-pointed bistoury or a urethrotome. The catheter having been passed, and the bladder emptied through it, the "evacuator" is applied to it. Numerous forms of evacuator have been invented since 1878, but they are all founded on the same principle as Clover's apparatus—viz., a strong India rubber bottle, which can be emptied into the bladder by squeezing, and which is of sufficient strength to expand forcibly, and empty the bladder again, the moment the pressure of the hand is removed. Oris has lately invented an extremely compact and handy evacuator, of which a drawing is given in Fig. 897. Attached to the evacuator in situations varying in different instruments is a glass receiver, into which the fragments may fall by gravitation. It is essential that the India-

rubber bulb must be of sufficient strength. Otherwise the regurgitant stream will not be sufficiently forcible to withdraw any but the smallest fragments from the bladder. The fluid in the bottle should always contain some antiseptic; boracic acid, or permanganate of potash, are perhaps the best. The evacuator, previously filled, having been attached to the catheter, by alternately compressing and relaxing the rubber bulb of the instrument the bladder is filled and emptied.

Fig. 897.—Otis's Evacuator.

At each injection the fragments are thrown up. At each relaxation of the bulb, some are sucked out in the rush of water. These drop into the glass receiver, where they can be seen by the Surgeon, who thus judges of the progress he is making. This process is continued until all fragments are evacuated. Should some have been left behind, too large to pass through the evacuating catheter, the lithotrite must again be introduced, and these broken up sufficiently for evacuation, which must then be resumed and continued until the bladder is emptied of all calculus. The Surgeon knows when fragments are left behind too large to pass, by their falling against the eye of the catheter, blocking it, and thus preventing the return of water into the bulb of the evacuator, as shown by its failing to expand. This may arise also from the eye of the instrument having come in contact with the wall of the bladder, or from the catheter having been

accidentally withdrawn till its end lies in the prostatic urethra. Before concluding that the obstruction is due to a fragment, these two conditions must be excluded, by pushing the catheter a little further in and rotating it. A more certain sign of a fragment is a loud and distinct click every time the bulb is allowed to expand.

The removal of every fragment is the essence of the operation. No stone must be left behind. The operation must be concluded at one sitting, however prolonged. In this way stones of large size, or masses of multiple calculi, may be broken up and removed without reference to the state of the bladder or the prostate; for it is perfectly applicable in cases of subacute cystitis, of atony of the bladder, and enlarged prostate.

That this operation constitutes an immense and most important advance in lithotripsy is undoubted, and its universal adoption by lithotritists is the best evidence of its utility. It makes lithotripsy applicable to numerous cases which under the older and more slowly conducted system were not adapted to and could not be safely treated by it.

Sir Henry Thompson, who has largely and most successfully practised "lithotripsy at a single sitting," has made several important modifications in Bigelow's method of procedure. He neither uses the large and heavy lithotrite nor evacuating catheters of so large a size as those recommended by the American Surgeon. The lithotrite he uses is that with the cylindrical handle which he invented many years ago, and his catheters are not, as a rule, larger than Nos. 15 to 16, English scale. His evacuator also is of a somewhat different construction (Figs. 898, 899).

The longest time that Sir Henry Thompson has occupied in an operation at a single sitting has been 70 minutes. This was in the case of an unusually

hard uric acid calculus weighing 2½ ounces. In the performance of prolonged operation at a single sitting, he enjoins the very important caution that the patient's lower extremities should be encased in long woollen stockings, and that especial care be taken to prevent his getting chilled by exposure.

Fig. 898. Sir H. Thompson's Early Evacuator.

Fig. 899.—Sir H. Thompson's Improved Evacuator.

ACCIDENTS IN LITHOTRITY.—In considering the accidents in lithotomy, I put out of consideration those that may arise from the Surgeon acting carelessly, or with improper force, and thus occasioning laceration of the urethra, or injury to the coats of the bladder; so also accidents occurring from the bending or breaking of the instruments will scarcely happen, if these have been properly tested on a piece of sandstone grit before being employed in the bladder.

Impaction of Angular Fragments of Stone in the Urethra.—This most dangerous and painful accident was not uncommon in the old system of lithotomy. In modern lithotomy it can happen only if a large fragment has been accidentally left behind or if from any cause the operation has to be left incomplete. If there is any reason to believe that fragments are left in the bladder the patient must be kept in a recumbent position, as impaction most commonly arises from the patient moving about too much or straining to pass water in an upright position. The lodgment of a fragment not only occasions great local irritation, ending perhaps in cystitis or abscess, but may give rise to severe rigors and nervous prostration. The fragments are especially apt to lodge in the prostatic urethra, or about the bulb, and there give rise to a very great degree of irritation, and even of fatal mischief, producing great constitutional disturbance of an irritative and asthenic type. When the pieces are impacted low down in the urethra it is absolutely necessary to remove them from the canal as speedily as possible, lest the constitutional disturbance occasioned by them prove fatal to the patient. This may be done in various ways. Most frequently, they may be pushed back into the bladder, by passing a large catheter carefully down to them. The most convenient instrument for this purpose is one that is open ended, so that the fragment may be received in the aperture at the end of the instrument,

and so pushed on before it. Through such a catheter as this a stream of water may be injected and the fragment thus forced back. Sometimes these manoeuvres fail, it has been proposed to crush the fragments in the urethra with a small lithotrite (Fig. 890), but this plan is somewhat hazardous, and

Fig. 890.—Urethral Lithotrite

is very difficult to avoid pinching up the mucous membrane of the canal with the bits of stone. The safest practice seems to be, either to extract them through the urethral orifice, or to cut them out through the perineum. Extraction through the urethral orifice may be effected by the forceps (Fig. 901, 902), or by Civiale's instrument (Fig. 354, vol. i.). Should these mean-

Fig. 901.—Urethral Forceps

fail, or should the fragment be very deeply seated, as in the membranous portion of the urethra, and the local and constitutional irritation produced by it be so great as to threaten abscess or a fatal termination the better plan would be to make an incision directly down upon it, and to remove it through

Fig. 902.—Urethral Forceps, with Alligator Jaw. The smaller figure represents the jaws of the forceps open.

the perineum by a median operation of lithotomy. If such an operation thus be required, the surgeon might possibly feel disposed to extend the incision a little, and empty the bladder of any remaining detritus by means of a scoop.

The Chronic Enlargement of the Prostate of old persons was formerly one of the most serious complications of the operation of lithotomy, arising from the difficulty it caused in the introduction of instruments as it presented an obstacle to the expulsion of the fragments. But even before the introduction of the more perfect evacuator now in use enlarged prostates were not considered by any means an insuperable bar to lithotomy, as after the stone had been crushed, the bladder could be emptied by means of the syringe by Clover's apparatus, or by Sir P. Crampton's device, which consists in exhausting the air from a properly constructed bottle, fitted with a siphon.

and then attaching this to a catheter previously introduced, and opening the stopcock, when the pressure of the atmosphere drove the contents of the bladder, urine, and grit, into the exhausted bottle. With the present evacuators moderate enlargement of the prostate can scarcely be termed an inconvenience. As a general rule it is neither necessary nor desirable to turn the blades of the lithotrite downwards, lest the floor of the bladder be injured; but when the prostate is enlarged, the stone, if small, or the fragments after the first crushing, fall into a pouch behind the neck of the bladder, and it is then impossible to seize them except by this manœuvre. When the blades are reversed the handle of the lithotrite must be well depressed between the patient's thighs, the blades are then gently opened and closed over the base of the bladder. When the stone is seized the blades must be carefully turned into the ordinary position before it is crushed.

DANGERS IN LITHOTRITY.—The principal dangers in lithotripsy arise from the state of the bladder and kidneys. When death follows the operation, it results, in the great majority of cases, from septic suppuration of the kidney, preceded by cystitis. Atony of the bladder adds seriously to the dangers. Pyæmia is a rare complication.

Cystitis.—The occurrence of cystitis was formerly attributed solely to the mechanical irritation to which the bladder is subjected during the operation. The success which has attended lithotripsy at a single sitting has, however, demonstrated beyond a doubt that the bladder is much more tolerant of mechanical irritation than was at one time believed. The effect produced directly by the operation is, in most cases, limited to slight catarrhal inflammation, with an abundant secretion of mucus and some irritability of the bladder. In the operation by numerous sittings this was frequently aggravated by the presence of large and angular fragments. The thick mucus secreted under these circumstances is never perfectly expelled, but a certain amount remains adhering to the mucous membrane of the bladder after micturition. This speedily undergoes decomposition, and the most potent cause of cystitis is the contact of this foul mixture of mucus and urine within the interior of the bladder. When decomposition sets in, the alkaline products of the decomposing urine render the mucus thick andropy, and this still further adds to the difficulty of its complete expulsion. Under these circumstances the patient becomes poisoned by the absorption of the putrid contents of the inflamed bladder, the temperature rises, the tongue becomes brown, and if not relieved the condition will very likely terminate in death, the immediate cause of the fatal result being, in most cases, extension of the decomposition to the pelvis of the kidney and setting up suppurative nephritis. Such a condition necessarily offers an insuperable obstacle to any further crushing operation, supposing any stone to be still present, and the only course that gives a chance of life is to perform median lithotomy, by which not only are the fragments removed, but the bladder is efficiently drained of its decomposing contents. The prevention of this complication is best accomplished by the use of antiseptics. There is a very reason to believe that the putrefaction of the urine is due to the introduction of an organized ferment from without. This may be carried in by the instruments or by the water used in washing out the bladder. The instruments should therefore be oiled with carbolized oil and washed in carbolic lotion before being used, and the water used to wash out the bladder should contain some antiseptic. There is, however, another way in which decomposition may reach the bladder. As before stated the mechanical irritation of the operation sets up some catarrh of the bladder and of the urethra also. The thick mucus secreted in consequence of this adheres to the mucous membrane of the urethra so that this canal, instead of being washed clean

by the urine at each act of micturition, always contains a stagnant or partially stagnant layer of mucus down which decomposition may extend to the bladder. It is not sufficient therefore merely to carbolicize the instruments and to use antiseptic solutions in the evacuator; the end of the penis should be constantly covered with a strip of lint soaked in glycerine and carbolic acid. In spite of all precautions, however, decomposition will often take place, and then the bladder must be washed out twice a day with an antiseptic solution. The mechanical irritation caused by so doing is of little importance when compared with the dangers of a septic accumulation in the bladder.

Atony of the Bladder is one of the most dangerous conditions that can occur in lithotripsy. This state of things happens usually in old people, in whom the urinary organs may appear to be in a peculiarly quiet and favorable condition before the operation, the patient being able to hold his urine for six or eight hours, and to bear the injection of ten or twelve ounces of fluid. In these circumstances, the Surgeon should be upon his guard; for the danger of this condition is, that the bladder does not possess sufficient contractile power to expel its contents. These consequently accumulate in the lower fundus, and irritate the mucous membrane; and thus the foundation may be laid for fatal cystitis, which in these cases always assumes a septic type.

The atony of the bladder appears to arise partly from that natural want of expulsive power which is not unfrequent in old people, and partly from a kind of paralysis of the organ, induced by the contact of the instruments, especially after long sittings. Such patients usually die of suppurative inflammation of the kidney.

Atony of the bladder is not so serious a complication in the operation at a single sitting, although it necessitates the careful washing out of the bladder for some time afterwards to prevent the risk of a septic accumulation. In the operation by repeated sittings atony was much more serious, and it was essential that the Surgeon should rid the patient of the fragments he could not expel by washing out the bladder; but it was usually safer to get the patient in as good a condition as possible, and then cut him by the median operation.

This I once did in an interesting case under my care at the Hospital; the patient, an old man, had been lithotriized by a Surgeon out of doors a few weeks before admission, but no fragments had passed; on sounding him, I found a moderate-sized calculus, with what appeared to be a large mass of soft concretion, of the nature of which I was not aware until after its removal; the patient having concealed the fact of his having been lithotriized. On cutting him in the usual way, I removed a lithic acid calculus about as large as a pigeon's egg, and a handful of fragments of another calculus of the same composition, which had been crusted over and matted together by phosphatic deposit. The patient made a very good recovery.

Disease of the Kidneys is in Lithotripsy, as in all other operations on the urinary organs, the most common cause of danger and of death. The various forms of fatal kidney disease have been so fully described in Chapter LXVII. that I must refer the reader to it.

Constitutional Disturbance.—Very considerable constitutional disturbance occasionally follows lithotripsy. The patient is seized with severe and long continued rigors, followed by profuse sweating, lasting for many hours. These serious symptoms are most apt to come on after the first sitting; but the experience of Bigelow's method seems to show that they are not much more prone to occur after a moderately prolonged operation than after the short sittings formerly adopted. They may pass off quickly, apparently

being analogous to those nervous phenomena that are apt to follow the introduction of instruments in strictures, etc., or they may persist and assume the character already described as indicating septicæmia or renal inflammation. These serious consequences are especially apt to happen when there is previous disease of the kidneys. Indeed, there is no condition that is more directly antagonistic to the success of lithotripsy than interstitial nephritis. When this is present to any considerable extent, with or without much albumen in the urine, casts of tubes and blood, the increased irritation induced by the operation will almost to a certainty prove fatal. In other instances, again, the fatal result is more directly dependent on the irritation induced by the operation leading to the formation of abscess in the neighborhood of the prostate, or around the neck of the bladder; and in other instances, again, on the supervention of unhealthy suppuration in some of the sacculi that are occasionally met with in this organ.

The *Treatment* of this state of things should consist in the free administration of stimulants—brandy, ammonia, and ether—followed by a full dose of opium, and abundant warm diluents. If the bladder contains foul urine, this must be removed by washing out with antiseptic solutions. Especial care must be taken in those cases in which any stone remains not to repeat the sitting for at least a week or ten days after the rigors have passed off.

PERINEAL LITHOTRITY.—After a stone has been broken up but not completely removed at one sitting, it occasionally happens that the fragments become a source of so much irritation that the crushing operation has to be abandoned, and lithotomy is required in order to relieve the patient. Again, during the operation of lithotomy, the operator may meet with so large a stone, that he cannot extract it with safety, and he then breaks it up in order to remove it in a fragmentary manner, or the stone may be so soft that it crumbles under the pressure of the forceps. These circumstances, familiar to all lithotomists, have led various Surgeons to recommend, as a formal operation, the breaking up of calculi before extraction, in order that the removal of the broken stone might be effected through a smaller incision than would be required for its extraction if entire. Without going back to the records of ancient or even mediæval surgery for illustrations of this operation, it suffices to say that in modern times such a procedure has been advocated by many distinguished Surgeons, more especially by Matigaigne, under the term of "Lithotriptic Lithotomy."

Dolbeau has reduced to a formal operation, which he has described as "*Perineal Lithotripsy*," those procedures which were formerly undertaken without any very definite rules.

The operation itself is extremely simple. It consists of four stages: 1. The making of an incision in the median line into the membranous portion of the urethra on a grooved staff; 2. The slow and gradual dilatation of the neck of the bladder by means of a six-bladed "dilator;" 3. The introduction through the dilated neck of the bladder of the "lithoclast," a powerful forceps for seizing and breaking up the stone; and the extraction of the fragments and pulverized stone by means of small forceps and the scoop.

M. Dolbeau gives very minute directions for the proper performance of the various stages of the operation. They resolve themselves into the simple rules of a moderate external incision, very slow and methodical dilatation of the prostatic urethra and vesical neck, and complete "fragmentation" of the calculus.

From our knowledge of what happens when a stone is accidentally broken by the crush of the forceps during an ordinary lithotomy operation, we should not entertain very sanguine views of the results of the same procedure when purposely performed. The delay in extracting the broken fragments

is great—the bladder emptied of its urine contracts upon and is irritated by them, and the uncertainty and difficulty of clearing away all fragments by means of forceps, scoop, and injections, are very considerable. The accident is one that is justly dreaded and guarded against as far as possible by the practical lithotomist.

Results.—The results of perineal lithotomy do not appear hitherto to have been either very brilliant or even satisfactory. In thirty operations there were five deaths, which, considering that at least four of the patients were under twenty years of age, is fully as high as, if not higher, than what occurs in lateral lithotomy, and far exceeds that resulting from lithotripsy.

Fig. 903.—Perineal Lithotomy. Introduction of Lithotribe (Dolbeau).

Applicability.—When we compare perineal lithotomy with ordinary lithotomy, or lithotomy, whether lateral or median, it presents positive disadvantages in many cases, no advantage in others, and appears to be applicable only to a few exceptional instances.

In cases of small or medium-sized calculi, the results of ordinary lithotomy are infinitely more satisfactory; and no object can be gained by complicating this operation with an incision into the urethra. For ordinary calculi, too large for lithotomy, the lateral and supra-pubic operations offer fully as successful, if not more successful, results, than those which have been obtained by perineal lithotomy; and very few Surgeons would, when once they had seized the stone, trouble themselves to break it up before extracting it, or subject their patient to the delay in the operation that always occurs, even when the stone is accidentally broken after seizure—a delay occasioned by the prolonged manipulations which then become necessary, and which are not without their own special dangers.

The only cases, indeed, in which I can conceive that perineal lithotomy

would be adopted by a Surgeon, are those in which he has to do with a very large, soft, phosphatic calculus. As such a stone almost inevitably crumbles down when seized before extraction, it might possibly be as well to convert into a step of a regular operation that occurrence which would otherwise happen as an accident in ordinary lithotomy. Should it become necessary, after ordinary lithotripsy, to cut a patient for the speedy extraction of the fragments, Dilbeau's method of dilating the neck of the bladder, and his small forceps, might be found useful.

COMPARISON BETWEEN LITHOTOMY AND LITHOTRITY.

Lithotomy and lithotripsy differ so entirely from one another in principle and detail, that it is useless to attempt to establish a comparison between the different steps of these two operations. It is, however, a question of the very first importance and interest to ascertain by which operation a patient can most safely have a calculus removed from his bladder. In determining this point, it is necessary not only to make a comparison between the general results of cases that have been subjected to the two procedures, but more especially to ascertain those circumstances that influence the result of each operation in particular cases—to determine, in fact, in what cases lithotomy, and in what lithotripsy, holds out the best prospect to the patient. It is, I think, in the highest degree impractical to enter into a discussion as to which should be the general method of treatment in cases of stone. That Surgeon shows his practical skill the best, who chooses which operation is most appropriate to the particular case before him, and who knows best how to apply the operation that he selects most wisely. Both operations have been reduced to great simplicity and certainty; but, neither should be exclusively practiced. It is undoubtedly the duty of the Surgeon to make himself familiar with the practice of both, and to adopt that one which promises best in the particular instance with which he has to do. In all cases in which it is practicable, and in all cases, even, in which the chances of the two operations are evenly balanced, lithotripsy should, as a matter of humanity, be preferred to lithotomy. Probably about four-fifths of all cases of stone occurring in the adult are proper for lithotripsy, and the proportion would be much greater if the patients applied earlier for relief, or if, instead of being subjected to medical treatment, they were at once put under proper surgical care, and the stone detected.

STATISTICS.—The statistics cannot represent the true state of the question so far as a general comparison between the operations is concerned. For it must be borne in mind that those cases that are lithotripsyed have invariably been picked; whilst lithotomy has been performed on almost all patients indiscriminately as they have presented themselves. For lithotripsy to be successfully done, it is necessary that the stone be of moderate size, and that the urinary organs be in a healthy state and free from irritation; and this is the state in which most of the cases have been, in which crushing has been done. In lithotomy cases, on the other hand, the Surgeon has had to contend with all the difficulties of large or multiple calculi, diseased bladders, and bad constitutions. Hence, in comparing the statistics of the results of lithotripsy with those of lithotomy, we compare the statistics of the results of operations performed under the most favorable circumstances on a series of selected cases, with those of cases taken indiscriminately and often presenting most unfavorable conditions.

As Sir Henry Thompson has recently pointed out in his admirable course of lectures, delivered at the Royal College of Surgeons, the only method by which we can ascertain the effect of lithotripsy in reducing the mortality from

stone in the bladder, is to contrast the results obtained, when lithotomy was the sole operation practised, with those of the present day, when lithotripsy has become the rule and the cutting operation the exception. For this purpose he contrasts the statistics of three periods: first, when lithotomy only was performed; secondly, the transitional period from 1835 to between 1860 and 1870, when about an equal number of cases were submitted to each operation; and, lastly, the modern period, when lithotomy has been the exception. For the first period he selects the statistics of the Norwich Hospital from 1770 to 1830, as published by Crosse. During that time 704 patients of all ages were operated on for stone; of these, 35 were females, of whom 2 died; 243 were males under 20, of whom 27, or 8 per cent., died. The remaining 326 were adult males, and of these 64 died, or 20 per cent. Of the adult males, 75 were over 60, and of these 22, or 29.3 per cent., died. These correspond very closely to the larger statistics collected by Thompson, including 1827 lithotomies. Of these 1028 were on patients from 1 year of age to 16 inclusive; of these 68 died, or 6.6 per cent.; 528 between 17 and 58, with 86 deaths, or 16 per cent.; and 271 between 59 and 81, with 75 deaths, or 27.7 per cent.

For the second period Thompson gives the statistics of Keith, of Aberdeen, and Sir William Fergusson. Keith operated upon 304 cases of all ages; 4 were females, none of whom died; 23 were children; 19 were submitted to lithotomy, and 4 to lithotripsy, with 1 death. The remaining 277 were male adults; of these 161 were cut, with 38 deaths, or 24 per cent.; 116 were submitted to lithotripsy, with 7 deaths, or 6 per cent. The total death-rate amongst male adults was, therefore, 1 in 61, or 15 per cent. Fergusson's cases amounted to 271, including 52 children, all cut, with 2 deaths, or 4 per cent. The remaining 219 were male adults; of these 110 were cut, with 33 deaths, or 30 per cent.; and 109 crushed, with 12 deaths, or 11 per cent.; the combined death-rate for the 219 cases being 20 per cent.

For the third period Sir Henry Thompson gives his own results, although possibly the earlier cases might be more properly included in the intermediate period. The proportion of lithotomies in his practice has steadily diminished. Of his first 200 cases, 48 were cut; while since 1878, of 211 cases, he has cut only 15; and, of the last 125, only 4 were submitted to lithotomy. Sir Henry Thompson's cases, being derived chiefly from private practice, show but a small proportion of children, 15 in all, of whom 12 were cut, with 1 death, and 3 successfully crushed; 13 were females, of whom 10 were cut, with 1 death, and in 3 lithotripsy was performed. Excluding these, there remain 782 adult males. Of these 110 were cut, with 39 deaths, or 35 per cent.; 672 were treated by lithotripsy, with 43 deaths, or 6.5 per cent., or 1 in 151; making a total of 782 cases, with 82 deaths, 1 in 94, or 104 per cent. No less than 595 of these patients were over 50 years of age. The number of individuals upon whom these operations were performed was 716; 61 cases being operated on a second time, 9 a third, 3 four times, and 2 five times. Cases of small secondary phosphatic accumulations were not included as operations. During the last five years Sir Henry Thompson has uniformly adopted the operation by the single sitting, and the results have been most satisfactory. Of 121 cases treated by this method, only 4 died, 1 in 30, or 3.3 per cent.

The general result of these figures is to show that when lithotomy was the sole mode of treatment, about 1 in 5 of all adult males operated on died; that during the transition period the death-rate was about 1 in 6; and that since lithotripsy has been more extensively adopted, it has fallen to about 1 in 94, and that this has still further been reduced by the adoption of the operation at one sitting.

The mortality from lithotripsy in hospital practice has usually been higher than in private. Thus Malgaigne many years ago, before lithotripsy was brought to its present perfection, estimated the death-rate at 1 in 4 in the Parisian hospitals, while he calculated that of private cases to be 1 in 8. This difference between the results of this operation in hospital and in private practice can easily be accounted for by the difference in the constitutions of the patients, and by their applying for relief in private in a less advanced form of the disease than in hospital practice. We find that the same holds good with regard to the results of lithotomy. Thus, Coulson states that Dudley lost only 1 in 36 of the private patients that he cut; Mettauer, 1 in 36; Martineau, 1 in 42; and Mott, 1 in 50. These results, which are fully as favorable as the best statistics of lithotripsy, must, however, be regarded as exceptional; but they suffice to show the influence which the constitution of the patient, and a proper selection of cases, may exercise upon the results of the cutting operation.

Lithotripsy, as has already been stated, cannot be applied to all cases of stone; in most that are unsuited to this operation, lithotomy may be done with success. In some cases, however, no operation can be practised, in consequence of serious disease of the genitals, bladder, or kidneys, or of some visceral mischief that would necessarily interfere with the performance of any capital operation. The necessity of selecting cases of lithotripsy is as great as ever, although the field of the operation has been greatly enlarged by the modern improvements in its performance.

SELECTION OF OPERATION: LITHOTOMY OR LITHOTRIPSY.—The circumstances that must chiefly determine the Surgeon in the selection of the particular operation to be performed are: 1, the Age of the Patient; 2, the Size and Character of the Stone; and, 3, the Condition of the Urinary Organs.

1. Age.—The age of a patient is an important element. As a general rule, it may be stated that at the middle and advanced periods of life lithotripsy is most successful; while, in early ages lithotomy is the preferable operation. In children under the age of puberty, the genito-urinary organs are undeveloped; the urethra is narrow, and the bladder small. These conditions not only necessitate the employment of instruments specially constructed of reduced size, and render great care in their manipulation requisite, but the narrowness of the urethra is especially apt to render the expulsion of the fragments of the crushed stone extremely difficult, and to favor their impaction. If, in addition to this, we bear in mind the great sensitiveness of the bladder in young children, and their restlessness under the repeated instrumental interference which may be necessary, it can easily be understood that lithotripsy is neither an easy nor a safe operation in them unless the calculus be so small—not larger than a cherry-stone—that it can be crushed and brought away by a single introduction of the lithotrite. Lithotomy, on the other hand, is so successful an operation in children, that the Surgeon would gain nothing by substituting lithotripsy for it. Thus, of 35 children under 10, operated on by Cheselden, only 1 died; of 58 children cut for stone at St. Thomas's, but 1 case proved fatal; and the average mortality of lithotomy cases in children is not more than about 1 in 14. Guersant, at the Children's Hospital in Paris, performed lithotomy in children 40 times—35 of the cases being in boys; of these, 7 died, and 3 at least of the others required to be afterwards subjected to lithotomy. Of the deaths, 4 were caused by croup and scarlatina, and 3 were attributable to the operation. These results are anything but satisfactory when compared with those of lithotomy in children in this country, or even in Guersant's own practice; for, of 100 that he cut, 14 died. I think that the best and most experienced Surgeons are agreed

in this, that, although lithotripsy is practicable on boys, yet lithotomy, being much safer and far speedier, should be preferred to lithotripsy in all patients under puberty.

At very advanced periods of life, the irritable state of the urinary organs, the tendency to the supervention of cystitis, and the enlarged state of the prostate, are often such as to prevent the performance of lithotripsy with any prospect of success. At the same time, the success of lithotripsy in old age has been very great in the hands of some Surgeons. Thus, Segalas states that, of 14 octogenarians whom he lithotripsed, he did not lose one; and of 27 septuagenarians, but two. Lithotomy, on the other hand, is very fatal in aged persons.

It is at the middle period of life, or in persons who, though advanced in years, preserve their powers unimpaired, that lithotripsy is most generally applicable and most successful.

2. Size and Character of the Stone.—With regard to the size of the stone, there is no doubt that a small stone is more favorable to lithotripsy than a large one. All calculi below one inch in diameter may easily be crushed, provided no special circumstance is present rendering the operation undesirable. In regard to larger stones, it is difficult at the present day to lay down any hard and fast line. Until recently, it was not considered advisable to attempt to crush a stone that was above one inch and a half in diameter; but since the introduction of Bigelow's method, many stones considerably above this size have been successfully removed. Much will depend on the composition and density of the calculus. The chief objection to lithotripsy in large stones was not so much that the stone could not be broken, because unless it is too large to get into the blades of the lithotrite this could usually be done; but that the mass of fragments to come away by the urethra and the repeated operations required for their removal would produce a dangerous amount of irritation. The use of evacuators has to a great extent overcome these objections for stones of two inches in diameter; but we are not in a position as yet to say what is the maximum size that can be safely attacked. The different forms of stone vary in the ease with which they are broken up. Uric acid calculi, giving a clear ringing sound, do not disintegrate readily, but split up into sharp and angular spicula and scales. *Oxalate of lime* calculi, occurring chiefly in young people, comparatively rarely admit of lithotripsy, but, when crushed, break up very readily; and, as there is usually a coexisting healthy state of the urinary organs, the cases have a favorable issue. *Phosphatic calculi*, which are soft and friable, and do not yield angular fragments requiring repeated disintegration, may, even if of larger size than that mentioned, be broken up. At the same time, the patient may often derive great benefit from the thorough washing out of the bladder with the evacuator, as these concretions are commonly the result of chronic cystitis, with alkaline decomposition of the urine. But the shattered state of system, and the irritable condition of the urinary organs accompanying phosphatic calculi, often counterbalance the advantage that would otherwise have been derived from the character of the stone.

If there be *several stones*, the propriety of performing lithotripsy will depend in a great degree upon the size of the calculi. If these be small—not larger, perhaps, than small nuts, and not very numerous, the bladder being healthy—the operation may be performed with safety. I have removed successfully in a few sittings five or six calculi about half an inch in diameter. But if the calculi be larger than that, lithotripsy is not a very successful procedure; for, though each calculus may not be very large, yet the aggregate of the whole is considerable; and, besides this, the calculi will each require a separate operation, as it were, and may each contain a hard and possibly very

resisting nucleus. Occasionally the bladder contains a large number of small pea-shaped calculi. These may be successfully broken up, and washed out through a large eyed catheter; from 50 to 100 separate ones may be thus removed. Sometimes a calculus, after having been broken up into several fragments, has been left in the bladder, each fragment forming the nucleus for a new stone. Such cases are usually most successfully cut; but in favorable circumstances as to the condition of the urinary organs, they may be subjected to lithotripsy.

3. **The Conditions of the Urinary Organs** that influence the propriety of performing lithotripsy or lithotomy have reference to the state of the *kidneys*, the *bladder*, the *urethra*, and the *prostate*.

As a general rule, it may be stated that, the greater the irritability of the urinary organs, the less successful will lithotripsy be. The repeated introduction of instruments, however carefully and skillfully conducted; the presence of fragments of calculus, should any be left behind, and their tendency to impaction or entanglement in the urethra, necessarily dispose to inflammation, even in the most favorable cases, and very readily excite it, if there be any tendency to it existing in the parts. If, however, the stone be small, or of moderate size, and friable; the bladder healthy, and of good contractile power; the urethra capacious; and the patient of sound constitution and quiet temperament, the stone, even under the old system of many sittings, is often broken up and the fragments expelled with comparatively little suffering. In fact, in such a combination of favorable circumstances, lithotripsy ought unquestionably to be preferred.

If, however, the bladder be very irritable, or if the patient's constitution be an excitable one, so that he does not bear well the introduction of instruments; more particularly if it be found that this local and constitutional sensitiveness, instead of being blunted by the methodical introduction of sounds or bougies, is rather increased thereby; and especially if the stone be of considerable size, lithotomy was formerly the only safe mode of treatment. At the present time, however, by the use of anæsthetics and the adoption of the operation at one sitting, even these difficulties may be safely overcome.

The existence of organic disease about the urinary organs, constitutes the greatest obstacle to lithotripsy; and, when extensive, must form a complete bar to the performance of that operation. It is not easy, however, to determine the amount of local disease that should thus be held to contraindicate lithotripsy. On this point the opinions of Surgeons differ much; and it is particularly in the management of these cases that the advantages of tact and dexterity in the use of the crushing instruments, which habit alone can give, is well exemplified.

The condition of the *kidneys* merits special attention. If these organs be diseased, as indicated by the presence of casts of tubes, or of a considerable quantity of albumen in the urine, or in any other way, the performance of a prolonged operation in the bladder would be likely materially to increase the mischief in them, and consequently ought not to be undertaken. Organic disease of the kidneys is a more serious obstacle to lithotripsy than to lithotomy, on account of the prolonged nature of the operation, and the greater liability to sympathetic or propagated irritation in these organs. It is not only by the operation increasing the renal mischief that harm might result, but also in consequence of the tendency to diffuse inflammation of the bladder, prostate, and surrounding areolar planes, and to pyæmia, that always coexists with kidney disease.

The conditions of the *bladder* that interfere seriously with lithotripsy are partly functional, partly organic. The functional derangements are of two very opposite kinds; viz., a state of extreme irritability of the organ, and an

abnormal want of sensibility of it—a state of atony. The organic lesions consist of hypertrophied, fasciculated, sacculated, and permanently contracted states of the viscus, which is then most commonly irritable as well.

A *chronically inflamed or irritable* state of the bladder, more particularly if the organ be thickened and fasciculated, so that it will not bear the injection of a few ounces of tepid water, seriously interferes with the success of lithotripsy. A very irritable and sensitive bladder will not only be the seat of severe suffering on the introduction of instruments, but may not be able to hold sufficient urine to make the operation a safe one, and may readily become dangerously inflamed in consequence of the repeated introduction of instruments, and the presence of angular fragments. Hence, if the ordinary operation of sounding occasion much distress; if the patient cannot hold his urine long, but pass it in small quantities; if it be bloody, or much loaded with viscid mucus, he will scarcely be able to bear the procedures necessary for the operation. In some instances, however, the irritability of the bladder may be overcome, and in all it may be materially lessened, by keeping the patient in bed, and, as Brodie recommends, daily injecting tepid water. If the bladder be *sacculated*, there will be a still greater risk of an unfavorable result; the sacculi not only retaining fragments of calculus, but also becoming filled with decomposing mucus and urine, in consequence of which unhealthy inflammation of a very serious character, followed by pyæmic symptoms and metastatic abscesses, may result, or in some cases leading to perforation of the peritoneum. In such cases as these, early lithotomy offers the only chance to the patient. The existence of a moderate amount of vesical catarrh, if the bladder be otherwise healthy, is no objection to lithotripsy.

In *encysted calculus*, lithotripsy is, for obvious reasons, inadmissible.

Atony of the bladder is not only a serious inconvenience, but a great source of danger in lithotripsy. It cannot in all cases be positively ascertained beforehand; though it may be suspected if the patient can hold his urine for a great many hours, and can bear without complaint the injection of a large quantity—eight or ten ounces—of fluid, the interior of the bladder feeling large and smooth to the sound. This condition occurs chiefly in old men of feeble habit of body. Civiale considered this condition to be a source of great danger after lithotripsy, the organ not possessing sufficient expulsive power to rid itself of the fragments of the presence of which it seems to be insensible, so far as the feelings of the patient are concerned; while its low vitality renders it peculiarly liable to subacute cystitis, excited by the presence of the fragments in the lower fundus. By the use of the modern evacuator, a stone of moderate size may, however, be safely removed at one sitting from an atonic bladder. It must be borne in mind, that this atony of the bladder may, especially in feeble and aged individuals, be induced by the contact of the instrument, and especially by prolonged sittings.

If the *urethra* be the seat of stricture, or be very irritable, lithotripsy—which may require the frequent introduction of instruments of large size—cannot be safely performed. Stricture of the urethra does not, however, absolutely prevent the performance of lithotripsy, but only retards the operation until the constriction can be properly dilated. Should this, however, be not practicable to the full extent of the urethra, lithotomy on a small staff must be practised.

Moderate enlargement of the *prostate*, such as is often met with in elderly people, does not prevent the performance of lithotripsy; though it slightly complicates the operation. The introduction of the lithotrite will be attended by considerable difficulty; and the fragments have a tendency to become lodged in a pouch of the lower fundus behind the enlarged gland. This

more especially happens if the middle lobe be enlarged; yet in these circumstances, the stone may be crushed without great difficulty, and the fragments removed by the evacuator. Any inflammatory disease or abscess of the prostate must necessarily prevent the performance of lithotripsy.

Diabetes is not commonly associated with calculus. I have, indeed, but very rarely seen the two conditions combined. The only form of calculus that I have seen in diabetic patients has been the uric acid. It is necessarily very hazardous to operate in such cases, at least by lithotomy. And even if lithotripsy be determined on, it would be well to defer the operation until the glycosuria has been checked or removed, at least for a time, by proper treatment.

I have said nothing in this comparison between lithotripsy and lithotomy of the comparative painfulness of the two operations; for, as anæsthetics may be administered with equal advantage in both cases, there is little difference in this respect, except that perhaps the advantage lies on the side of lithotomy, as being the shorter proceeding.

From all that precedes, then, it would appear that although lithotripsy, as at present performed, is adapted to by far the larger number of cases of stone in the adult male, it cannot be looked upon as a universal mode of treatment, being applicable only in favorable conditions of the urinary organs, to calculi of moderate size, and after puberty; and that a considerable number of cases will always be left in which lithotomy offers the sole means of relief.

Choice of Operation of Lithotomy.—The particular operation of lithotomy to which recourse should be had, will also vary according to the character of the stone. If this be small, and the patient an adult, the *median* operation may advantageously be performed. If it be of moderate or tolerably large size, and more particularly if the operation be practised on a child, the *lateral* appears to me to be the more applicable. If, again, the calculus be of inordinate magnitude, the *suprapubic*, the *mediobilateral*, or the *rectovesical* operation should be the method selected. In fact, the Surgeon should not confine himself too exclusively to any one method of operating, but should adopt that procedure which appears to be best adapted to the special circumstances presented by the particular case before him, and should vary his method according to the state of the urinary organs, the age of the patient, and the size and character of the stone.

The Result of Operations for Stone will depend in a great measure upon the condition of the bladder, and the character of the stone. If the bladder be healthy, all symptoms will cease on the removal of the calculus, and the patient will be restored to perfect health. This usually happens when the calculus is of the lithic acid or the oxalate of lime variety, and of renal origin. If, however, the bladder be unsound, irritable, and the urine alkaline from decomposition, and disposed to the deposit of phosphatic matters, the calculus being phosphatic, and chiefly, if not wholly, vesical in its origin, then an irritable state of bladder may be left, or may speedily return after the operation, which will consequently have been productive of little, or only of temporary benefit.

REURRENCE OF CALCULUS AFTER OPERATION.—This may take place from four distinct causes: 1. In consequence of a continuance of the constitutional condition, under the influence of which the calculus was originally formed; 2, from the descent of a renal calculus, which has existed in the kidney before the first operation; 3, from a fragment of calculus having been accidentally left in the bladder; and, 4, from the accumulation of phosphatic deposit in the fundus of the bladder, or in the line of imperfectly healed incisions.

Relapse from the first cause is probably not very common. When it occurs the recurrent calculus is of course of the same composition as the previous one. The occasional occurrence of relapse shows the necessity of continuing constitutional treatment adapted to the particular diathesis, after the removal of the calculus from the bladder.

Recurrence of calculus from the descent of a new stone from the kidney every now and then occurs, and is especially liable to be met with in those cases in which the primary calculi are multiple and small. In these cases the relapse may take place very shortly after the first operation, and is usually preceded by the usual symptoms of the descent of a stone from the kidney.

Relapse from the retention of a fragment which serves as the nucleus of another stone, will undoubtedly occasionally occur, although its occurrence is fairly attributable to want of due care on the part of the Surgeon. It is liable to happen more frequently after lithotomy than after lithotrity, and is probably to this cause chiefly that we must refer the greater frequency of relapse after the crushing than the cutting operation. But it may happen after lithotomy, that a fragment is left behind when the stone has been broken during extraction, and the bladder not thoroughly washed out. But even in this case, the bit of stone will usually be carried out of the bladder by the flow of urine through it.

Recurrence from the formation of a phosphatic calculus in the bladder as the result of chronic cystitis with decomposition of the urine, may occur occasionally after lithotomy, but is much more common after lithotrity. In these cases a lithotrite must be passed, and the soft mass crushed upward and washed out with a catheter and evacuator. The patient must be taught to wash his own bladder out regularly every day with a dilute acid solution, to which some quinine may be added. I have lately had under my care a patient eighty years of age, on whom I performed lithotrity for a very large calculus about five years ago, and from whom I have removed large phosphatic concretions more than a dozen times since. At the present time a year has elapsed since the last operation, and no new formation has taken place. On some occasions the mass measured over an inch and a half in diameter, yet under anesthetics it was broken up and washed out with Higdon's apparatus without the slightest irritation, the patient usually returning to the country on the second day after the operation.

Phosphatic deposit may take place also in the track of a partially healed lithotomy wound, forming a crust on its surface. I have known such a deposit to form in the perineum, when the wound had degenerated into a sinus.

According to C. Williams, the relapses in the Norwich Hospital are 1 in 101 operations, or 1 in 36, or in 255 lithotomies, 1 in 33. Lithotomy was performed a second time in 24 patients; a third time in 3, and a fourth time in 1. Twenty-three were cured, 3 died. All the patients were cured. The registers of the Lonsville Hospital give 1 relapse in 116 cases of lithotomy; and, according to Civiale, the return of calculus after lithotomy was in Bavaria, 1 in 32, in Bohemia 1 in 46, in Dalmatia, 1 in 43, and in France 1 in 74.

After lithotrity, relapse is more common; although it is probably less frequent now than formerly, and will become less frequent as the details of the operation come to be better understood, and more carefully practised. In the practice of Civiale it occurred about once in every tenth case. His estimate, high as it, falls below what happened formerly in surgical practice. Civiale stated that, of 36 private patients on whom he operated in 1820, 13 had previously been operated on, the stone having reappeared. These would evidently have arisen from some fragment of calculus having escaped after

tion and being left behind, thus constituting a nucleus for a fresh formation. The frequency of the occurrence of secondary calculi after lithotripsy has greatly diminished since the time of Civiale, and can no longer constitute an objection to that operation, yet it still occurs often enough to show the necessity of the Surgeon most carefully examining the bladder before he pronounces the patient cured: and even then watching him for some length of time, in order to meet a recurrent calculus at its first formation, and to adopt means for its early removal. Lithotripsy cannot therefore be said to be so complete a cure in all cases as lithotomy. Not only is recurrence of calculus more common after the former than after the latter operation, but it not uncommonly happens that patients who have been lithotripsy successfully, and in whom no recurrent calculus has formed, continue to suffer for a great length of time afterwards from very distressing irritability of the bladder, which resists in the most obstinate manner all the ordinary methods of treatment. This is not the case after lithotomy; when a patient once recovers, his bladder usually regains its tone completely, and no trace of evil consequences is left.

Treatment.—In the event of a secondary calculus forming, whether after lithotomy or lithotripsy, either method may again be employed, according to the nature of the case. Most generally, the bladder may be cleared of the recurrent calculus by means of the lithotrite. If lithotomy have previously been performed, and it be thought proper again to have recourse to it, this may be done again in the usual way, through the cicatrix left by the former wound; or the Surgeon, if ambidextrous, may adopt Liston's advice to cut through the right side of the perineum on a staff with a groove to the left of its convexity. As this procedure, however, would entail the use of the left hand for cutting and extracting, most Surgeons would prefer either the operation through the site of the old wound, or, better still, the median operation. Whatever procedure, however, may be adopted, it should be borne in mind that the rectum may have become rather firmly adherent to the membranous portion of the urethra and the apex of the prostate, in consequence of the contraction of the old cicatrix, and may thus be endangered.

URETHRAL CALCULUS.

Calculi are not unfrequently found impacted in the urethra, especially in children. These are most commonly formed in the kidney, whence they pass into the bladder, and thence into the urethra, through which they usually escape; but in some instances they lodge in the latter channel, more especially at the bulb or in the navicular fossa. These calculi are commonly of the uric acid or oxalate of lime varieties; they are generally round, but not uncommonly elongated or spindle shaped.

Although most urethral calculi are undoubtedly renal in their origin, there can be little doubt that in some more rare cases they may be primarily formed in the canal. They will then be found to be phosphatic, usually consequent upon stricture, and perhaps of large size. In some cases these concretions are moulded in the prostatic and bulbous portions of the urethra, being elongated, rounded at one end, and pointed at the other. In other instances, again, they appear to be formed in a pouch that lies to the outside of the urethra, and that is connected with it only by a small aperture. I have removed a stone of this kind composed of triple phosphate, weighing an ounce, and about the size of a walnut, smooth and rounded, from a point lying between the upper wall of the urethra and the symphysis pubis, in a clergyman who had for many years suffered from very tight stricture. One

of the most remarkable instances of this kind is represented in the annexed cut (Fig. 904), taken from a drawing in Sir R. Carswell's collection at University College. The stone here was of very large size—equal in bulk to two horse chestnuts.

Symptoms.—In the adult, the presence of a calculus in the urethra may be suspected by the difficulty that is occasioned in micturition, and ascertained by the possibility of feeling the stone through the walls of the canal, or of detecting it by introducing a sound into the urethra. In boys, impaction of calculus in the urethra is almost the sole cause of retention of urine. When called, therefore, to a child suffering from this condition, we should always at once suspect calculus as being the cause, and examine the urethra from the perineum or rectum, and by the introduction of a sound.

Treatment.—The treatment of urethral calculus will vary in the adult and in the child. *In the adult*, urethral calculi may be removed by extrac-

Fig. 904.—Extra-urethral Calculus.

tion, incision, or lithotripsy. When situated towards the anterior part of the canal, a urethral calculus may frequently be extracted by quietly working the stone forwards between the finger and thumb, the patient being under chloroform. Should this plan not succeed, it may be removed by passing a long and very narrow-bladed pair of forceps down to it, by which it is seized and drawn forwards; occasionally, when it has reached the navicular fossa, it will not pass through the urethral orifice unless this be enlarged by incision with a probe-pointed bistoury. If the calculus be too large to be extracted in this way, and appear to be firmly fixed, an incision may be made down upon it, through the urethra, by which it may be removed. It is a good rule not to make this incision in any part of the urethra anterior to the scrotum; for, in consequence of the coverings of the penile portion of the urethra being very thin, the aperture will probably not close, but a fistulous opening

will be left. When the stone is situated in the scrotal portion of the urethra, there would be some risk of abscess and of urinary infiltration if the incision were made through the lax tissues of the scrotum. Hence it is better, if possible, to push the stone back towards the membranous portion of the canal, to cut down upon it, and extract it through the perineum by an incision in the mesial line. This operation may readily be done by passing a staff, grooved along its convexity, or an ordinary director, as far as the calculus, and making an incision upon the end of it, so as to lay open the urethra; the staff is then removed, and the calculus extracted by means of a slender pair of forceps. A catheter should next be passed into the bladder, and retained there for a few days, in order to lessen the tendency to the formation of urinary fistula. Should it not be thought advisable to cut the patient, the stone may be pushed back into the bladder, and then crushed by a lithotrite.

It may happen that the calculus, impacted in the urethra, is only one of several; others being lodged in the bladder. In order to ascertain this, the Surgeon should, after removing the calculus for which the operation has been performed, pass a sound into the bladder, so as to ascertain whether any other concretions exist in that organ; and, if so, they should at once be removed by the median operation of lithotomy, the incision of the membranous portion of the urethra being extended backwards to the prostate.

I once saw Liston extract two vesical calculi, after having removed one that had blocked up the urethra, by converting the perineal incision into that of lateral lithotomy.

Impaction of a Calculus in the Urethra of a Boy may lead to very serious consequences. In the majority of instances, it occasions more or less complete retention of urine, which requires relief. This may be given in one of two ways: 1. If the stone be near the urethral orifice, it may be extracted; and, 2, if situated more deeply, it may be pushed back to the perineum, there fixed by the finger, and cut down upon in the mesial line. It should never be pushed back into the bladder, as such an act would render lithotomy necessary.

If the stone is allowed to continue fixed in the urethra, very serious consequences may ensue. If it completely obstructs the canal, the membranous part of the urethra may give way during the violent efforts at micturition, and extravasation of urine will take place. In other cases, if it be irregular in shape, a small quantity of water may pass. Under these circumstances, there is intense irritability of the bladder, the urine passing with much pain every few minutes, or constant dribbling may set in. The distended bladder can be recognized above the pubes. Some purulent discharge will be observed about the meatus, and there will be some hard, ill-defined swelling in the perineum, with much tenderness in this region. The presence of the stone may at last cause ulceration of the urethra, with the formation of urinary abscess in the perineum, followed, perhaps, by extravasation of urine into the scrotum and its diffusion beneath the superficial fascia in the usual direction, with the ordinary disastrous results of inflammation and sloughing. On passing a sound, no stone, probably, will be found, as this has escaped from the urethra, and is lying in a pouch in some part of the perineum, and in the midst of broken-down areolar tissue and pus; into this cavity, the sound will readily pass.

The *Treatment* in these cases is simple. It consists of introducing a grooved staff, placing the boy in the lithotomy position, and then freely incising the mesial line of the perineum, so as to open up the urinary abscess; in this the stone may be found, or it may be so enveloped in the sloughy tissues as to escape detection; perhaps it will escape through the wound in a few days, and be found lying on the bed. Should there be much hemorrhage, a catheter may be tied in and the wound plugged with saleylic or iodoform-wool secured by a T-bandage. If extravasation of urine have occurred, free incisions must be made in the usual way, and the child be put upon a stimulating diet.

PROSTATIC CALCULUS.

Prostatic calculus differs from all other urinary concretions in situation and composition, being formed in the ducts of the prostate gland, and composed principally of phosphate of lime and some animal matter; usually about 85 per cent. of the phosphate, to 15 of the organic ingredients. The concretion is said to consist sometimes of carbonate of lime (p. 904). It generally occurs in old people, though it may sometimes be met with in young subjects. From a lad of nineteen, whom I cut for vesical calculus, I extracted two prostatic concretions.

CHARACTERS.—Prostatic calculus is usually of a gray or ashy color, somewhat triangular in outline, smooth and polished (Fig. 995), having facets, being very hard, and seldom much larger than a cherry or plumstone; though it may occasionally attain a considerable bulk, having been met with as large as a hen's egg, and then presenting a branched or irregular

appearance. Though usually but one or two exist, which are sometimes deposited in a kind of cyst in the organ, as many as thirty or forty have been met with, the ducts being filled, and its whole tissue being studded with them.

SYMPTOMS.—Calculus in the prostate gives rise to a sense of weight, pain, and irritation in the perineum, sometimes to retention of urine, and, in fact, to the ordinary symptoms of enlarged and irritated prostate; it often occasions a tolerably free discharge of mucus in the urine. On introducing a sound, this passes over the stone, sometimes rumbling or striking it with a distinct grate or click before its beak enters the bladder. This is increased by the finger in the rectum pushing the organ up, and thus bringing the stone into more direct contact with the sound. In some instances the calculus is deeply imbedded in the prostate, and cannot be touched by the sound. In these cases, the stone may usually be felt through the rectum. If there be many

Fig. 905. Prostatic Calculus.

small calculi in a sacculus in the prostate, they may be felt by introducing the finger into the rectum, when a peculiar cracking or grating sensation may be experienced by the rubbing together of the calculi, something like that produced by beads in a bag.

TREATMENT.—The treatment of prostatic calculus will depend upon the situation, size, and number of the concretions. When they are large, single, or at most two or three in number, readily struck with the sound, and situated on the urethral surface of the organ, the ordinary median operation may advantageously be performed, and the calculus removed with a scoop or forceps. If the calculi be small and very numerous, not to be felt with the sound, but only through the rectum, it will be wiser not to have recourse to operation, which could not remove the whole of the concretions. In such circumstances, a palliative treatment directed to the subduing of the irritation of the prostate, and the use of the catheter to relieve retention, is the only course to pursue. When prostatic and vesical calculi occur together, the same operation will rid the patient of both forms of the disease. (For foreign bodies in bladder, *vide* vol. i. p. 837.)

CALCULUS IN THE FEMALE.

Stone is of rare occurrence in women; in London, certainly, it is not often met with. Thus, South states that, during a period of twenty-three years, 144 males were operated on for stone at St. Thomas's Hospital, and only 2 females. In some districts, however, stone would appear to be more common in women than this. Thus, according to Crosse, at the Norwich Hospital, the proportion has been about 1 woman to 19 men. Civiale states, as the result of his researches, that in the North of Italy, the proportion is 1 to 18; and in France, about 1 to 22. At University College Hospital we had not had a case of stone in the female for many years until 1855, when three came under my care in the course of a few months; and since that period many have occurred.

Vesical calculi in the female are often nothing more than phosphatic incrustations deposited around some foreign body that has, either accidentally or from depraved motives, been passed up the urethra and has been dropped into the bladder. In this way hair-pins, pieces of bougie, of catheter, or of pencil, will often be found to form the starting point and the nucleus of the concretion.

SYMPTOMS.—The symptoms of stone in the female closely resemble those that occur in the male, and its presence may usually be easily detected by

means of a short and nearly straight sound, or a female catheter. It is often simulated very closely by the irritation occasioned by a vascular urethral tumor, or by an irritable bladder; but exploration of the viscus will always determine the diagnosis. The larger calculi can be felt from the vagina if firm pressure be made at the same time above the pubes.

Large calculi may be met with in very young female children. I have removed a uric acid calculus incrustated with phosphates, measuring $1\frac{1}{2}$ inch in length by $\frac{1}{2}$ inch in breadth, from a little girl four years old. The stone was removed unbroken, by gradual dilatation of the urethra.

In the adult they may attain a very large size. I have extracted one from a young woman measuring 8 inches in its long, and 6 inches in its short circumference.

Calculus in the female bladder, if allowed to remain unrelieved, will not only occasion the various morbid conditions in the urinary organs that have been described as following the long-continued presence of stone in the male, but will give rise to diseased states peculiar to the female. Thus the stone may be spontaneously discharged through the urethra; if of small size, without any bad results following; but if large, by a process of ulceration, in consequence of which permanent incontinence of urine will remain; or it may slough through into the vagina; or lastly, it may offer a serious obstacle during parturition to the descent of the fetal head, when, if it cannot be pushed aside to be dealt with afterwards, it must be cut out, or craniotomy be performed.

REMOVAL. A stone may be extracted from the female bladder by one of three methods: 1, by Lithectasy, through a dilated urethra; 2, by Lithotomy; 3, by Lithotrity. These different operations cannot be employed indiscriminately, but each one is more especially adapted to certain kinds of calculus.

1. **Lithectasy** may be performed in two ways—either by simply *Dilating the Urethra*, or else by *Incising the Mucous Membrane* at the same time that the canal is being expanded.

a. **Simple Dilatation** of the urethra may be effected quickly by the introduction of a three-bladed dilator, which is rapidly screwed up. In this way, in a few minutes the canal may be easily dilated sufficiently to allow the introduction of a pair of forceps, and the extraction of a calculus of moderate size. Some Surgeons prefer a slow process of dilatation, continued through many hours, by means of a sponge-tent; but this appears to me to possess no advantage over the more rapid expansion, and has the very decided disadvantage of prolonging the patient's sufferings. In the absence of a proper urethral dilator, it is always easy to dilate the canal by means of the finger. With this view a director is first passed, and along this the Surgeon gradually insinuates the tip of his finger, and then soon succeeds in expanding the urethra sufficiently for all ordinary purposes.

b. **Dilatation** may be employed conjointly with **incision**, in order to prevent injurious stretching of the urethra, and consequent laceration of its mucous membrane. The incision should be made after the urethra has been dilated to some extent, a probe-pointed bistoury being introduced by the side of the canal, and the mucous membrane divided. Brodie made an incision directly upwards; Liston downwards and outwards on each side—on the whole, I think, the best direction for the incisions, as more space may thus be obtained.

By dilatation, either alone or with incision of the mucous membrane, small stones may readily be extracted; and those calculi that are formed by the phosphatic incrustation of foreign bodies, may be removed in this way. I have thus extracted, by dilatation, a full-sized gum-elastic bougie from the

bladder of a young woman. In the removal of moderate-sized stones, the great objection to this operation is the liability to incontinence resulting from it. It is difficult to say to what extent the bladder can be dilated without incontinence resulting; this must depend on the constitution of the individual. It certainly can be expanded to a considerable extent by the introduction of the index-finger, and the extraction of stones of a size equal to the diameter, without any evil resulting. The operation is not complete; but a weakened state of the bladder results, so that the patient cannot hold her urine for more than two or three hours at the most.

2. **Lithotomy in the female** may be performed in three ways. There are, however, only three modes of practising it which appear to me to deserve serious attention; viz., the *Suprapubic*, the *Urethral*, and the *Vaginal*.

The **Suprapubic** or **high** operation in women differs from the same procedure in men: except that more care is required in consequence of the difficulty there is in causing the patient to retain enough urine or water to make the viscous mass of the stone easier to remove. The extraction of the stone is easy, as it can be done by the forceps by being pushed up from the vagina.

Urethral Lithotomy is a very simple and efficient operation. In placing the patient in the lithotomy position, a straight grooved staff is then introduced into the bladder, and a curved staff, guided by it, is pushed through the floor of the bladder, an inch and a half from the meatus, the canal being then enlarged. The forceps may then be readily carried in and the calculus of good size removed. After the bladder is emptied, a small sized catheter should be introduced, and left in the bladder, the edges of the urethra brought together over it by two or three sutures.

Vaginal Lithotomy is an operation easy of performance, and may be performed by passing a straight grooved staff into the bladder, and well down against the anterior wall of the vagina, and the left index finger. A scalpel is then pushed through the vagina and inferior fundus of the bladder into the bladder, and is made to enter just behind the urethra, and is then retracted, an inch; through the aperture thus made the forceps are introduced, and the stone extracted. The incision into the bladder through the vagina should be brought together by metallic sutures, as in vesico-vaginal fistula, and may thus be successfully performed by J. Lane, Aveling, and others.

On Comparison of these three operations, urethral lithotomy is the easiest, the least severe at the time of its performance, and the least attended by after evil consequences. It is quite sufficient for the removal of all ordinary calculi. The only possible evil is the want of union of the incision. But should this occur, the operation at a subsequent period can easily remedy that defect.

Both the high and the vaginal operations are easy of performance. In the high operation, there would, with care, be but little risk of incontinence; and the chance of urinary infiltration, which is the great danger in the male, may be prevented in the female by the introduction of a catheter into the urethra. The vaginal operation, though it is open to the objection of possibly leaving a per-

If, however, the lips of the incision have not been bruised by the forceps, or in the extraction of the stone, and be immediately brought together by metallic sutures, the risk of a fistula is, after all, not great. Vaginal lithotomy may, in some cases, be the only alternative. I extracted, by this operation, a calculus measuring eight inches by six in circumference, from the bladder of a woman twenty-three years of age, who had suffered from symptoms of stone from childhood. The stone by its size offered so serious an obstacle to the descent of the foetal head during parturition, that craniotomy had been rendered necessary; the anterior vaginal wall had been a good deal bruised, and I feared that sloughing of it might take place; hence, I extracted the stone by the vaginal method.

Lithotomy is not so dangerous an operation in the female as in the male; yet death occasionally occurs, especially in feeble children, from cystitis and peritonitis, more particularly if the extraction of the stone have been tedious and difficult, the bladder being much manipulated.

3. **Lithotrixy** in the female requires to be practiced on the same principles as in the male. The details of the operation differ, however, in some important particulars. The chief obstacle in the performance of the operation in the female, consists in the difficulty with which the bladder retains urine or water that is injected into it. In consequence of this there is not only great difficulty in seizing the stone, the bladder collapsing and falling into folds around it, but also danger of injuring the mucous membrane with the lithotrite. In order to cause the bladder to retain the necessary quantity of urine, the pelvis must be well tilted up, and the urethra compressed against the lithotrite. It is well not to dilate the urethra before the introduction of the instrument, as the incontinence is thereby increased.

The ordinary male lithotrite is not a very convenient instrument to use in the female bladder, the handle being awkwardly long. This is especially the case in female children. Hence, I have found it convenient to have a shorter instrument constructed, with which it is far more easy to manipulate in the female bladder. If urine or water cannot be retained, the calculus may more safely be seized and crushed by means of a small and strong-bladed pair of lithotomy-forceps; or, if the stone be large, by a crushing instrument, made of the shape of that depicted in Fig. 906. In performing lithotrixy in the female it is not necessary to pulverize the calculus, but merely to break it up into fragments of such a size as to admit of easy extraction through the urethra.

After the stone has been broken up, the urethra (unless this has previously been done) may be dilated by means of the three-bladed instrument to a moderate degree, the larger fragments removed by means of a pair of slender

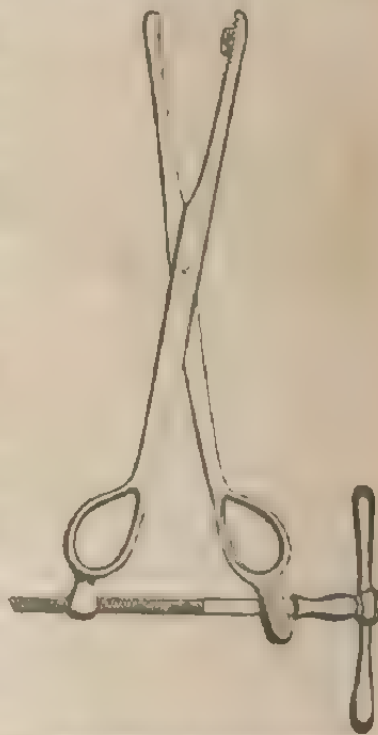

Fig. 906.—Crusher for large Calculus in Female Bladder.

forceps, and the detritus and smaller fragments cleared out of the bladder by repeated injections of tepid water, or by an evacuator, such as is used in the male. The whole of the fragments and detritus should be removed at one sitting. The shortness and wide capacity of the female urethra will readily allow the escape of any detritus that may unavoidably be left.

For all calculi in the female bladder, except those of the very largest size, this operation is the most applicable. I have in this way crushed and extracted at one sitting, from the bladder of a lady about 50 years of age, a phosphatic calculus fully as large as a hen's egg. By this operation the stone may be removed piecemeal and at once, without the necessity of dilating the urethra to such a degree as to incur the risk of incontinence of urine resulting. Lithotrixy may be had recourse to at all ages, in the very young as well as the old. I have crushed and successfully removed a large calculus from a child three and a half years of age, the youngest patient on whom I have operated by this method. Although the urethra of so young a female child cannot, without danger of incontinence, be much dilated, yet it may safely and easily be enlarged sufficiently to admit a moderate-sized lithotrite.

CHAPTER LXX.

DISEASES OF THE BLADDER.

CONGENITAL MALFORMATION.

EXTROVERSION OF THE BLADDER, consisting in an absence of the anterior wall of the organ, with deficiency in the corresponding part of the abdominal parietes, is occasionally met with as a congenital malformation. It may occur in either sex, but is most common in males.

This condition essentially consists in an arrest of development, in consequence of which the anterior part of the pelvic girdle is deficient, the bodies of the pubic bones being imperfectly developed and the symphysis being absent. The recti muscles separate at their lower part, and pass obliquely outwards to be inserted into the lateral abutments of the pubic bones. A triangular space is thus left, which is filled up by the posterior wall of the bladder, which is continuous with the common integuments, the anterior wall being absent, and the interior of the bladder exposed. The cleft commonly extends up to the spot at which the umbilical cord enters, so that the umbilicus is wanting. The penis is cleft along its dorsal aspect, exposing the floor of the urethra, forming the condition known as epispadias. The posterior wall of the bladder, being pushed forwards by the pressure of the abdominal viscera behind, forms a rounded tumor about the size of a small orange just above the pubes. The surface of this tumor is red, vascular, and papillated, evidently composed of mucous membrane; at its lower part the orifices of the ureters will be seen discharging urine in drops or in a stream. For a full description of the mechanism of the passage of the urine in this malformation, I would refer to a case which fell under my notice, and in which I made a number of experiments on the rapidity of the passage

of foreign matters through the kidneys, reported in the *Medical Gazette* of 1845.

This malformation is of the most distressing kind. The odor constantly exhaled from the patient by the dribbling and decomposition of the urine is a source of annoyance to himself and of disgust to others. In order to render his presence at all tolerable to others, this dribbling must be prevented by some mechanical contrivance. With this view the patient should wear a properly constructed instrument to receive and collect the urine, consisting of a hollow shield strapped over the part, communicating by means of a tube with an India-rubber bottle, which may be attached along the inside of the thigh.

Treatment.—Up to a comparatively recent period this condition was considered incurable. Of late years, however, operations have been devised and practised with the view of covering in the exposed bladder, forming an anterior wall to the viscus, and restoring the urinary canal; so as to protect the tender extroverted surface of the bladder, to prevent the pain and irritation arising from contact of the clothes with it, and, by giving a proper conduit to the urine, to which an apparatus can be applied, to save the patient all the annoyance of constant dribbling.

The first operation for the remedy of this malformation that was successfully performed was done, in 1859, by Ayres, of New York, in the case of a young woman, 28 years of age. He, consequently, has the merit of having been the pioneer in this branch of Surgery. He was followed by Pancoast, of Philadelphia, and subsequently by Holmes and Wood, of London.

Ayres's Operation.—The operation practised by Ayres comprised two steps. The first consisted in dissecting down a long flap of integument and of superficial fascia from the anterior wall of the abdomen above the bladder, and turning this down so that the cuticular surface was innermost and lay over the exposed bladder as far as its inferior border. Lateral union was then secured in this position, but the lower part of the flap was left open, so as to allow a free exit for the urine. In this way the bladder was covered in completely by a skin flap, having its cuticular surface underneath, and consequently next to the exposed vesical mucous membrane. The integuments of the abdomen were now sufficiently separated from their areolar connections with the muscles beneath, on each side of the reversed flap, to admit of their sliding forwards, and being united by sutures along the mesial line, so as completely to cover in the exposed raw surface of the flap. In this way the bladder was overlaid by integumental structures, which readily united along the mesial line; and were the patient a male, little more would require to be done than to dissect up the integumental structures below this flap, and so to close in the epispadias and form an anterior wall to the urethra. In Ayres's case, as the patient was a female, the second step of the operation (which was practised after a lapse of three weeks) consisted in fashioning a covering for the vulva, by dissecting up the integuments covering the pelvic bones on each side, and uniting them to one another on the mesial line and to the lower part of the reversed flap.

The principle of the operation adopted by Pancoast, Holmes, and Wood, is essentially the same as that practised by Ayres—viz., that of raising integumental flaps from the abdominal wall, and covering in the bladder by turning the cuticular surface of these flaps towards it. But the details of the operations differ chiefly in this, that the flaps have been taken from the groins and lateral aspects of the abdominal wall, with their bases downwards, so that they might be nourished by the superficial branches of the common femoral artery.

Wood's Operation.—A flap composed of the skin of the abdominal walls above the extroverted bladder is somewhat square in shape, and its base should be exposed mucous membrane of the bladder. Its length should cover the whole of the exposed mucous membrane with its skin-surface towards the bladder. The base of which is about equal in width to the length, is dissected up from each groin, the base of the flap being at the scrotum and thigh" (Fig. 907). These two flaps

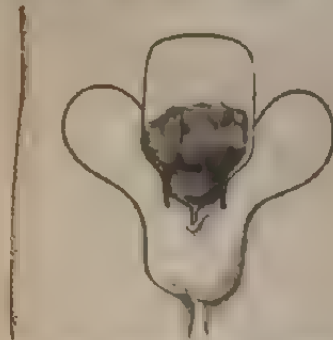

Fig. 907.—Wood's Operation for Extroverted Bladder. Outline of Incisions

Fig. 908.

to meet in the median line, and to cover in the faces of the two groin flaps being in contact with the reversed umbilical flap. The flaps are then secured by pins, each pin passed so as to transfix both the flaps and the umbilical flap beneath, holding the three firmly

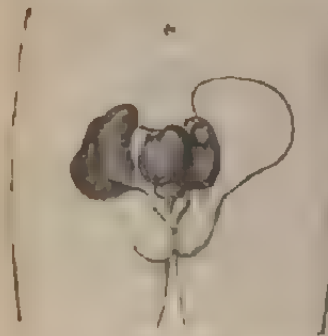

Fig. 909.

Wood's Operation by Lateral Rotation
(After Wood.)

sutures are required in the flaps. The edges of the flaps from which the flaps have been raised are then secured by pins and wire sutures (Fig. 908), and broad strips of lint are so as to support the parts and to remove, as far as possible, the flaps. The patient must be kept in bed with his knees drawn up.

If the operation be successful, all the pins and sutures may be removed by about the sixth or eighth day, and cicatrization will probably be complete before the end of a month; the exposed surface of the bladder being completely covered in, leaving only a small opening about the root of the fissured penis, to which an apparatus may be readily adapted to catch the urine. If the umbilical flap be not of sufficient length, very troublesome fistulae are apt to be left at its angles, requiring further plastic operations for their cure. Experience has shown that, if the operation be left at this stage, the benefit is not permanent. The contraction of the cicatrices, and the constant tendency to protrusion of the mucous membrane of the bladder from beneath the new covering at the opening left at the root of the penis (Fig. 908.), lead to a gradual increase in the size of the opening and a partial return of the symptoms. To prevent this, the fissured penis may be covered in by the following method. The whole front of the scrotum, including the dartos, is raised so as to form a bridge of skin connected with the groin at each side. This is lifted over the penis, and placed upon a raw surface prepared by turning down a collar or flap from the lower arched border of the new bladder-covering and from the sides of the urethra and penis as far forwards as the glans. A continuous wire suture is applied to keep the flaps in place; and the transplanted scrotal structures are united to the border of the bladder-covering by a line of interrupted sutures. The scrotal wound is readily closed by some wire sutures. By this means a sort of urethra is formed, containing the muscular tissue of the dartos in its roof, which may even give it a slight power of contraction, so as to enable the new bladder to retain small quantities of urine. This second stage of the operation is often somewhat interfered with by erections of the penis. These are best controlled by ice-bags. The knees should be kept drawn up so as to relieve tension, especially in the first stage of the operation. After the cure is complete, the patient is often troubled by the growth of hair from the under surface of the umbilical flap, and the accumulation of phosphates upon the hairs and in the angles of the new bladder. This is best relieved by extracting the hairs with a pair of forceps, and by using weak acid injections to remove the accumulation of phosphates.

CYSTITIS.

Idiopathic inflammation of the bladder is of rare occurrence. When it is met with it is usually in gouty subjects from exposure to cold. Acute cystitis most commonly originates from traumatic causes, as from the passage of instruments, the irritation of broken fragments of calculus, etc. Occasionally it arises from the extension of gonorrhoea to the interior of the organ. It may be caused, also, by certain irritant poisons, of which cantharides is the most important. Occasionally it is directly dependent on decomposition of retained urine, but more commonly this aggravates inflammation originating from other causes.

ACUTE CYSTITIS.—The *Symptoms* of cystitis consist not only in local pain and weight about the hypogastric and iliac regions, with tenderness on pressure in these situations, and a good deal of constitutional irritation, but in the existence of extreme irritability about the bladder. So soon as a few drops of urine collect, they excite so much irritation that they cannot be retained, and are expelled by a kind of spasmodic or convulsive effort, constituting *strangury*, often accompanied by a good deal of tenesmus and great suffering. The urine will be found to be high colored, mixed with more or less mucus or pus, and often tinged with blood.

Termination.—An acute attack of cystitis usually terminates in the chronic

form of the disease, and thus gradually undergoes resolution. Occasionally, however, it terminates fatally; and, when this is the case, the urine becomes excessively foul, and death takes place from septicæmia, suppurating kidney, or, more rarely, from peritonitis. The temperature, which at first may have been elevated, gradually sinks, the tongue becomes brown and dry, the pulse rapid and weak, and the patient sinks into a drowsy, semi-comatose state before death. On examination after death, the bladder is found to contain foul urine mixed with mucus; the mucous membrane is of an intense purple color, and frequently covered in parts by an adherent membranous layer almost like that of diphtheria. In other cases, the inflammation has gone on to gangrene of the mucous membrane, collections of pus may be found in the substance of the wall of the bladder, and not unfrequently the peritoneum is implicated and diffuse peritonitis set up. Occasionally the bladder has been perforated, and infiltration of urine in the deep areolar tissue of the pelvis may be met with. Very commonly the mischief has extended to the ureters and kidneys.

Treatment.—The first step in the treatment is, if possible, to render the urine less irritating by diluting it by the free administration of barley-water or mucilaginous drinks, and by giving liquor potassæ or bicarbonate of potash in doses sufficient to neutralize it. The patient must be confined to bed, and hot fomentations or poultices applied over the lower part of the belly. Long-continued hot hip-baths usually give great relief. To these means may be added the administration of henbane in full doses and morphia suppositories. No specific medicines are of any use. No instruments should be used during acute cystitis if they can possibly be avoided; but should the urine become foul, an attempt may be made to wash out the bladder, as the mechanical irritation of the catheter is a less evil than an accumulation of putrid mucus and urine. If it be necessary to do this, great gentleness must be used, the quantity of fluid injected being limited to about an ounce. The diet must be carefully regulated; no salt or spiced food must be allowed. As a rule, a pure milk diet will be found the best.

CHRONIC CYSTITIS.—Chronic cystitis is by far the most common morbid condition of the bladder. It may follow acute inflammation, the intensity of the process gradually subsiding, or it may from the first be chronic. It is met with in all cases of stone in the bladder after the disease has existed for a certain time; in all old and tight strictures; and it is the inevitable consequence of the presence of decomposing urine in the cavity of the bladder. In some cases it is apparently of gouty origin; but perhaps the most persistent form is that which sometimes follows gonorrhœa, which may be acquired in youth, and lead to life-long misery.

Pathological Changes.—On examining the bladder of a patient who has suffered from chronic cystitis, the mucous membrane will usually be found to be of a dark gray or slate color. As in most cases there has been some exacerbation of the condition immediately before death, dark red or purple patches are usually seen in various parts, especially on the summits of the rugæ. Dilated and tortuous veins commonly ramify on the surface, the blood in which is usually blackened by the contact of the decomposing urine after death. The mucous membrane is tougher and thicker than natural, and not uncommonly there is distinct thickening and induration of the submucous tissue. Ulceration of the mucous membrane is occasionally met with. The muscular coat of the bladder is seldom unaltered, as in the great majority of cases chronic cystitis is associated with conditions which interfere with free micturition. If the obstruction has been of such a kind that no amount of increased force could have emptied the bladder, as in many cases of enlarged prostate, the bladder is dilated, and its muscular coat may be thinned and atrophied with an excess of fibroid tissue between

the muscular elements. In cases of stricture of the urethra, and other obstructions which can be overcome by increased force, the bladder is usually contracted, and its muscular wall greatly hypertrophied and thickened. The hypertrophied fasciculi of muscular tissue form folds or ridges beneath the mucous membrane, having irregular depressions between them, so as to cause the interior of the bladder to resemble somewhat the inside of one of the cavities of the heart, with its projecting columnæ carneæ. The hypertrophy is usually dependent on the same cause that has given rise to the chronic inflammation, but in some cases cystitis alone may cause the hypertrophy. It would, then, seem to be due to the obstruction caused by the thickropy mucus, which requires greater force for its expulsion than healthy urine, and it is consequently only an indirect effect of the inflammation. Sacci are commonly found projecting at the posterior and lateral parts. These are of two kinds, both of which are formed by projections between the fasciculi of the wall of the bladder. In the first and least common kind, the muscular as well as the mucous coat is pushed outwards; in the second form, the mucous coat alone forms a kind of hernial protrusion (Fig. 911). In the sacci thus formed, accumulations of various kinds may take place; mucus, pus, phosphatic deposits, and even calculous concretions, not unfrequently being met with in these situations. The urine, mixed with mucus and pus, retained in these pouches, where it undergoes decomposition, is the cause of the great fetor of the urine in such cases, and of the difficulty in cleaning such bladders by washing them out. Sometimes ulceration takes place as a consequence of the irritation of the fetid accumulation, and perforation may occur, followed by peritonitis and death. Ulceration of the mucous membrane and abscesses in the sub-mucous tissue are occasionally met with in bladders which have suffered from chronic cystitis, but they are usually the result of the exacerbation that often sets in before death. The effect of chronic cystitis in causing disease of the kidney has already been described.

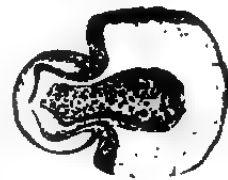

Fig. 911.—Saccus in the Wall of the Bladder.

Symptoms.—Chronic cystitis gives rise to symptoms closely resembling those of the acute form but differing in degree. The diseased and tender bladder is unable to bear more than a slight degree of distention without pain, consequently there is a frequent desire to pass water, and the urgency is such that the slightest delay gives rise to considerable suffering. This pain before micturition is always one of the most prominent symptoms. The fluid is generally ejected forcibly or even spasmodically, and in small quantities at a time. Its passage may be attended by some pain, but seldom enough to be termed strangury. If the cystitis is not complicated by stone, there is distinct relief after micturition. The urine is turbid, always contains an excess of mucus. In slight cases this is small in amount, but more commonly it becomes abundant, viscid, and

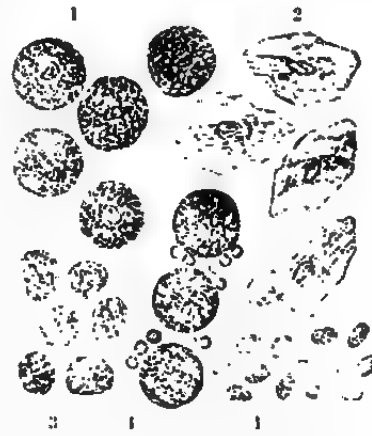

Fig. 912.—Microscopical Appearances in Mucus of Vesical Catarrh. 1, 1. Mucus. 2, Epithelium. 3, Pus. 4 "Organic Globules," met with in the Urine.

All urine undergoing ammoniacal fermentation is found to contain one or more organisms of various kinds. The most constant is a small, ... but with their rod-shaped organisms or bacteria, ... are almost invariably present. These organisms are very generally regarded as the actual ferment, and they are supposed to be carried into the bladder in most cases by instruments used in the treatment of the various conditions upon which the cystitis is dependent. ... cannot be fully discussed here, but it is briefly stated that experiments by Lister and others have shown that urine drawn from the bladder with proper precautions against the access of organisms from the air, into vessels which have previously been exposed to the flame of a spirit-lamp, shows no tendency to undergo ammoniacal decomposition, and may be preserved for months in contact with filtered air without becoming ammoniacal. It is not uncommon, however, in practice, to meet with cases in which the patient has been unable to empty his bladder for many months in consequence of prostatic disease, and yet the urine has remained acid and free from decomposition throughout; at last a catheter is passed, and within three days the urine decomposes and strongly ammoniacal.

These facts seem to suggest strongly that the ferment is carried into the bladder from without. Cases are, however, not unfrequently met with in which the urine is foul, and yet no instrument has ever been passed. In these the explanation suggested is that the mucus secreted as the result of cystitis hangs in the urethra, which is not washed clean at every act of micturition, and constantly forms a channel of communication between the external air and the bladder by means of which decomposition may enter into the bladder. Urine which is mixed with a considerable portion of alkaline mucus decomposes far more readily than the healthy secretion.

The constitutional symptoms of chronic cystitis are chiefly due to the disturbance at night and want of rest, unless the urine is allowed to become foul. If this happen, the ordinary symptoms of chronic renal disease usually manifest themselves, irregular febrile disturbance, loss of appetite, foul tongue, and progressive emaciation.

Chronic cystitis is not unfrequently fatal, death resulting in most cases from septicaemia, or from extension of decomposition to the ureters and pelvis of the kidneys with suppurative nephritis. These conditions are accompanied by the symptoms already described. Chronic cystitis in old patients, the constant disturbance may cause death by exhaustion.

Treatment of Chronic Cystitis.—The treatment of chronic cystitis must have reference to its cause. If it be due to stone or stricture,

permanent improvement can be obtained till these causes are removed, but before undertaking this, if the symptoms are verging on those of the acute form, hot hip-baths, fomentations, mucilaginous drinks, henbane, with alkalis, and especially potash, will be found most useful. The bowels must be kept regular by enemata or castor oil. If there should be strangury, morphia or belladonna suppositories will give most relief. By these means the disease may be prevented from assuming the form of chronic vesical catarrh; but in order to insure this it is most important that decomposition of the urine should be prevented, or if it have already commenced that it should be arrested. For the prevention of the decomposition all instruments should be washed in carbolic acid lotion (1 in 40) before being used, and then greased with "Lund's oil," composed of absolute phenol, 1 part; castor oil, 4 parts, and olive oil, 15 parts; or with the following, which has the advantage of not crystallizing in water: absolute phenol, 1 part; castor oil, 7 parts; and almond oil, 8 parts. The penis may also be washed with boracic acid or carbolic acid lotion after micturition and covered with lint soaked in glycerine of carbolic acid, or a piece of salicylic wool. If the urine has once become foul, it becomes necessary to adopt local means to correct it. No good can be expected from medicines so long as the bladder is full of putrid mucus and urine. The bladder must therefore be washed out with some antiseptic solution, once, or if necessary, twice daily. This is done as follows, a soft catheter is passed and the urine drawn off, about two ounces of fluid are then thrown in from an India-rubber bottle fitted with a brass nozzle and stop-cock. The fluid is then allowed to run out again, and this is repeated till that which comes back is quite clean. Nothing is gained by injecting larger quantities, which only cause needless pain and irritation. There is another method of washing out the bladder which will often be found useful. It consists in attaching an India-rubber tube, about three feet long to the catheter. At the other end of the tube is a glass funnel. By raising the funnel about two feet above the patient's body and pouring the fluid into it, sufficient force will be obtained to fill the bladder. When sufficient fluid has entered, the funnel may be allowed to hang over the side of the bed over a vessel, when the fluid will be withdrawn from the bladder, the tube acting as a siphon. Amongst the most useful of all antiseptic injections is permanganate of potash; the solution may be injected repeatedly till it comes back purple. Its effect is, however, very temporary, and it is well after the bladder has been cleaned by Condy's fluid and water, to throw in a small quantity of some more powerful antiseptic. Perhaps the best of these is quinine, in the strength of two to three grains to the ounce of water, with a minim of dilute sulphuric acid added for each grain; of this about one drachm may be left in after the catheter is withdrawn. Other antiseptics also are useful, as boracic acid, a concentrated solution; iodoform, or mercury gr. 1 to 5*ss*, a concentrated solution of thymol; dilute nitric acid $\text{m} \frac{ij}{j}$ to $\frac{5j}{j}$, etc. One of the most efficient of all antiseptics I have found to be iodoform, in the proportion of from two to four grains to the ounce of water, with a little mucilage to suspend it. The only drug which seems to exert any influence over the decomposition of urine in the bladder is benzoic acid. This becomes converted into hippuric acid, and is discharged in that form with the urine. It may be given in ten-grain doses three or four times a day, either in pill or in a mixture containing mucilage to suspend it.

When by these means the urine has been brought into a tolerable healthy condition, so far as putrefaction is concerned, there still may continue a considerable excess of mucus which renders it prone to decompose, and unless constant care is exercised the patient may speedily relapse. To check this

various astringent injections are sometimes of use, such as tannin (gr. j to ʒj); acetate of lead (gr. i to ʒj); or nitrate of silver (gr. i to ʒj).

Simultaneously with antiseptic or astringent injections, medical treatment may also be carried out. The greatest benefit will be derived from warm, stimulating and balsamic diuretics. Amongst the best of these are infusion of buchu, uva ursi, and triticum repens; but these remedies are useless, unless taken in quantities of a pint or a pint and a half in the day. When the disease is very chronic no remedy appears to me to possess so much influence over the mereropy mucoid discharge as the balsam of copaiba. Turpentine, cubeba, and tincture of the sesquichloride of iron, will be found useful. It is often difficult to say beforehand which diuretic will suit best, and I can lay down no precise rules to guide the practitioner in this respect. But they may often be tried or alternated with advantage. In many cases great relief is obtained from each new remedy, but it is not maintained.

The diet must be very carefully attended to; no hot or spiced food should be allowed, and little or no salt. Alcoholic stimulants are better entirely avoided, but should any be required weak gin, or Hollands and water, or whiskey and water are the best. Coffee must be strictly forbidden, but weak tea may be taken without restraint. Much benefit may often be derived from a pure milk diet for some weeks if the patient can bear it; if it prove too rich, the cream may be taken off. A course of one of the alkaline mineral waters may sometimes prove of service, especially in gouty subjects. The body must be warmly clothed and all exposure to cold avoided.

IRRITABILITY OF THE BLADDER.—This is not a disease, it is merely a symptom. It is of very frequent occurrence and is met with at all ages, and arises from a great variety of causes. It consists in a frequent desire to pass water, not dependent on an increase in the quantity of the secretion. The desire is usually so urgent as to amount to actual pain, and in extreme cases it is impossible to delay the act by any voluntary effort. The urine is generally ejected forcibly, or even spasmodically, and in small quantities at a time. It may or may not be attended by strangury according to the cause, and the part affected. Strangury is most marked in those cases in which it is due to disease of the prostate or neck of the bladder.

Causes.—Irritability of the bladder may arise, as has already been stated, from a great variety of causes. These differ somewhat as the disease occurs in men, in women, or in children. The causes of irritability of the bladder in men may be arranged under the following heads.

1. *Morbid Conditions of the Urine.* If this secretion be preternaturally acid and loaded with lithates, or uric acid, it is especially apt to occasion an irritation of the bladder, attended by pain and a frequent desire to expel the offending fluid. Urine containing oxalates in large quantity is sometimes, though more rarely, a source of irritability of the bladder, which in these cases is perhaps increased by the morbidly sensitive state of the nervous system sometimes coexisting with these conditions of the urine. Amorphous phosphates passed at the end of micturition may cause severe pain, with a constant desire to pass water, lasting for an hour or less. It passes off as soon as the alkaline-tide in the urine has passed.

In *gout*, irritability of the bladder is not unfrequently met with. This may in some cases be owing to the acid character of the urine; in others, to the excitation of a distinct gouty inflammation of the bladder and prostate, coexisting or alternating with the articular form of the disease.

2. *Renal Disease.* more particularly the lodgement of a stone in the kidney, will often occasion sympathetic pains in the bladder, with much irritability of that organ, so as closely to simulate vesical disease, or even to lead to a suspicion of the existence of stone in the bladder. Tuberculous pyelitis will

give rise to similar symptoms, in fact in some cases the frequency of micturition may be greater than in almost any other affection of the urinary organs.

3. *Disease of the Bladder itself*, as a chronically inflamed state of its mucous membrane, will give rise to pain and irritation on the accumulation of a small quantity of urine, with frequent desire for its expulsion. So, also, when the interior of the organ is fasciculated, or sacculated, and more especially if there be a tumor in a state of ulceration, a degree of morbid irritability will be induced, often of the most severe and intractable kind.

4. *The Lodgement of a Stone in the Bladder* will always, by its mechanical action, by its weight and pressure, by rolling about when the body is in motion, irritate the interior of the organ; and, in fact, the "rational symptoms" of stone in the bladder are simply those of irritability of that organ.

5. *Inflammation, Ulceration, Abscess, Tubercle, or other Diseases of the Prostate*, and inflammation, gonorrhoeal or simple, and abscess or stricture of the deeper portions of the urethra, also not unfrequently occasion irritability of the bladder.

6. *Various Diseases in Neighboring Organs* will occasion this condition. Amongst the most frequent are fissure and ulcer of the rectum and anus, piles, prolapsus, intestinal worms, gall-stones, and varicocele.

Diagnosis.—The diagnosis of irritability of the bladder is made by the patient himself; but it is often a matter of no little difficulty to the Surgeon to ascertain the precise cause of that irritability. This can of course be done only by a careful surgical exploration of the whole of the urinary organs, and often of the neighboring parts; no mere inquiry into the nature of the symptoms can do more than establish the fact of the existence of "irritability of the bladder," and afford some evidence of a negative kind as to the absence of certain causes. But nothing short of a careful surgical exploration by means of the catheter, finger, and sound, of the urethra, prostate, and bladder, can enable the practitioner to state with absolute certainty on what this condition of irritability depends. I have repeatedly seen cases of stone in the bladder, and of prostatic disease, vainly treated by medical means for months as cases of simple "irritability of the bladder;" the existence of the real cause of the symptoms having been overlooked altogether, until a proper surgical examination of the urinary organs was instituted. So closely, in fact, do the symptoms of vesical irritation, arising from gout, or sympathetic with kidney disease, simulate those that are occasioned by stone in the bladder, that it is impossible for the most experienced medical practitioner to refer them with certainty to the right cause without exploring this cavity. I have known several patients who had been operated on for stone, and who, some years afterwards, suffered from gouty irritability of the bladder, imagine, but erroneously, that they were laboring under a recurrence of the calculus, so closely do the two classes of symptoms coincide in character.

A few cases, however, will be met with now and then, in which, in spite of the most careful examination and prolonged observation, no tangible cause will be found for the irritability of the bladder.

Treatment.—In the treatment of irritability of the bladder it must be borne in mind that this condition is not a substantive disease, but is an assemblage of symptoms resulting from the influence of a great number of very various causes, which must first be removed before the bladder can recover its normal sensibility and tone. When once the occasioning cause has been removed, whether that be a calculus, or gout, or prostatic disease, or a pile, such local vesical irritability as may remain may be removed by alkaline and mucilaginous drinks. Sedatives may be of use; some in one case, others in another.

Opium and belladonna, either by mouth or in suppository, are amongst the best. Henbane, or Indian hemp, suits some patients; and chloral is amongst the most generally useful remedies. The diet should be carefully regulated, and warm hip-baths used frequently.

Cystotomy.—In cases in which no tangible cause can be found and removed, and which prove hopelessly intractable to every means of treatment local and constitutional, nothing can be more miserable than the state of the unfortunate victim of an "irritable bladder." In such extreme and long-continued cases in which the patient's life has become a burden to him, in which every constitutional remedy and local sedative has been unavailingly tried, the idea has occurred to Surgeons of incising the inflamed and diseased parts by an operation as for lithotomy. Guthrie, who in 1834 strongly recommended this procedure, states that Sir W. Blizard successfully practised it in several cases as far back as 1806, dividing the enlarged prostate and neck of the bladder with a double gorget. Of late years it has been proposed to make an incision as for median or medio-lateral lithotomy, into the neck of the bladder, and by introducing a caoutchouc tube, allow the urine to drain away. This operation has proved successful in the hands of Verneuil, and is certainly a proper procedure in hopelessly chronic and otherwise incurable cases.

Irritability of the Bladder in Boys may, as in adults, arise from a variety of causes. Among the less common is stone, but this should always be excluded first by careful sounding lest time be lost in useless treatment of some other supposed cause. A long foreskin, especially with accumulation of the preputial secretion beneath it, or a phimosis, may give rise to considerable frequency of micturition and pain in a young boy. If neither stone nor phimosis be present the urine should be examined, and possibly a deposit of uric acid may be present, which is not uncommon in young children who are overfed or exposed to an impure atmosphere in a crowded city. If much mucus be present, or even pus, it may be due to chronic cystitis. This affection appears to be analogous to the strumous inflammation of the mucous membranes of the eyes, nose, and throat, that commonly occur in scrofulous children. In this condition the child passes water with great frequency and with much pain; the urine is offensive, and usually phosphatic; there is much uneasiness complained of about the groins and along the penis; in fact, many of the ordinary symptoms of stone are present. On sounding the bladder, it will be found roughened, fasciculated, and often containing sabulous matters mixed with mucus. Occasionally, though rarely, tubercular disease of the urinary tract is met with in children. It presents the same appearances as in the adult. Irritable bladder in children is very frequently due to thread-worms in the rectum, which should always be sought for in all doubtful cases. More rarely it may arise from the presence of a polypus.

The *Treatment* consists in removal of the cause when this is possible. In the strumous affection of the mucous membrane, if the urine be foul, the bladder must if possible be cleaned out as in the adult, should the child be old enough for this to be done. The bladder may also be washed out from time to time with a weak solution of nitrate of silver. Beyond this the treatment consists in attention to the general improvement of the health, in the removal of intestinal irritation, in the regulation of the digestive functions, and in the administration of copaliba in small doses, either alone or combined with a few minims of liquor potassæ.

Irritability of the Bladder in Women often simulates stone so closely, that it is only after very careful sounding that the Surgeon is satisfied that no calculus exists. This condition may arise from a variety of causes, simi-

lar to those described at p. 988, as occasioning irritability of the male bladder. There are some conditions, however, in which it occurs, that are peculiar to women. 1. It may be a truly neurotic or hysterical affection. 2. It is often sympathetic: being connected with some local disease of the genito-urinary organs, with a vascular tumor at the meatus of the urethra, or with some congestive affection of the uterus, which will require to be cured before the bladder can be brought into a sound state. 3. Prolapsus of the anterior wall of the vagina, drawing down the corresponding portion of the bladder, will keep up this condition; if so, the prolapsus must be cured by some plastic operative procedure. In all circumstances, however, when this state has once been set up, it is very difficult to remove. 4. In many cases it is undoubtedly due to the irritation produced by a morbid state of the urine, dependent on mal-assimilation, and usually connected with an excess of lithates. In cases of this kind, careful regulation of diet, and the administration of potash with henbane, will afford much relief; but the complaint is of a very intractable nature, and under the most careful treatment will often continue for years. 5. In strumous girls it may be due to a congested, thickened, and irritated state of the vesical mucous membrane, similar to that which is met with in other parts of the body, as the eyelids, nose, and throat. It is commonly associated with a muco-purulent discharge from the vulva. In cases such as these, the patient requires to be put upon a general anti-strumous treatment, and the bladder should be mopped out with a very strong solution of the nitrate of silver. This is best done by dilating the urethra, passing a silver tube into the bladder, and then through it a small sponge-probang charged with the solution.

ATONY OF THE BLADDER.

By *Atony of the Bladder* is meant such a degree of weakness of this organ that its power of emptying itself is partially or wholly lost. It is in the great majority of cases a condition of old age, and is not to be confounded with paralysis of the bladder, such as occurs in cases of injury or disease of the spinal cord. In atony, the nervous supply is unimpaired, it is the muscular tissue that is at fault. The muscular tissue of the bladder may be impaired from several causes. By far the most common is the chronic strain to which it is exposed in over-distention of the bladder from mechanical obstruction at its neck, arising from enlargement of the prostate. In this condition, if the dilated bladder be examined microscopically, its walls will be found to contain a great excess of somewhat dense fibroid tissue, amongst which lie scattered patches of muscular tissue.

In some rare cases, atony of the bladder may result from a single, prolonged, voluntary or involuntary over-distention. In such cases, the structural changes just described would, of course, not be present.

Besides these, there is another variety of atony of the bladder commonly met with in early middle life, though it may occur at any age. In all the cases in which I have seen this form of atony, it has been the consequence either of gonorrhoeal cystitis or of cystitis following lithotripsy. It may lead to partial or complete retention. It is often, but not always, associated with vesical catarrh and fetid urine. This condition, when once it has become chronic, is, I believe, incurable. In it, structural changes take place in the bladder consequent upon the extension of the chronic inflammatory process from the mucous membrane to the submucous tissue and muscular coat. Its walls become thickened, rugged, and pouched. The bladder is able neither to retain the normal amount of urine, nor completely to empty itself. The

retained urine usually undergoes decomposition, and this condition is very apt to end in fatal disease of the kidneys.

Excluding all these conditions, there is yet another form of atony of the bladder which may be regarded as the most typical variety. It is essentially a condition of old age, and appears to be a senile degenerative change analogous to those of the heart and other organs so commonly met with at the time of life. Such a change occurring in a bladder causes its distention from slight causes of obstruction, which could be readily overcome by the healthy organ of a younger man. Thus, we not unfrequently see a dilated atonic bladder occurring as the result of stricture of the urethra in an old man, instead of the contracted hypertrophied organ commonly met with as the result of this disease. A strong bladder may overcome a moderate amount of obstruction to the escape of the urine—an atonic bladder utterly fails to do so. Thus, we see that a condition of atony of the bladder may occur in an otherwise healthy man from the obstruction of prostatic disease, while, on the other hand, a degree of obstruction that would be harmless to a healthy man may cause serious symptoms in one whose bladder is atonic to begin with. It is difficult to determine in most cases which is to be regarded as the primary condition. The fact that atony of the bladder is rarely met with in women would suggest that in the great majority of cases mechanical obstruction from enlargement of the prostate is to be regarded as the primary factor in the production of the disease.

Symptoms. When this condition comes on slowly as the result of advancing years, the patient usually finds that the urine escapes in a dribbling manner; that there is some difficulty, and at last an impossibility, in emptying the bladder completely; that there is not that forcible ejection of the last drops of urine that is characteristic of a healthy tone in the organ: at the same time, there is not unfrequently a tendency to the dribbling away of a few drops towards the end of the emission of urine, and after its apparent cessation. The patient feels a desire to pass water more frequently than usual. He cannot retain his water for more than an hour or two—is often disturbed during the night, and if he does not at once obey the impulse, is apt to wet his clothes. This frequent desire to pass water is due to the bladder never emptying itself, a certain quantity—several ounces—of residual urine being left behind; by the addition of a small quantity, the bladder becomes overloaded, and the desire to micturate is felt. Temporary relief is afforded, but as secretion continues the bladder soon fills up again, and so the process goes on. When complete retention occurs, whether this take place gradually or suddenly, the bladder slowly enlarges, rising out of the pelvis into the abdomen, stretching up into the hypogastric region, reaching even as high as the umbilicus. On examining the lower part of the abdomen, the organ will be felt hard, elastic, rounded, and pyriform in shape, projecting above the pubes, and feeling much like an enlarged uterus. In this situation, also, percussion will elicit a dull sound; and on exploring the part through the rectum, the bladder will be found to project in this direction also; and on tapping with the fingers above the pubes, fluctuation may be felt through the wall of the gut.

The distention of the bladder is sometimes so very gradual and slow, that the over-distended organ has been mistaken for an abdominal tumor. No pain and but little inconvenience is felt; the urine dribbles away; but at the end of two or three months the over-distended bladder is felt as a large, firm, elastic, and rounded tumor, stretching up to, and, perhaps, above the umbilicus. (Edema of the legs may occur from its pressure on the iliac veins.

Atony of the bladder is a sufficient cause for incomplete retention of urine

But it does not appear to be adequate to explain the complete retention with distention of the bladder, that is commonly seen. For this to occur, there must be some mechanical obstacle, however slight, to the outward flow of the urine—contraction of the neck, or a congested or enlarged prostate. Could complete retention occur from a merely atonic bladder, we should meet with it as frequently in women as in men. It is the mechanical obstacle at the neck of the male bladder which intensifies the effects of its atony and leads to the complete stoppage.

After the bladder has once become distended, the retention may be complete, but it more commonly happens that a quantity of urine continues to dribble out of it; in fact, the amount that escapes in this manner may be very considerable, though the retention continue unrelieved. This *retention with dribbling* is a condition of much practical importance, as the continued escape of urine may lead the patient, and even the Surgeon, to overlook the true nature of the disease; the more so, as in elderly people retention slowly induced often occasions but little inconvenience. I have drawn off nearly a gallon of urine from a patient in whom it had not been suspected that retention existed, in consequence of the continuance of this dribbling. In women, retention is not by any means so common as in men, but the bladder will sometimes attain an enormous size, rising as high as the umbilicus; and such large bladders have been tapped under the supposition of the tumor being an ovarian cyst, or some similar growth. I once witnessed such a case in which the Surgeon, to his surprise, on tapping the tumor, drew off a quantity of clear and healthy urine, instead of ovarian fluid; fortunately, no bad effects followed. This retention with dribbling occurs in consequence of the bladder, as it rises out of the pelvis, elongating its neck; and as the body becomes bent forward over the pubes a sharp curve or angle is formed at the junction of the neck and body of the viscus, through which a small stream of urine continues to dribble away, and escapes rather by its own gravity than by any expulsive effort on the part of the patient.

Diagnosis.—Retention from *Atony* can easily be diagnosed from retention from *Obstruction*. In the former, on introducing the catheter when the patient is lying on his back, the instrument will not only readily enter, but the urine will simply flow out in a slow uniform stream, not being projected in a jet by the contraction of the walls of the organ, but rising and falling in obedience to the respiratory movements, or to the contractions of the abdominal muscles. In retention from obstruction there will be experienced some difficulty in passing the instrument at some one point, either in the urethra or prostate; and when once it is introduced into the bladder, the urine will escape in a free and far projected stream.

Results.—The habitual retention of a small quantity of urine in an atonic bladder which is incapable of discharging completely the whole of its contents occurs much more frequently than is suspected. The quantity thus retained will vary from an ounce to half a pint: the patient believing that he has emptied his bladder. The existence of this residual urine is readily determined by telling the patient to try to empty his bladder. He thinks he has done so, but the introduction of a catheter will prove the existence of retained urine. This condition will be a source of serious inconvenience, and eventually of disease, to the patient. In consequence of the bladder never being completely emptied, there will be frequent, sudden, and almost irresistible calls to pass urine, so as to simulate irritability of the bladder. The retained urine becomes offensive, ammoniacal or fishy in odor, and mixed with mucus or mucopus. The constituents of the urine become reabsorbed or are not excreted, derange the health, give rise to impaired nutrition, and, being eliminated by the skin, irritate it and occasion intractable forms of

skin-disease. I have seen chronic eczema of the most inveterate character produced in this way, and yield to treatment only on care being taken to keep the bladder clear and free from residual urine.

The effects of retained urine and of retention are not identical. In retained urine the general health suffers, the patient becomes slowly poisoned by the inability to get rid of an excretion. In retention the danger is more immediate and directly dependent on the liability to secondary disease of the bladder and kidneys. Subacute cystitis, followed by low fever, will come on as the result of the continued over-distention of the bladder. The symptoms are such as described at p. 880 as being indicative of urinary fever. The patient suffers from chills and small rigors, followed by depression and low spirits. Fever of a typhoid type comes on, with brown tongue, occasional retchings, mild delirium, and great prostration of strength. This condition occurring in an aged man long suffering from atony of the bladder, with most probably an unsound state of the kidneys secondary to this, is commonly fatal. It is thus that chronic retention from bladder-atony destroys life, not by ulceration of the organ or by extravasation of urine, which does not occur in these cases as in other forms of more acute retention.

Treatment.—Atony of the bladder, except in a few cases that arise from a single over-distention, is an incurable affection. It is dependent upon senile changes in the viscus of an organic character that may be relieved but cannot be remedied. The great danger in this state arises from the retained urine, even though retention be by no means complete. So long as this residual urine is in small quantity no harm results. Even when it accumulates so as to amount to several ounces, it may give rise to no symptoms beyond frequency of micturition. Sooner or later, however, the over-distention causes some irritation of the bladder, and the urine becomes cloudy from excreta of mucus. Decomposition of the retained urine then frequently takes place, either from extension of decomposition down the urethra or after the passage of instruments, as already described. It must not be supposed that mere retention of a small quantity of urine after each act of micturition is sufficient in itself to cause decomposition. Nothing is more common than to find patients who have not emptied their bladders for many months, and yet whose urine is perfectly normal in every respect. The statement sometimes made that decomposition never takes place till after an instrument has been passed, is, however, not accurate, although in the great majority of cases the urine becomes ammoniacal only after surgical interference. When this takes place all the symptoms of chronic or subacute cystitis set in. Febrile disturbance of the type of chronic septic poisoning sets in, and death may follow. This is more especially likely to happen when the kidneys are affected by chronic interstitial nephritis, which, as already pointed out (p. 884), is a common result of prolonged over-distention of the bladder.

The primary object of all treatment in ordinary uncomplicated senile atony of the bladder is to free the patient from the residual urine, which he is no longer able to expel. This can be done only by the use of the catheter, and it is the duty of the Surgeon to teach the patient how to use this instrument for himself, so that at all times he may be the master of his own situation, and relieve himself when necessary.

The commencement of "catheter-life," as it has been appropriately termed by Sir Andrew Clark, is an important period in a man's existence. For when once the use of the instrument has been begun, it can rarely be discontinued. Hence it is well not to begin it unnecessarily early. But it is of at least equal importance not to fall into the opposite error of delaying its use too long, lest the residual urine be allowed to accumulate to such an extent as to

become a source of discomfort to the patient, of injury to his general health, and of danger by inducing septic cystitis and all its concomitant evils.

The use of the catheter in cases of atony of the bladder for the removal of residual urine is a very simple business, and, if the kidneys be sound and the most ordinary precautions taken, unattended by any danger. The safest catheter to use is a soft one. Metallic instruments need not be used by the Surgeon, and should never be employed by the patient himself. The ordinary elbowed prostatic catheter, or the conical one with a bulbous end of medium size, will be found the most convenient. This should be passed whilst the patient is standing up, with every possible care and gentleness. The instrument should be lubricated with an antiseptic oil. After and before use the instrument must be washed in cold carbolized water, so that all chance may be avoided of fermentative material being carried into the bladder, and thus leading to putrefaction of the urine. At first it may be quite sufficient if the residual urine is drawn off every third or second day. After a time this will be required once or twice daily. Until the patient becomes accustomed to the use of the catheter all unnecessary exertion, fatigue, and, above all, chills, should be most carefully avoided. When once the habit has been established, these precautions may be relaxed, *provided there is no evidence of renal disease*, and the urine continues clear and healthy.

The catheter must not be retained lest it occasion subacute cystitis. If, as often happens in senile atony, the prostate is somewhat enlarged, care must be taken that the catheter really enters the bladder, and that the dilated prostatic urethra be not alone emptied. The weight of the residual urine causes the fundus of the bladder to pouch behind the prostate. This pouch must be thoroughly emptied by slowly withdrawing the catheter when the body of the bladder has been drained. Should subacute cystitis come on, with decomposition of urine, during the treatment, the bladder must be washed out after emptying, with antiseptic lotions of the permanganate of potash, quinine, or iodoform.

When once a bladder has become atonic in advanced age, it never completely recovers its contractility. The regular use of the catheter becomes imperative, and, by taking off the habit of retention and of overloading of the bladder, it may do much to restore the normal contractility, in some degree at least. When once fairly established, "catheter-life" may continue for many years without discomfort or appreciable danger.

No medicines are of any special service in these cases; except, perhaps, nux vomica or strychnine in small doses long continued. The general health must be attended to on ordinary principles; and it must not be forgotten that one great difficulty and source of disease in advancing years is for the system to rid itself of its excreta—to clear away its own ashes—from organs and tissues, and that the residual urine found in an atonic bladder is but one, though possibly the most obvious evidence of this lack of power.

The treatment of that form of atony of the bladder which arises in younger subjects, as the effect of gonorrhoeal cystitis or stone in the bladder, consists in the daily use of the catheter with the same precautions that are to be adopted in cases of senile atony. Whenever the urine becomes turbid or offensive, antiseptic injections must be used to clear the bladder. All this the patient may, in most cases, be readily taught to do for himself. When once he has acquired the art of auto-catheterism, he may pursue the ordinary business of life with comfort and without peril. But he must never relax his care of himself, lest subacute cystitis may come on, or phosphatic deposits form in the bladder.

INCONTINENCE OF URINE.—This term is usually applied to all cases in which the urine is passed involuntarily. It occurs in three forms: 1. Passive

incontinence in which the urine dribbles away as fast as it is secreted the bladder remaining empty. 2 Distention of the bladder with overflow. Active incontinence in which the bladder is emptied involuntarily at intervals by its own contraction.

1. **Passive Incontinence** arises most commonly from paralysis of the neck of the bladder, from disease or injury of the spinal cord. It is occasionally met with in children from causes that are not clearly ascertained. It is stated that it has been known to arise from impact of a candle in the neck of the bladder in such a way as to prevent its closure, and to leave insufficient room for the urine to pass. Very rare cases have been recorded occurring in later life in which it was due to enlargement of the middle lobe of the prostate, with a middle lobe situated between them in such a way as to keep them apart, and yet not to block the opening into the urethra. In tubercular disease of the prostate, with extensive destruction of the middle lobe, complete incontinence may occur. Passive incontinence is occasionally met with in women, as the result of dilatation of the urethra for the removal of stone.

2. **Distention of the Bladder with Overflow**, as it is termed by Thompson, may be due to atony of the bladder (p. 1903), or to enlargement of the middle lobe of the prostate. The effects of atony in causing overflow of urine have been already described; overflow from prostatic disease is described subsequently. It is of the utmost importance that this condition should be distinguished from true incontinence.

3. **Active Incontinence** is met with most frequently in children, and by a rule, not constant, occurring only at night. It occurs almost invariably in boys. It seems to arise in some cases from the patient losing control over the sphincter during sleep, so soon as a small quantity of urine has accumulated behind it. This troublesome condition may last to adult age and is a source of great misery and discomfort. In children it is in some cases sympathetic, being dependent on the irritation of a tight bowstring, worms in the rectum, or of a polypus. In other cases it may be merely a symptom of stone in the bladder. In strumous children, nocturnal incontinence may be produced by the irritation of urine containing uric acid crystals. All these conditions must be carefully sought for in every case, and removed if possible.

Treatment.—In true incontinence little can be done beyond providing the patient with a proper India-rubber urinal, which can be worn day and night. The treatment of overflow consists solely in the periodical use of the catheter (p. 1905). In the nocturnal incontinence of children, if it be not connected with some evident source of local irritation, which should then be removed, the administration of tonics will be found useful, either quinine or tincture of perchloride of iron, alone or combined with tincture of cod-liver-oil. If there be irritation of the mucous membrane of the bladder, administration of alkalis, in conjunction with a tonic, as the potassium of iron, or a little copaiba mixed with honey, will be found very serviceable. Cold sponging, light clothing at night, and means calculated to break the habit, such as waking the child at the time at which it generally occurs, or changing his position in bed, etc. should not be omitted. Of all remedies for incontinence of urine in children, belladonna is the most specific. Ringer advises it to be given in full doses; from 10 to 20 minims of tincture three times a day.

Hysterical Retention and Incontinence of Urine not unfrequently occurs in nervous girls, and require to be treated by antihysterical remedies, amongst which preparations of perchloride of iron, either alone or combined with cod-liver-oil, will be found most useful. Cold douches are also of great service.

In cases of hysterical retention, it may sometimes be necessary to use the catheter; but in such circumstances it is well not to employ this instrument too frequently, as the patients are apt to get into the habit of having it introduced, and will, with that morbid propensity that characterizes hysteria, continue for a length of time to require its introduction. If left to themselves, though the bladder may become much distended, it will not burst but will probably empty itself without further trouble, particularly if the patient be put into a tub and well doused over the hips and loins with cold water. In some cases, these morbid conditions in women appear to be connected with some local irritation about the urethra or uterus; and then proper treatment must be directed to these organs before the disease can be removed.

PAINFUL CONDITIONS OF THE BLADDER.—The bladder may be the seat of severe pain, either continuous or remittent, without any disease being discernible in it on the closest examination; the pain being either a kind of neuralgic condition, especially occurring in hysterical or hypochondriacal patients: or else being sympathetic with, and dependent on, disease at a distance, as in the kidneys, uterus, rectum, etc. At the same time, it must be borne in mind that the secretion of acid or irritating urine will, in some individuals, be a source of much and constant suffering; and that any disease seated about, or coming into contact with, the neck of the bladder, as tumor, stone, etc., is especially apt to give rise to severe suffering, and will, in many cases, be accompanied by frequent desire to micturate, with much spasm about the part.

TUBERCLE OF THE BLADDER.

Tubercular Disease of the bladder appears to be very rarely primary. It is usually an extension from similar disease of the kidney and ureter, or of the prostate. The bladder usually presents the ordinary appearances of chronic cystitis; but, in addition to these, ulcers are found slightly raised at the edge, having a yellow granular surface, and situate exclusively near the trigone. The symptoms are merely those of chronic cystitis, and often closely resemble those arising from stone. The urine contains pus, usually abundantly. The diagnosis can be made only by the coexistence of tubercular disease elsewhere, more especially in the kidneys, prostate, and testicles. Little can be done in the way of treatment beyond washing out the bladder to diminish pain and the irritation as far as possible. Morphia injections may give great relief.

SACculI OF THE BLADDER.

Sacculi have already been mentioned at pp. 876, 914, and 995, as arising in connection with overdistention of the bladder or obstruction to the escape of urine from it. These are of small size, not usually exceeding a pigeon's egg. They arise, as already described, in the bladders of elderly men who have suffered from severe mechanical obstacles to the passage of the urine, in the shape of stricture or enlarged prostate, are associated with a generally thickened fasciculated state of the organ, and appear to be the result of pressure on the contained urine during efforts at expulsion, causing extrusion of the mucous and serous coats, and perhaps of the thinned muscular coat at some points of least resistance.

Sacs connected with the bladder are, however, occasionally met with, the origin of which can hardly be explained in this way. These may be single or multiple, and may attain an enormous magnitude. The largest I have seen occurred in a man 35 years of age, otherwise perfectly healthy. He was

admitted into University College Hospital, and was under the joint care of Wilson Fox and myself. There was a tense elastic tumor, somewhat rounded, occupying the whole abdomen and extending into the pelvis, to be felt through the rectum. Had it occurred in a woman, the tumor would probably have been pronounced ovarian. The tumor had existed for six months, had gradually increased, but occasioned no uneasiness except by its pressure effects. There was and had been no difficulty in passing urine or in defecation. The tumor was aspirated at its most prominent part, and seven pints of clear urine were drawn off. The patient suddenly became faint, and died of syncope. On examination after death, two cysts were found connected with the bladder, one on each side, by a rounded spring that would admit the little finger. These orifices were equidistant from the mesial line, and about an inch and a half above each ureter. They were thin-walled, composed chiefly of mucous membrane and perhaps possibly having scattered muscular fibres in their composition, both emptied through the bladder by the one puncture. The ureter on each side was adherent to the wall of the sacculus and considerably pressed upon, as the result of this the pelves of the kidneys were dilated, the pyramidal portion of the kidney was absorbed and the cortex greatly thickened and indurated by chronic interstitial inflammation. The bladder was greatly dilated and hypertrophied, its mucous membrane was opaque and white, it showed no signs of old or recent cystitis. The prostate and urethra were healthy, and no source of mechanical obstruction was detected. The cause of the condition is extremely obscure. There is a similar specimen, somewhat less marked, in the museum of University College, the sacculus springs from the same spot, which, indeed, from comparison with other specimens, seems to be the common point of origin of all sacculi of the bladder which reach any considerable size.

TUMORS OF THE BLADDER.

Various forms of tumor, both malignant and simple, are met with in the bladder. The most common simple growth is the **Villous Tumor** or **Papilloma**. It consists of delicate branched processes which, when the growth is immersed in water float out, so that it somewhat resembles a sea anemone. These may spring from a narrow base forming a pedunculated mass, or spread over a considerable area of the bladder wall. The base from which they arise may be almost level with the surface of the bladder, or may form a fleshy mass of some thickness. Microscopic examination shows that each papilla is composed of a fine capillary loop, surrounded by an extremely delicate connective tissue, in some parts almost homogeneous, with numerous rounded or spindle-shaped cells scattered through it. The surface is covered with epithelium of the same character as that of the bladder, but more delicate. The cells are often oval or fusiform, and are arranged in several layers. The delicate epithelium separates almost immediately when the growth is put in water, and is consequently often lost in immersed specimens. The base is composed of loose and highly vascular connective tissue. These tumors almost invariably spring from some part of the trigone, usually near the orifice of one ureter or the meatus internus. They are usually single, but occasionally two or more are found. Sir H. Thompson states that only about one in six or seven are distinctly pedunculated, the great majority being more or less sessile. When pedunculated the pedicle may, in rare cases, be of considerable length, sometimes an inch or more.

Other simple tumors are occasionally met with. Thus in children the

mucous polypi have been observed. They are smooth or nearly smooth on the surface, and composed chiefly of myxoma tissue, similar to that seen in the simple polypus of the nose. In others the connective tissue basis of the tumor was so firm and the papillation on the surface so imperfect that the growth has been described as a *fibroma*. Probably all these growths are closely related to each other, consisting essentially of an outgrowth from the submucous tissue of the bladder. *Myomatous* also, or tumors containing non-striated muscular fibre have been met with springing from the wall of the bladder.

Sarcoma of the bladder has been met with in a few cases. The growth is composed of round cells, or mixed round and spindle cells, and is papillary on the surface. The distinction between this and a papilloma with a thick base which has been inflamed is not easy to make out, and further investigation is required before a clear separation can be made between these tumors; more especially as all new growths in the bladder, whether simple or malignant, tend to assume a papillary form. Sir Henry Thompson describes tumors which, in his opinion, occupy a place between papilloma and sarcoma, and which he terms "transitional."

Symptoms.—Simple tumors of the bladder occur usually in youth or early middle age. The earliest symptom in all forms of simple tumor is hemorrhage. At first it is small in amount and intermittent, but as the disease progresses it becomes more abundant and almost constant. The characteristic sign of hemorrhage from a villous tumor is that the blood is not uniformly mixed with urine, but comes chiefly towards the end of micturition, sometimes dropping away almost pure after the urine has ceased to flow. The quantity may be very large, and clots are often passed. As the disease advances frequency of micturition and the general signs of irritability of the bladder may make their appearance, but hæmaturia may form the only symptom for many months or even years. I have known abundant hæmaturia to continue for many years—for twelve or fourteen—probably from a papilloma, without deranging the general health to so great an extent as might be expected from so continuous and copious a loss of blood. The most important sign, and one which should always be persistently sought for, is the passage of recognizable fragments of the growth in the urine. But little information is gained by sounding; occasionally some irregularity may be felt, but its nature and outline cannot be determined. A hollow sound may, however, return with some of the growth in its eye, and thus determine the nature of the case. Profuse hemorrhage, after sounding, commonly occurs, but is not sufficient to found a diagnosis upon. Examination of the trigone from the rectum never gives any information unless the tumor be very large, when it might possibly be recognized by pressing firmly above the pubes at the same time. Careful examination of the bladder by means of a small flat-bladed lithotrite may detect the presence of the tumor, as in the first case recorded by Thompson.

These tumors occasionally become encrusted with *phosphatic* matter, deposited upon them by the urine, and then they will resemble still more closely a calculus when the bladder is sounded; from it, however, they may be distinguished by their fixed character, and by the impossibility of passing a sound around them.

If the disease be left unrelieved it terminates fatally sooner or later, sometimes by exhaustion from constant loss of blood, but more often by disease of the kidneys induced by the obstruction to the orifices of the ureters by the growth, or by septic cystitis extending to the pelvis of the kidney.

The diagnosis can usually be made by attention to the above points; but should this not be possible, the bladder may be explored in the following

admitted into University College Hospital, and was under the joint care of Wilson Fox and myself. There was a tense elastic tumor, smooth and rounded, occupying the whole abdomen and extending into the pelvis, as to be felt through the rectum. Had it occurred in a woman, the tumor would probably have been pronounced ovarian. The tumor had existed for six months, had gradually increased, but occasioned no uneasiness except at its pressure effects. There was and had been no difficulty in passing urine or in defecation. The tumor was aspirated at its most prominent part, and seven pints of clear urine were drawn off. The patient suddenly became faint, and died of syncope. On examination after death, two sinistral sacs were found connected with the bladder, one on each side, by a rounded pedicle, one of which would admit the little finger. These orifices were equidistant from the mesial line, and about an inch and a half above each ureter. The sacs were thin-walled, composed chiefly of mucous membrane and peritoneum, possibly having scattered muscular fibres in their composition, both were emptied through the bladder by the one puncture. The ureter on each side was adherent to the wall of the sacculus and considerably pressed upon, and as the result of this the pelvis of the kidneys were dilated, the pyramidal portion of the kidney was absorbed and the cortex greatly thickened and indurated by chronic interstitial inflammation. The bladder was greatly dilated and hypertrophied, its mucous membrane was opaque and white, and showed no signs of old or recent cystitis. The prostate and urethra were healthy, and no source of mechanical obstruction was detected. The cause of the condition is extremely obscure. There is a similar specimen, not somewhat less marked, in the museum of University College; the two springs from the same spot, which, indeed, from comparison with other specimens, seems to be the common point of origin of all sacculi of the bladder which reach any considerable size.

TUMORS OF THE BLADDER.

Various forms of tumor, both malignant and simple, are met with in the bladder. The most common simple growth is the **Villous Tumor** or **Papilloma**. It consists of delicate branched processes which, when the growth is immersed in water float out, so that it somewhat resembles a sea anemone. These may spring from a narrow base forming a pedunculated mass, or spread over a considerable area of the bladder wall. The base from which they arise may be almost level with the surface of the bladder, or may form a fleshy mass of some thickness. Microscopic examination shows that each papilla is composed of a fine capillary loop, surrounded by an extremely delicate connective tissue, in some parts almost homogeneous, with numerous rounded or spindle-shaped cells scattered through it. The surface is covered with epithelium of the same character as that of the bladder, but more delicate. The cells are often oval or fusiform, and are arranged in several layers. The delicate epithelium separates almost immediately if the growth is put in water, and is consequently often lost in intermediate specimens. The base is composed of loose and highly vascular connective tissue. These tumors almost invariably spring from some part of the trigone, usually near the orifice of one ureter or the meatus internus. They are usually single, but occasionally two or more are found. Sir Henry Thompson states that only about one in six or seven are distinctly pedunculated, the great majority being more or less sessile. When pedunculated, the pedicle may, in rare cases, be of considerable length, sometimes an inch or more.

Other simple tumors are occasionally met with. Thus in children simple

mucous polypi have been observed. They are smooth or nearly smooth on the surface, and composed chiefly of myxoma tissue, similar to that seen in the simple polypus of the nose. In others the connective tissue basis of the tumor was so firm and the papillation on the surface so imperfect that the growth has been described as a *fibroma*. Probably all these growths are closely related to each other, consisting essentially of an outgrowth from the submucous tissue of the bladder. *Myxomata* also, or tumors containing non-striated muscular fibre have been met with springing from the wall of the bladder.

Sarcoma of the bladder has been met with in a few cases. The growth is composed of round cells, or mixed round and spindle cells, and is papillary on the surface. The distinction between this and a papilloma with a thick base which has been inflamed is not easy to make out, and further investigation is required before a clear separation can be made between these tumors: more especially as all new growths in the bladder, whether simple or malignant, tend to assume a papillary form. Sir Henry Thompson describes tumors which, in his opinion, occupy a place between papilloma and sarcoma, and which he terms "transitional."

Symptoms.—Simple tumors of the bladder occur usually in youth or early middle age. The earliest symptom in all forms of simple tumor is hemorrhage. At first it is small in amount and intermittent, but as the disease progresses it becomes more abundant and almost constant. The characteristic sign of hemorrhage from a villous tumor is that the blood is not uniformly mixed with urine, but comes chiefly towards the end of micturition, sometimes dropping away almost pure after the urine has ceased to flow. The quantity may be very large, and clots are often passed. As the disease advances frequency of micturition and the general signs of irritability of the bladder may make their appearance, but hematuria may form the only symptom for many months or even years. I have known abundant hematuria to continue for many years—for twelve or fourteen—probably from a papilloma, without deranging the general health to so great an extent as might be expected from so continuous and copious a loss of blood. The most important sign, and one which should always be persistently sought for, is the passage of recognizable fragments of the growth in the urine. But little information is gained by sounding; occasionally some irregularity may be felt, but its nature and outline cannot be determined. A hollow sound may, however, return with some of the growth in its eye, and thus determine the nature of the case. Profuse hemorrhage, after sounding, commonly occurs, but is not sufficient to found a diagnosis upon. Examination of the trigone from the rectum never gives any information unless the tumor be very large, when it might possibly be recognized by pressing firmly above the pubes at the same time. Careful examination of the bladder by means of a small flat bladed lithotrite may detect the presence of the tumor, as in the first case recorded by Thompson.

These tumors occasionally become encrusted with *phosphatic* matter, deposited upon them by the urine, and then they will resemble still more closely a calculus when the bladder is sounded; from it, however, they may be distinguished by their fixed character, and by the impossibility of passing a sound around them.

If the disease be left unrelieved it terminates fatally sooner or later, sometimes by exhaustion from constant loss of blood, but more often by disease of the kidneys induced by the obstruction to the orifices of the ureters by the growth, or by septic cystitis extending to the pelvis of the kidney.

The diagnosis can usually be made by attention to the above points; but should this not be possible, the bladder may be explored in the following

manner as practised by Sir Henry Thompson, the exploration being followed, if possible, by removal of the growth, should it seem suited for such treatment.

The patient being placed in the lithotomy position, and a centrally grooved staff introduced, the median perineal section is made upon this, the membranous portion of the urethra opened, and the finger passed into the bladder; the interior of which may thus be reached and explored in all its parts by pressing down the anterior abdominal wall, the muscles of which must be thoroughly relaxed by full anesthesia. Should the papilloma be found, this incision will serve for its removal. Should there be no papilloma, the method of exploration will determine the condition of the interior of the bladder, the presence or not of malignant disease, or of encysted calculus.

The *Treatment* of simple tumors of the bladder was up to a recent period of the most unsatisfactory character. Surgeons usually contenting themselves with restraining the hemorrhage by means of gallic acid and similar astringents. Operative means were seldom employed. It is true that Civiale removed a small growth of this kind situated near the neck of the bladder by seizing and twisting it off with a lithotrite. Warner removed a tumor of this kind the size of an egg from the bladder of a woman after dilating the urethra.

Billroth removed a tumor from the bladder of a boy which proved to be in part a myo-sarcoma in others a myo-carcinoma. It was as large as the fist, and had a pedicle which appeared to be connected with the muscular coat. The operation consisted of cystotomy by the ordinary lateral operation. But as the tumor was too large to be got away through the perineum, the bladder was opened above the pubes by a free transverse cut. The tumor was then torn away by the finger, and the pedicle cut across with a knife guarded by the finger. The patient did well.

Humphry in 1877 operated on a boy who had a tumor in the bladder causing dysuria and hemorrhage. He opened the bladder by lateral cystotomy through the perineum, and removed the tumor with forceps and the finger-nail. It proved to be a fibro-sarcoma. The patient made a good recovery.

Volkmann and Marcacci have both performed supra-pubic cystotomy for the removal of vesical myomata, but with fatal results. In 1881, Ransohoff, of Ohio, removed a tumor as large as a small peach growing from the posterior wall of the bladder. The operation he practised was lateral cystotomy; the tumor was then scraped away by means of one of Volkmann's sharp spoons. The patient recovered after a tedious convalescence.

To Sir Henry Thompson is due the merit of having simplified the operation and placed it on a more definite basis. His operation consists in opening the urethra by the ordinary median perineal section, dilating the prostatic urethra and neck of the bladder with the finger, feeling for the tumor, and then removing it by properly constructed forceps, by which it is seized and crushed or torn away from the mucous membrane. The bladder is then washed out and drained with an elastic tube till all hemorrhage ceases, when the perineal wound is allowed to heal.

Thus it will be seen that three operations have been adopted for the removal of intravesical tumors, viz., cystotomy by the suprapubic method; cystotomy by the lateral perineal incisions, and urethrotomy by the median perineal incisions. The operation that the Surgeon will select must necessarily in a great measure depend upon the size and consistence of the tumor. When this is very large and firm, as in Billroth's and Humphry's cases, cystotomy by one or other of the methods adopted by these Surgeons will be required; when of smaller size and soft, urethrotomy, with dilatation of the

neck of the bladder, as adopted by Thompson, suffices for the extraction of the growth, and being the simpler and less dangerous method should be adopted.

In papilloma and myoma of the female bladder the urethra should be dilated so as to admit the forefinger; along this the sharp spoon, or Thompson's forceps may be slipped and the growth scraped away or crushed off.

CANCER OF THE BLADDER.—The bladder is not a common seat of primary cancer; it is more often implicated by the extension of malignant disease from some neighboring part, as the rectum or uterus. According to Walshe, it never appears before the 40th year. The form of cancer occurring in the bladder as a primary disease is squamous epithelioma. Scirrhus is said to have been met with, but most probably it commenced in the prostate and not in the bladder itself. Epithelioma of the bladder often commences on the posterior surface, extending secondarily to the trigone. The ulcerating surface of the tumor occasionally becomes encrusted with phosphatic deposit, and sometimes a phosphatic calculus may form in the diseased bladder, and thus add greatly to the intense pain that usually attends this affection. The *Symptoms* it gives rise to are intense dysuria, with discharge of blood, and viscid mucus, in which fragments of the tumor may be found. No conclusion of any kind can be drawn from single cells; it is only when a distinct group of cells is found, possibly attached to a portion of stroma, that any opinion can be formed as to their source. In a case under the care of Berkeley Hill, the nest-like arrangement of the epithelial cells was recognized in some fragments passed in the urine. Sir H. Thompson states that the diagnosis of cancer from simple tumors may be made by the age of the patient, and by the fact that pain and frequency of micturition appear early, often before the blood. The rapid progress of the disease, and the intensity of the patient's sufferings, differ widely from the slow progress and slight discomfort caused by simple tumors during the early period of their development.

When secondary to rectal cancer, a communication will usually have been established between the two cavities through which flatus and feces pass into the bladder, and thus greatly aggravate the patient's sufferings.

The *Treatment* of cancer of the bladder is necessarily of a purely palliative character, for in these miserable cases nothing of a curative character can be attempted. Morphia hypodermically administered, the frequent use of the catheter, with disinfectant injections, possibly drainage of the bladder through a median perineal section, and, in those cases that are secondary to rectal cancer, colotomy, constitute the main elements of the treatment of this incurable malady.

HÆMATURIA.

The admixture of blood with the urine may usually be recognized by the color that it communicates to this fluid. If the blood be in large quantity, the urine will be dark brown, chocolate, or morone colored, and will stain red the bottom of the utensil or a piece of white blotting-paper. If it be in smaller quantity, the urine will be brown in varying shades—smoky, or having something the aspect of thin beef-tea; and in other cases it will be little discolored, but will deposit a red or brown sediment on standing. Under the microscope, blood-disks may be detected in large numbers. Heat coagulates the blood into a brownish-gray deposit, leaving a clear supernatant fluid. Microscopic examination should never be neglected in doubtful cases, as by that means small traces of blood may be certainly recognized; and, moreover, it must be remembered that in the condition known as hema-

tinuria the urine is darkly stained with blood-pigment. ~~It~~ contains no pus-cells. The patient's word that he has passed blood should never be taken upon too implicitly, as high-colored urine depositing uric acid or urates is often ignorantly supposed to contain blood.

Hematuria may arise from a constitutional condition or from a local cause. When constitutional, it is usually the consequence of scurvy. In these cases it will necessarily be associated with other, and probably marked, evidences of the disease. A form of hematuria, depending on the presence of a parasite—the *Bilharzia hematobia*—is prevalent in Africa, and has been thoroughly investigated by Leuckart, John Harley, Cobbold, and others.

When arising from local causes, hematuria is a symptom of disease existing in some part of the urinary apparatus, and it often assumes great importance from the loss of blood induced.

Sources.—Hematuria may arise from, 1, the Kidneys; 2, the Bladder; 3, the Prostate; or, 4, the Urethra; and from each source several different causes will produce it. The recognition of the precise morbid condition that gives rise to hematuria is of the first importance in its treatment.

1. **Hemorrhage from the Kidneys.**—When occurring from the kidneys the bleeding may be the result of congestion, acute inflammation or any morbid disease of those organs, of acute, tubercular, or calculous pyelitis, and passage of a calculus down the ureter. The most certain evidence that the blood comes from the kidney is the presence of blood-casts of the renal tubules. The renal congestion may be inflammatory or passive; in the latter case the urine will present, after the discharge of blood has ceased, evidences of chronic renal disease in the form of albumen, pus, or casts of tubes. When the hemorrhage arises from renal calculus, either stationary or descending, the symptoms of that morbid condition, described at p. 998 and 1001, will be well marked. Blood from the kidney does not often appear as clots and is uniformly mixed with the urine. Blood-casts of the ureter have been seen in cases of very profuse renal hemorrhage from cancer or injury.

2. **Hemorrhage from the Bladder.**—If the blood proceed from the bladder, it may be the result of congestion of the mucous membrane, of the presence of a calculus, of a papilloma or other villous tumor, or of the presence of a malignant disease. When it depends on vesical congestion, there will be a sensation of weight in the region of the bladder, with frequent desire to pass urine; when on calculus, the special symptoms of the existence of stone will be present. When it occurs from a villous tumor at the neck of the bladder, the quantity of blood lost is usually very great, and the hemorrhage persistent. If it arise from malignant disease, the discharge of pus and of the debris of the ulcerating tumor, may afford evidence of the source of the hemorrhage. Blood from the bladder usually is most abundant towards the end of micturition, especially in cases of tumor. The first urine that passes, or that is drawn off by a catheter, being pale and less bloody than the last, and at the termination nothing but blood may flow. In stone and cystitis it is more often uniformly mixed with the urine. Irregular masses of clot are often passed when the hemorrhage has become abundant.

3. **Hemorrhage from the Prostate.**—If the prostate be the seat of hemorrhage, the discharge may be occasioned by congestion of that organ or by its ulceration, simple or malignant. In these cases, exploration of the rectum and urethra will indicate the true cause of the bleeding. The blood usually finds its way back into the bladder rather than towards the urethra, and thus may appear towards the end of micturition, or be uniformly mixed with the urine, as in hemorrhage from the bladder.

4. Hemorrhage from the Urethra.—The bleeding may arise from simple congestion of the mucous membrane, from inflammatory irritation of it, or may follow rupture of the walls of the canal, consequent on injury or on the introduction of instruments.

Blood from the urethra usually flows independently of micturition, as in recent injuries, or passes with the first few drops of urine. It may, however, occasionally come with the last drops expelled. This is by no means uncommon in gonorrhoea, or in cases of gleet dependent upon a granular condition of the mucous membrane of the bulbous portion of the urethra. It seems, then, to be due to the contraction of the ejaculator urine squeezing a drop or two of blood from the inflamed spot.

Treatment.—The treatment of hæmaturia must necessarily have reference to its cause. When it depends on a morbid constitutional state, as scurvy or malarial poisoning, the treatment of the disease, of which the hæmaturia is merely a symptom or an effect, must be conducted on ordinary medical principles. If it arise from inflammatory congestion of the kidneys, bladder, or prostate, cupping, or the application of leeches over the affected part, demulcents, and saline drinks, will be most efficacious; if from passive congestion, saline purgatives, followed by the use of astringents, will speedily induce a cessation of the hemorrhage. The astringent that exercises the most marked influence in arresting hæmaturia, when that condition is purely passive, is undoubtedly gallic acid. This may be given in five or ten grain doses, frequently repeated, in infusion of buchu or uva ursi.

Sometimes the bladder becomes distended by a large soft coagulum, filling up its interior, and causing it to reach to the umbilicus, forming a rounded solid tumor, like a gravid uterus. In such circumstances, the largest catheter that can be introduced must be passed, and the syringe of an aspirator adapted to it. By this means the blood, even when coagulated into a single large clot filling the whole bladder, may be easily removed, and thus a complication formerly most troublesome to the Surgeon and agonizing to the patient is overcome without the slightest difficulty. The evacuator used in lithotomy would answer the purpose equally well. If these instruments be not at hand, the fluid contents of the bladder must be drawn off by a large catheter, and the more solid portions broken down and washed away by the injection of one of the antiseptic solutions recommended for cleaning the bladder in chronic cystitis (p. 997). Should decomposition occur, the bladder must be frequently washed out with antiseptic fluids.

CHAPTER LXXI.

DISEASES OF THE PROSTATE

The prostate is subject to Acute and Chronic Inflammation, to Hypertrophy, and occasionally to Atrophy, Malignant Disease, Tubercle, and the formation of Calculi.

PROSTATITIS.

Acute Inflammation of the Prostate, or Prostatitis, very rarely occurs as an idiopathic affection. When met with, it is usually the result of gonor-

rhœa, or of the use of stricture-instruments, more especially in middle-aged men.

Symptoms.—These are—deeply seated dull pain, with heat and weight in the perineum, a frequent desire to pass urine, and very great and spasmodic pain accompanying the act; in fact, the irritability that is set up about the neck of the bladder is perhaps the most marked and distressing feature in the disease. These symptoms are, however, common to various inflammatory affections of the urinary organs, and they can be distinctly referred to the inflamed prostate only by rectal exploration. On introducing the finger into the gut, the prostate will be found much enlarged and exquisitely tender to the touch; and the patient often suffers considerably from the pressure of the inflamed organ upon the rectum during defecation.

Treatment.—This should be of an actively antiphlogistic character, so as to prevent, if possible, the formation of abscess. The perineum must be cupped or well leeches; warm hip-baths and poppy fomentations assiduously employed; and salines with antimony administered. In this way, the formation of abscess within or around the prostate may, in many cases, be prevented. Morphia suppositories may be used to relieve pain.

Prostatic Abscess may form either as a consequence of acute inflammation running on to the suppurative stage, and in this way it is not very unfrequently met with as a complication of gonorrhœa; or it may occur with comparatively little antecedent inflammation—as sometimes happens in pyæmia, or if the organ be accidentally bruised during lithotomy. In these cases, abscess perhaps as frequently forms in the areolar envelope as in the organ itself. Idiopathic suppuration of the prostate, irrespective of any of the above causes, is of rare occurrence; but it may occur in individuals of broken health, the matter then usually accumulating in large quantity, and discharging itself into the bladder.

Symptoms.—When inflammation of the prostate terminates in abscess, rigors, with strangury, and perhaps retention of urine, occur. In many cases the perineum becomes brawny; in others, tenderness of the gland and deep fluctuation may be felt through the rectum. When left to itself, the abscess most usually gives way into the urethra or neck of the bladder; but it may, especially when occurring in the prostatic capsule, open externally into the perineum, or even into the rectum. In many cases, the abscess presenting on the urethral surface of the prostate is burst during the introduction of the catheter, used for the relief of retention of urine induced by the pressure of the tumefaction; the matter escaping along the side of and through the instrument.

Treatment.—It not unfrequently happens that the first certain indication afforded to the Surgeon of the formation of a prostatic abscess is the escape of pus by the urethra, or mixed with the urine, so as to give this fluid a thick milky appearance. In such circumstances, the only available treatment is that which is directed for the relief of strangury and local vesical irritation on ordinary medical principles, such as have already been described. But if, as sometimes happens, the pus come forward into the perineum, then a more decided line of treatment is required. In these cases a hard brawny mass will be felt lying deeply on the side of the perineum; and into this a deep incision should be made. The Surgeon must not wait for fluctuation, but must cut deeply in the direction of the matter, keeping, however, as nearly as possible in the mesial line, with the back of the knife towards the rectum. Even if no pus escape at first, it may do so if the part be well fomented for a few hours; and thus communication with the urethra or rectum may be prevented. When the abscess points towards the rectum, and fluctuation can clearly be felt by the finger in the bowel, it may be

opened in this situation. To do this, the bowels must first be thoroughly opened, and the rectum cleaned with an enema. The patient is then anaesthetized and tied up in the lithotomy position, the pelvis being well raised on a pillow. A duck-bill speculum is then passed, and the fluctuating spot explored with a good sized aspirator needle. If pus is found, a scalpel may be pushed in; the opening is then dilated with a pair of polypus-forceps and a drainage-tube inserted. The tube falls out in a few hours, and need not be replaced as the cavity usually closes rapidly as soon as the pus is let out. If the incision be limited, and kept as nearly as possible in the middle line, there is no hemorrhage of any consequence.

Retention of Urine from Prostatitis.—In prostatitis, retention may occur from the swelling of the organ, from the infiltration of exudation-matter around it, or from the formation of pus in it. In these cases the neck of the bladder will be carried to a considerable distance from the surface, and may very probably not be reached by an ordinary catheter, which may be buried up to the rings and yet not enter the cavity of that organ. In these circumstances a silver prostate-catheter should be employed; and this must be carefully introduced, lest, by entering the cavity of an abscess which has already burst *per urethram*, it might be supposed to have entered the bladder itself. In introducing the instrument in these circumstances, care should be taken to keep its point constantly in contact with the upper surface of the urethra, and to hook it round the pubea. The upper surface of the urethra is a sure guide to the bladder; for any abscess, false passage, or irregularity of direction will always first affect the lower aspect of this canal, being surrounded by yielding structures; whilst the upper part, being firmly supported by bone and ligament, cannot so readily alter its direction.

Chronic Inflammation of the Prostate may follow the acute affection, especially when it is gonorrhoeal. The patient is troubled by a sense of weight and fulness in the perineum, and there may be an occasional glairy discharge from the urethra, fine threads of mucus may often be seen floating in the urine, especially in that first passed, and in the last few drops expelled by straining if these be collected separately. Frequency of micturition and some pain during and after the act may be present. Examination by the rectum shows that the prostate is slightly tender, hard, and enlarged on one side than the other. A chronic abscess may slowly form without great increase in the intensity of the symptoms. This complication, which is fortunately rare, is recognized by examination from the rectum. Should the abscess burst into the urethra, the cavity in the indurated gland-tissue may be very slow in healing. I have known a case in which, after many years, the prostate remained hard and enlarged, and on pressing firmly on it from the rectum, pus could be made to flow from the urethra. The patient was obliged to draw off his water with a catheter, but suffered very little in his general health.

The *Diagnosis* of this condition from tubercular disease of the prostate is often extremely difficult. Its extremely chronic nature, the absence of any disease of the testicles or vesiculae seminales, the more uniform and regular enlargement of the gland, and the history of the case will usually determine its nature.

The *Treatment* of this consists in repeatedly blistering the perineum. Belladonna suppositories may sometimes relieve the uncomfortable sensations. Any treatment by the urethra, such as injections of nitrate of silver, will only aggravate the condition. Tonics, change of air, and sea-bathing are sometimes of use. Iodide of potassium may be given, or the iodide of iron if the patient is anæmic. Should an abscess form and point towards the rectum or perineum, it must be opened.

Prostatorrhœa has been described by Gross as a discharge of clear glairy mucus from the prostate, in consequence of irritation of that organ. The disease is characterized by the discharge of a few drops of ropy, viscid mucus from the urethra after micturition or defecation. It is of importance chiefly from its liability to be confounded with spermatorrhœa, and from the depressing effect consequently produced upon the patient's mind.

The *Diagnosis* of prostatorrhœa from spermatorrhœa may be effected by microscopical examination of the characters of the discharge.

The *Treatment* consists in attention to the state of the general health; the administration of tonics, more especially of iron and nux vomica; the removal of any local source of irritation in the urethra, rectum, or anus, as stricture, piles, or fissure; and the local application to the prostatic portion of the urethra of the nitrate of silver. The application of a blister to the perineum is beneficial in some cases.

Deep-seated and very Chronic Abscess will sometimes slowly form in the pelvis, between the bladder and rectum, behind the prostate, giving rise by its pressure to a long train of obscure symptoms, indicative of irritation about these organs, such as dysuria, strangury, and occasional admixture of pus with the urine. On careful examination of the perineum and rectum, some slight hardness may perhaps be deeply felt in the mesial line, or towards one side of it. This slowly increases, and perineal abscess of an ill-defined character develops. When this has become sufficiently evident, a free incision should be made into it, when pus in greater or less abundance will escape. On careful exploration by a probe of the cavity thus opened up, a deep sinus will probably be found leading into the pelvis, and to the original seat of the abscess. This requires to be opened up by a free incision on one side or other of the perineum, as if for lateral lithotomy, and a proper and direct exit given to the matter. The cavity must then be allowed to granulate from the bottom.

CHRONIC ENLARGEMENT OF THE PROSTATE.

Chronic Enlargement of the Prostate may be looked upon as a senile disease, seldom occurring before the age of fifty-five, but commonly met with after this. At that period of life, as Brodie observes, when the hair becomes gray and scanty, when the coats of the arteries begin to become atheromatous, and when the arcus senilis forms on the cornea, the prostate often becomes increased in size; but unless the enlargement of the prostate interferes with the free escape of the urine, no disease can properly be said to be established. If we look upon the diseased enlargement of the prostate as such an amount of hypertrophy of this organ as interferes seriously with the discharge of the urine, we shall probably not find it so frequent even in old men as is generally supposed. Guthrie states that it is not commonly found in the pensioners at Greenwich Hospital. Thompson found that an enlargement appreciable after death existed in 34 per cent. of men above the age of sixty; but that such a degree of enlargement as to give rise to symptoms during life was met with only in 15 or 16 per cent. of the cases he examined. Though age must be looked upon as the primary cause of this particular hypertrophy of the prostate, there can be little doubt that it may be predisposed to by any continued source of irritation of the urinary organs, such as stricture, or hard living.

Causes.—Enlargement of the prostate is due to hypertrophy of the muscular, fibrous, and glandular—of the organ. Most cases are due to an excess of development of the muscular and fibrous tissue. However, the size of the gland has been very slowly and

not greatly enlarged, there is nearly equal hypertrophy of all the tissues. In rare instances, there is excessive development of the glandular element; and in some cases homologous tumors are developed. The enlargement generally occupies the whole of the organ, and may cause its size to increase to that of a hen's egg or a small orange. In most cases, all the lobes are enlarged equally or nearly so, but sometimes there is a disproportionate development of one of the lateral lobes or of the middle portion. More rarely, the lateral lobes or the anterior commissure alone are enlarged.

The enlarged prostate, in the earlier stages, presents to the naked eye an appearance of rotundity and increased fulness; at a more advanced stage, there may be great irregularity of outline. There is usually no change of color externally, and the texture of the gland is generally indurated; though sometimes, when the glandular element is chiefly increased, it is found to be looser and softer than natural. On making a section, the cut surface bulges above the level; and the shades of color are more strongly marked than in the healthy prostate. Not uncommonly, single gland lobules are found hypertrophied; and in some cases, spheroidal prominences are seen, which are easily enucleated, and which are tumors formed in the substance of the gland. Of these we shall presently speak. In some instances, an abundance of fluid escapes from the cut surface and from the openings of the prostatic ducts; while in other cases this is entirely wanting. Small cavities, dilations of the gland-follicles, are occasionally found; sometimes empty, sometimes containing a yellow fluid resembling pus in appearance, but consisting of the prostatic secretion in a thickened state. The prostate may attain a very large size. The largest that I have seen is certainly one in the Norwich Hospital Museum, taken from a man of eighty; it weighs more than twenty ounces.

Simple Prostatic Tumors.—The nature of simple tumors of the prostate has been carefully studied by Sir Henry Thompson, to whose elaborate work on the diseases of this organ the student is referred for further information. According to Thompson, tumors of non-malignant character are met with in most cases of hypertrophied prostate, and also occasionally when there is no enlargement of the organ. He divides them into two classes:

"1. Tumors which are generally imbedded in the substances of the prostate, but the structures of which are isolated from those which surround it.

"2. Outgrowths which are continuous in structure with the parts of the prostate whence they spring, but which manifest a tendency to become partially isolated, by assuming a more or less polypoid form, and maintaining attachment to the parent organ through the medium of a pedicle only."

1. The *isolated tumors* in the substance of the prostate have been recognized by Sir E. Home, Cruveilhier, Rokitsansky, Paret, and other pathologists. They may occupy any portion of the organ; but are, perhaps, more numerous in the lateral lobes than elsewhere. They are easily enucleated, having but a loose connection with the substance of the gland. In diameter they vary from $\frac{1}{16}$ th to $\frac{1}{2}$ th of an inch. They are firmer, and mostly paler in color, than the proper prostatic tissue, and are less vascular.

"The basis of the tumors appears to be the fibrous basis or stroma of the prostate itself, an admixture of unstriped, soft, pale muscular fibres, and connective with a little elastic tissue, closely interwoven. Interspersed with this, there are present in most cases small cavities containing flattened polygonal or spheroidal epithelium, like that seen in a pouch at the extremity of a prostatic gland-duct, and sometimes, also, some prismatic epithelium. These cavities are sometimes solitary, sometimes slightly branched, and sometimes of an elongated or tubular form. In a few instances there is very

little, or, perhaps, no such glandular tissue to be found; generally, however, a careful search will discover it. In some of the outlying tumors, the glandular structure is more perfectly developed—in some it is quite so—and a duct is furnished which evidently carries secretion to the appointed destination."

2. The part of the prostate which is most usually the seat of *outgrowth* is the middle or urethral portion, which may become greatly enlarged in size, with or without hypertrophy of the lateral lobes. The growth assumes a pyriform shape, and is more or less pedunculated. It is continuous in structure with the prostatic tissues, and has its own duct, which opens into the urethra through the pedicle. Prostatic concretions are commonly found in these outgrowths; never in the isolated tumors.

Though most common in the middle portion of the prostate, outgrowths may occur from the posterior part of one of the lateral lobes, or from that portion of the gland which lies above or in front of the inner orifice of the urethra.

In rare instances, the verumontanum alone appears to be affected, forming a thickened polypoid projection, which projects in a valvular manner, and interferes materially with the flow of urine.

Thompson points out that, as has been suggested by Velpeau, remarkable analogies exist between these prostatic outgrowths and the fibroid tumors of the uterus. This view is in accordance with the teaching of Leuekart, Simpson, and others, that the prostatic utricle in the male is the analogue of the uterus in the female.

Mechanical Effects of Enlarged Prostate on the Urinary Organs.—Enlargements of the prostate are productive of inconvenience with regard to the flow of urine, giving rise either to retention or to incontinence, or to a kind of mixture of both conditions. When the lateral lobes are enlarged, there is a diminution of the lateral or transverse diameter of the canal, at the same time that the antero-posterior diameter is increased, so that the canal becomes a chink-like passage. The urethra also becomes greatly elongated and tortuous, and is diverted from the natural direction—this varying with the form of enlargement. When the median portion is enlarged, there is a more or less angular curvature of the canal at the prostatic portion. When, in addition, there is enlargement of a lateral lobe, the urethra is curved also laterally in the direction of the enlarged lobe. The lateral deviation may occur also when there is enlargement of the middle lobe; but it then affects both sides.

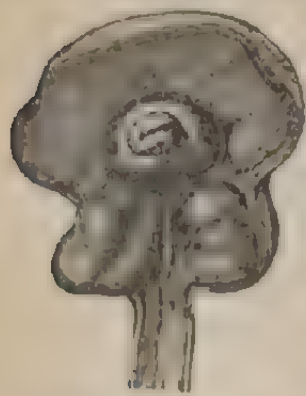

Fig. 913. — Bladder laid open, showing Enlargement of Urethral Portion of Prostate.

The inner orifice of the urethra also undergoes changes. Enlargement of the posterior part of the middle portion of the prostate gives it a crescentic form, with the convexity directed upwards; and, in enlargement of either lateral lobe, the convexity of the crescent lies towards the side opposite the enlarged lobe. Sometimes, when there are two or more irregularly enlarged lobes, the orifice is very much distorted, elongated, and tortuous. Sometimes, in cases of valvular or pedunculated projections from the posterior portions, the orifice appears to be overlapped altogether. This condition existed in the case from which the accompanying drawing (Fig. 913) was taken, the

third, or median lobe forming a pedunculated tumor which acted like a valve—obstructing the exit of the urine from the bladder, though it did not offer any obstacle to the introduction of a catheter.

The elongation and expansion of the prostatic portion of the urethra gives rise to an increase in its capacity, so that it sometimes holds two or three ounces of urine; and the elongation will carry the neck of the bladder upwards and behind the pubes, to a considerable distance from its normal position.

While the lateral enlargements cause the urethra to assume a somewhat tortuous course, the middle lobe, if hypertrophied, may readily occasion retention by projecting against the entrance to this winding channel, and falling over it like a valve whenever the patient attempts to pass urine, as in Fig. 914. In this condition, no urine is passed until by accumulation within the bladder the neck has become so stretched that the valve-like obstruction no longer closes the orifice. Then a small quantity of urine is expelled; the neck of the bladder collapses, and before the cavity is completely emptied the orifice is blocked by the projecting middle lobe, and the flow ceases. Thus a certain amount of urine is always retained, which is commonly termed the "residual urine," and none escapes till the bladder is in a state of considerable tension. As the middle lobe increases in size, a greater degree of stretching is necessary before urine can escape. Under this constant tension the bladder slowly yields and becomes dilated, its walls are thickened by fibroid tissue, and it gradually becomes completely "atonic," losing all active power of contraction. At last a condition is reached in which urine flows only when the bladder is greatly distended, and the escape of a few drops is sufficient to render the obstruction complete, and thus a condition of almost constant dribbling of urine is established.

This forms the most typical variety of prostatic obstruction. Less commonly, the obstacle to the passage of urine is of such a nature that it can be forced by increased pressure, and we then find the muscular coat of the bladder hypertrophied, as in stricture of the urethra. In still more rare cases, the middle lobe lies between the enlarged lateral lobes, thus propping the neck of the bladder open, and then true incontinence may occur with constant dribbling of urine.

The effect on the kidney will vary according to circumstances. If the bladder is in a constant state of over-distention, a similar increased tension will occur in the ureters, as it is evident that increased force will be required to drive the urine through their orifices. We consequently find all the signs of increased tension already described (p. 877); dilated ureters and pelvis, absorption of the pyramids, chronic interstitial nephritis, etc. (Fig. 914).

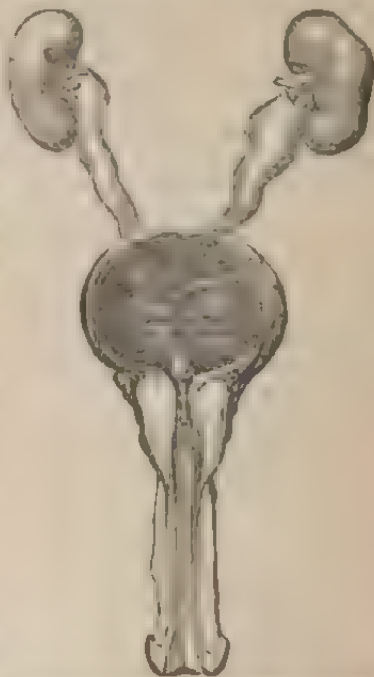

Fig. 914.—Results of Enlarged Prostate:
Bladder enlarged: Ureters dilated.
Chronic Disease of Kidneys.

Finally, should decomposition occur in the urine retained in the bladder, it may extend through the orifices of the ureter to the kidney; and in this way a large proportion of patients suffering from prostatic disease die of septic suppurative nephritis.

Moral Effects of Enlarged Prostate.—The irritation of a congested and enlarged prostate will excite libidinous ideas in the aged, which may lead to the perpetration of acts of indecency—such as exposure of the person, indecent assaults on children, or to a general impairment of the moral tone. But not only does the diseased state of this body thus excite a depraved condition of the mind; the converse will also happen. And if the true history of many cases of prostatic congestion and hemorrhage were told, the diseases would be found to begin in undue or irregular sexual or erotic excitement, by which the genital organs have been injuriously over-stimulated.

SYMPTOMS.—The symptoms of enlarged prostate arise primarily from the mechanical obstacle offered to the escape of the urine. The first symptoms usually consist in the feeling of a necessity to strain slightly before the urine will flow; and then, after the bladder has been apparently emptied, in the involuntary escape of a small quantity of urine. The patient also finds that he is much longer than usual in emptying the bladder; for, though the stream flows freely enough so soon as it has once begun to escape, yet it cannot be properly projected, the viscus having, to a certain extent, lost its tonicity. It commonly happens that the more he strains the less readily will the urine come away, whereas when he remains quiet, it will usually flow with more freedom. This is especially the case in pedunculated enlargements of the middle lobe. About this time frequency of micturition usually becomes a marked feature, especially at night. In fact, the great majority of patients apply to the Surgeon, not on account of difficulty in passing water, but because they are called upon to perform the act of micturition too frequently. This condition may gradually increase till it amounts to actual dribbling. The frequent discharge of a small quantity of urine may lead the incautious Surgeon to suppose that the patient is afflicted with true incontinence of urine or with irritability of the bladder. This error may always be guarded against by careful examination of the pubic region by percussion and palpation. Dullness will often be found extending half way to the umbilicus, and the tense distended bladder may be readily felt above the pubes.

The symptoms may for a long time remain limited to frequency of micturition with some difficulty in the act. The urine remains acid and normal in every respect, and the patient suffers but little, if at all, in his general health. The condition is, however, always one of considerable danger. The over-distended bladder is always prone to slight attacks of cystitis from exposure to cold or other causes. The urine then becomes cloudy from excess of mucus, and often acquires an offensive fishy smell, while still remaining acid. The mucus accumulates in the pouch behind the enlarged prostate, and is with difficulty expelled. Under these conditions ammoniacal decompositions may readily take place. This may occur without the passage of instruments, but in a considerable proportion of cases is not noticed before the use of the catheter has been commenced. Should it happen, the cystitis becomes more acute, and the symptoms of septic poisoning—feverish disturbance, great depression, brown tongue, nausea, delirium, etc.—may set in and terminate fatally, when septic inflammation of the kidneys, by extension up the ureter, will usually be found to have been the immediate cause of death.

Complete Retention of Urine from Enlarged Prostate is a common complication of the disease. It may arise in the patient who has not been able to empty his bladder for some time, and is little more than an aggravation

of his usual condition; or it may occur in an old man whose prostate is considerably enlarged, but who, under ordinary circumstances, gets rid of his urine without difficulty. In the latter case it is due to congestion and swelling of the diseased gland, usually induced by exposure to cold, or alcoholic or venereal excesses. It is especially apt to occur after drinking the sour, bad wines usually provided at public dinners.

DIAGNOSIS.—The exact condition of the enlarged prostate can be ascertained only by examination through the rectum and urethra. By rectal exploration with the finger, the degree of enlargement of the lateral lobes can best be ascertained; though, as in many cases the end of the finger cannot reach the further extremity of the gland, it will be impossible to say to what extent the hypertrophy has extended. The urethral exploration must be conducted by means of a long gum-elastic or a silver prostatic catheter, and will afford information that rectal exploration cannot give; by it are ascertained approximately the size of the middle lobe, and the condition of the urethra as to elongation and curve.

The diagnosis of obstruction in consequence of enlarged prostate has to be made from that produced by, 1. Stricture of the Urethra; 2. Calculus of the Bladder; 3. Vesical Tumor; 4. Chronic Cystitis; 5. Atony of the Bladder; 6. Paralysis of the Bladder.

1. In *Stricture* the stream of urine is small, but the jet is increased by straining, while in enlarged prostate the stream is dribbling, but not reduced in volume, and straining only makes matters worse. Stricture most commonly occurs before middle life, prostatic disease always after. In stricture the obstruction is within six inches of the meatus; in prostatic disease it is at least seven from the orifice. It is not wise, however, to trust too implicitly to measurements in inches, as the penis varies considerably in length. If the finger be passed into the rectum, it can at once be determined whether the point of obstruction is in front of the apex of the prostate.

2. *Calculus* presents many symptoms in common with enlarged prostate, and its more special symptoms may be absent. In stone the frequency of micturition is greater by day, in prostatic disease it is worse at night. The presence of a small quantity of florid blood in the urine passed after exercise should make the Surgeon strongly suspect the presence of a stone; but the use of the sound will alone lead to an exact diagnosis.

3. *Vesical Tumor* gives rise to more pain and tenderness on the introduction of instruments than prostatic enlargement; and the urine generally contains blood and mucus, often with sabulous matter. Microscopic examination of the contents of the urine may show the presence of the component tissues of the tumor. Tumors, especially of the malignant kind, may be felt through the rectum; while villous tumors give rise to the almost constant presence of blood in the urine.

4. In *Chronic Cystitis*, without complication, the absence of the physical signs of enlarged prostate, as ascertained by examination by the rectum and urethra, will establish the diagnosis.

5. *Atony of the Bladder* is, as before stated, very commonly associated with enlarged prostate. Its absence would be shown by the urine flowing from the catheter in a steady stream, not influenced by the respiratory movements, indicating an active contraction of the bladder.

6. True *Paralysis* of the bladder, accompanied with a similar affection of other parts, is recognized by its concomitant conditions, and by the absence of physical signs of enlarged prostate, and, as in atony, by the passive nature of the flow of urine through the catheter.

TREATMENT.—In the treatment of enlarged prostate, little can be done by medical means; though the patient's condition may be somewhat ameliorated

by remedies calculated to lessen irritation about the urinary organs, and to improve the condition of the urine. If it be very acid, alkalis with henbane should be given. If the symptoms of chronic cystitis make their appearance the various remedies recommended in the treatment of that disease may be given. If hemorrhage occur, tincture of perchloride of iron, infusion of uva ursi, or gallic acid, will be useful. Counter-irritation, the application of iodine, and other measures calculated to promote absorption of the enlarged gland, are not of the slightest service.

Various operative procedures have been recommended and practised by Mercier and others for the removal of the mechanical obstruction caused by the enlarged prostate, but they are both inefficient and dangerous, and have been almost unanimously condemned.

In fact, the sole treatment of enlarged prostate consists in the regular use of the catheter, in order to draw off retained urine; and when once this treatment has been commenced, it must be continued for the remainder of life, the patient being taught to use the instrument for himself. It is especially necessary to empty the pouch that forms in the *bas fond* of the bladder behind the prostate; and which, being below the level of the urethra, tends to collect an accumulation of viscid mucus and fetid urine which the patient cannot expel without aid, partly from their gravitating into this pouch, and partly from the muscular power of the organ being impaired. The removal of these matters is of great importance; as they may, by undergoing putrefaction, give rise to septic infection. The bladder should be effectually emptied at least twice *every day*. By far the most convenient instrument in

Fig. 215.—Keweenaw Catheter.

the majority of cases is the soft French "elbowed" catheter—the "*cathéter à coude*," of the size and shape here represented (Fig. 215). The stem is soft and pliable, but the angle and eyed point are made of firm gum-catheter material. By keeping the point well up against the urethra, it will often slip in very easily and smoothly in cases of enlarged prostate. These catheters are made with their points bent at different angles or with double elbows, instead of single, and very often when one will not pass, another of a slightly different form will slip in readily. The size of the instrument is of some importance. As a rule, No. 8 or 9 passes most readily. There is nothing gained by using a smaller instrument, as the passage through the diseased prostate, although it obstructs the flow of urine, is always larger than that through a healthy gland.

If the coude catheter does not pass, a flexible India-rubber catheter may often be of use. Hutchinson states "that in almost all cases of prostatic retention, a flexible India-rubber catheter without a stylet can be passed into the bladder." Its use is so perfectly painless and free from danger, that it may always be tried before adopting more severe measures. If from any cause it be necessary to retain such an instrument, Hutchinson uses a nozzle with rings passed into the orifice of the India-rubber catheter, and fitted with a "styletted plug." The nozzle is about three-quarters of an inch in length, and is fitted accurately by the plug. The stylet reaches about two inches down the catheter so as to stiffen it. With such an instrument in use, the patient need not be confined to bed.

If neither of these instruments will enter the bladder, a common French conical instrument may pass; but this very rarely succeeds when the coude catheter fails.

A common gum-elastic catheter of full size, which may be bent to any angle in hot water and fixed by immersing it in cold, may pass when other instruments fail. Sometimes, if it be bent to a curve like that of a lithotrite, it may slip over the enlarged middle lobe. It must be remembered that the heat of the urethra soon causes the catheter to lose the form impressed upon it, and consequently, if it does not enter at once, prolonged attempts to pass it are useless.

Sir B. Brodie recommended that a gum-elastic instrument, long and of large size, on a well-curved stylet, so that it might preserve its curve when that is withdrawn, should be kept in readiness for these cases. A manœuvre mentioned by Sir B. Brodie will often be of use in surmounting a large middle lobe; viz., after passing the gum-elastic catheter as far as it will go, to withdraw the stylet slightly, so as to tilt up the point of the catheter, which then passes over the obstacle.

If none of the foregoing means succeeds, the Surgeon must have recourse to silver instruments. If the prostate be much enlarged it may be necessary

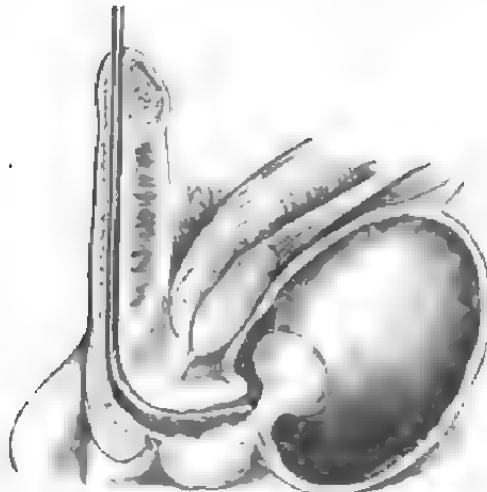

Fig. 916.—Enlarged Middle Lobe of Prostate, Arresting Progress of Catheter.

in order to reach and empty the bladder, to use a prostatic catheter. This instrument should be made of silver, and be of large size, equal to about No. 12. In order properly to enter the bladder, which is carried away from the surface by the elongated urethra, the prostatic should be about four inches longer than an ordinary catheter; and, as the neck of the viscus is usually pushed up high behind the pubes by the projection upwards of the lateral lobes, the curve of the instrument should be greater and longer than usual. I find the best-shaped prostatic catheter to be one, the curve of which is exactly the third of the circumference of a circle five and a half inches in diameter. The eyes should be large and rounded; and I have found it of use to have the lower end of the stylet provided with a piston-plate, so that, by withdrawing this, the mucus may be sucked in through the eyes of the instrument. In introducing the catheter, care must be taken when the point enters the prostatic portion of the urethra, to depress the handle well between

the thighs, while the instrument is drawn slightly towards the pubes, lest the end hitch against the enlarged middle lobe (Fig. 916). If it be simply depressed, without at the same time being held back a little, it will probably tunnel the obstruction. In some cases the ordinary catheter passed in the same way will enter more easily than the prostatic. It is sometimes possible to lift the catheter over the obstruction by pressing on it with the finger on the rectum. In fact, no one curve or one kind of instrument will answer in all cases. If it is necessary to use a rigid instrument, I certainly think a silver instrument is safer and more easily managed than the gum elastic. It might be supposed that a less chance of mischief would result from the gum-elastic than from the metallic catheter, as being the softer and more yielding instrument; but this is erroneous, if the stylet be allowed to remain in, as it is then as rigid at the point, as hard, and as likely to penetrate soft structures as a silver one would be. The patient himself should use a soft instrument, if possible, but it occasionally happens, as occurred in a case under my care, that no soft catheter of any shape could be made to pass; in such cases the patient can easily be taught to use a metal instrument.

Treatment of Complete Retention from Prostatic Enlargement.—In these cases the patient must be relieved by an instrument as soon as possible, as elderly people are liable to suffer severely if there is any delay, fever soon setting in, which may be fatal.

It cannot be too forcibly insisted on that in these cases there is no actual narrowing of the canal. The enlarged prostate is, no doubt, swollen, but there is always sufficient space left for the passage of the largest catheter, if only the proper way can be found. Nothing is gained by using small instruments; anything below No. 8 or 9 (English) is liable to wound the swollen mucous membrane, and cause troublesome hemorrhage. In complete retention the various modes of overcoming the obstacle in the prostate, which have just been described, must first be attempted, beginning with soft instruments, and using silver only after these have failed. If the retention is thus relieved, it becomes a question whether the catheter should be left in the bladder or withdrawn after the viscus is emptied. As a general rule, it is certainly far better not to leave the catheter in, for the reasons given at page 1005. The instrument should be introduced twice in the twenty-four hours; and care should be taken, if possible, to empty the pouch behind the prostate by depressing its point. Should the mucus be very viscid and offensive, the bladder may be washed out. After the bladder has been emptied for the first time, it will be found to refill in the course of a very few hours, usually in six or eight, the secretion of the kidneys appearing to be set free on the removal of the pressure.

Should any great difficulty be experienced in introducing the catheter, it may be thought desirable to leave it in the bladder for two or three days; and then a gum-elastic one is always to be preferred, as in these circumstances it presents a great advantage over the silver catheter, becoming soft, accommodating itself to the shape of the parts, and not being so liable to irritate the mucous membrane with its point, which, dipping down into the pouch behind the prostate, acts as a siphon, emptying this part of the bladder far better than a silver catheter could do.

Should the Surgeon fail to pass any instrument into the bladder, it becomes an important question what course is to be pursued. In these cases, which however, very rarely occur, three lines of practice may be adopted: *puncture of the bladder above the pubes, puncture through the rectum, or forcible catheterism.*

Puncture above the Pubes can very seldom be required. Since University College Hospital was opened, only three cases have presented them-

selves in which it was thought proper to adopt such a procedure for retention from enlarged prostate; and in one of these cases, which was under my care, the enlargement of the prostate was complicated with impermeable stricture, which was, indeed, the main cause of the retention. The operation consists either in pushing the trocar at once through the abdominal wall; or else, as in tapping for ascites, making a small incision about half an inch in length through the integuments, exactly in the mesial line, immediately above the pubes, and then pushing a curved trocar, with its concavity downwards and backwards, into the bladder behind that bone, and consequently underneath the reflection of the peritoneum (Fig. 917). After the bladder has been

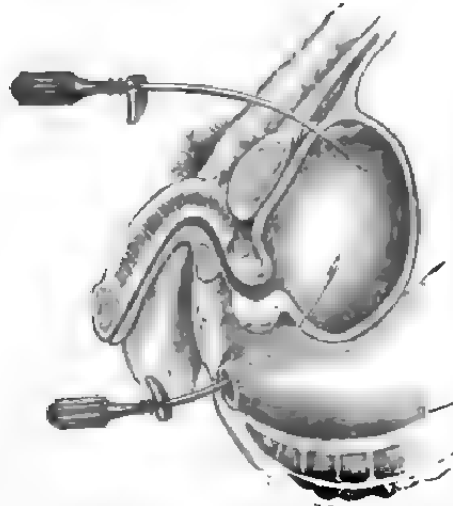

Fig. 917.—Puncture of the Bladder. The upper instrument is in the position of Puncture above the Pubes; the lower in that of the Puncture through the Rectum.

emptied, the canula or an elastic gum tube must be left in for the escape of the urine, whilst the continuity of the natural passage is being restored. When the bladder is greatly distended, in consequence of retention from enlargement of the prostate or any other cause, the peritoneal reflection is carried up with it, and a considerable portion of the anterior wall of the organ uncovered by peritoneum is left above the pubes. In a case of unrelieved retention from stricture, in which the patient died suddenly during the administration of chloroform, and which I had an opportunity of dissecting, I found that the summit of the bladder reached to five inches above the symphysis pubis, and was only two inches below the umbilicus; that the line of reflection of the peritoneum was 3½ inches above the bone; and that the space uncovered by serous membrane was 2½ inches wide. The bladder contained nearly forty ounces of urine, the retention having lasted forty-eight hours.

Brander, of Jersey, and others have modified this operation by puncturing through the symphysis pubis, by means of a trocar and canula. There is not, however, sufficient evidence to enable us to decide as to the merits of this procedure.

Puncture through the Rectum is not generally a safe procedure in retention from enlarged prostate, in consequence of this structure encroaching on that part of the inferior fundus of the bladder which is uncovered by peri-

toneum. When, however, the retention arises from enlargement of the urethral portion rather than of the lateral lobes, this operation may be safely done; and, indeed, I have known it put in practice with advantage in such cases (Fig. 917).

A procedure that was formerly recommended by Brodie, Liston, and most Surgeons of authority in these matters, was **Forcible Catheterism, or Tunnelling the Prostate**. As the retention is generally owing to an enlargement of the urethral portion of the prostate, relief was afforded by pushing the point of a silver catheter through this obstacle into the bladder. A false passage was thus purposely formed, in which the instrument was left for about forty-eight hours when it would usually enter it again with sufficient readiness on being reintroduced. This practice has, however, been very generally rendered unnecessary by the use of improved instruments, aided by anaesthetics; and "tunnelling the prostate" may be looked upon as belonging to a past age of Urinary Surgery, ruder than the present.

When the bladder has been relieved, the patient must be freely purged. Belladonna suppositories are often of use, but if there be much pain, opium or morphia will be preferable. In a few days the congestion of the prostate passes off, and the patient may be again able to pass water unaided. In many cases, however, the bladder of an old man which has, perhaps, not been completely emptied for some time, becomes permanently atonic after a single attack of retention, and he is never able again to dispense with the catheter.

OTHER DISEASES OF THE PROSTATE.

Atrophy of the Prostate sometimes occurs. It may be the result of exhausting disease, especially phthisis, of old age, of mechanical pressure from tumors or calculi, or of local disease of the gland itself. Congenital deficiency of the prostate may also occur.

Cancer of the Prostate.—The prostate is very rarely attacked by cancer, but rare as the disease is, I have seen at least three instances of it, and can therefore scarcely agree with the estimate of Tanchou, given by Walsh, that it only occurred five times in upwards of eight thousand fatal cases of cancer. The form met with is most commonly scirrhus; one case of colloid has been recorded by Stanley Boyd. I have seen true scirrhus in a man about 70 years old. He died with secondary tumors in the lymphatic glands, and with a liver studded with cancerous nodules.

The *Symptoms* are obscure pain and irritability about the neck of the bladder, with the occasional passage of blood. Digital examination by the rectum will probably detect a hard, ill-defined mass, occupying the situation of the prostate, nodular on the surface, and often peculiarly fixed. It is slightly tender on pressure. The rapid increase in size, with obstruction to the passage of urine, and frequent hæmaturia and increasing pain, will reveal the true nature of the disease.

The only *Treatment* that can be adopted is that calculated to relieve the bladder from the mechanical obstacle to the escape of urine, and to palliate suffering by ordinary means.

Tubercle of the Prostate is not uncommonly met with. It usually forms a part of extensive tubercular disease of the genito-urinary tract. In fact, it is rare to find it sufficiently advanced for a diagnosis to be made without one or both epididymes being similarly affected, and it is often very difficult to tell where the disease originally commenced. The vesiculae seminales are usually implicated, and the tubercular infiltration frequently extends to the floor of the bladder. Not uncommonly it is associated with tubercle of the

kidney. The *post-mortem* appearances are those of tubercle elsewhere. Softening yellow masses are found usually near the urethral surface. After a time the mucous membrane gives way, and a ragged cavity with yellow walls is left in the floor of the prostatic urethra. Sometimes the tubercular abscess may open into the rectum, and thus a fistula may be left between the urethra and the bowel. More rarely it causes an abscess pointing forwards in the perineum. Tubercle in the lungs is usually present at death. The *Symptoms* vary very much, according to the situation of the ulceration. If it is limited to the prostate, it may cause suprisingly little disturbance. In a case which occurred in University College Hospital, the patient died of tubercular meningitis, some months after castration for tubercular testicle. At the *post-mortem* examination two cavities were found in the prostate large enough to admit the top of the thumb, but the patient had made no complaint of any urinary trouble. If the ulceration extend towards the bladder, there may be extreme symptoms of irritable bladder. Digital examination by the rectum shows the prostate to be hard, nodular, and irregularly enlarged. Sometimes a softening patch may be detected in it. The vesiculæ seminales, if they can be reached, are usually found to be enlarged. There may be a purulent discharge from the urethra, and pus in the urine. The detection of the tubercle bacillus would determine the nature of the case. The *Treatment* is merely palliative. The disease is too widely disseminated when first recognized to make it possible to do anything by exposing the gland and scraping it.

Cysts or Cavities are sometimes found in the prostate; they may be dilata-tions of gland-follicles, abscesses, or cavities containing concretions or calculi.

Prostatic Calculi have been already described in the chapter on Urinary Calculus (vol. ii. p. 985).

CHAPTER LXXII.

DISEASES OF THE URETHRA.

URETHRITIS.

Simple Inflammation of the Urethra is especially apt to occur in strumous, rheumatic, or gouty individuals, from slight sources of irritation, either direct or sympathetic, that would not excite it in more healthy constitutions. In strumous children, it may arise from worms in the intestines, or from gastric irritation; and in gouty or rheumatic subjects, it appears often to occur in connection with an acid state of the urine. Excessive beer drinking may cause a slight discharge from the urethra—the “biertripper” of the German students. In other cases, the irritation of a stricture, the passage of instruments, or ordinary sexual intercourse, may occasion the disease, without there being anything of a specific character about it. Contact with women who are out of health, pregnant, or suffering from leucorrhœa, may, and often does, give rise to local irritation of this kind. Urethritis, especially when arising from sexual intercourse, is frequently mistaken for gonorrhœa. From

this it may, as a rule, be distinguished by the less intense degree of inflammation, and by the absence of the secondary consequences that frequently follow true gonorrhœa; yet, in many instances, the diagnosis is extremely difficult, especially from the subacute forms of gonorrhœa that are common in London.

Symptoms.—Urethritis is characterized by heat, pricking, and tension about the urethra for a day or two, followed by muco-purulent discharge, often rather profuse, and accompanied by some ardor urinae. The symptoms altogether are not severe, and the disease usually subsides at the end of a week or ten days; but sometimes it becomes chronic, especially if conjoined with stricture, and then constitutes an extremely troublesome affection, more particularly in gouty individuals.

Treatment.—The treatment of urethritis is mildly antiphlogistic. The bowels should be kept open, and salines freely administered; in cases in which there is reason to believe that the affection is of gouty origin, small doses of colchicum, in combination with alkalies, will be found of especial service in cutting the disease short. The use of emollient or slightly astringent injections, such as opiate lotions, or a very weak solution of acetate of lead, with belladonna, will be found serviceable as the disease is on the decline, but not until then; and when the affection has reached a chronic stage, small doses of copaiba may be advantageously administered. The diet in all cases should be of the blandest character, stimulants of all kinds being interdicted.

If the disease be conjoined with slight stricture, it may not unfrequently give rise to temporary retention of urine. This may, however, most commonly be readily relieved by antiphlogistic treatment, cupping or leeches to the perineum, the warm hip-bath, and salines, with, perhaps, opiate suppositories, and plenty of demulcent drinks. The catheter should not be used in these cases, if it be possible to give relief without it.

GONORRHOEA.

Gonorrhœa is a specific disease, accompanied by inflammation and an abundant muco-purulent discharge; affecting the urethra most commonly, but also the other mucous membranes of the genital organs, as of the prepuce and the glans in the male, and of the vulva and vagina in the female.

The urethra is the usual seat of gonorrhœa in the male; and the disease may be looked on as an infectious urethritis. Its seat of greatest intensity is usually the fossa navicularis; but it may extend over a much greater surface, affecting the entire length of the canal, and the whole mucous lining of the bladder. In the female it commonly spreads over the extensive mucous surface of the external organs of generation, and sometimes invades the uterus and Fallopian tubes.

CAUSE.—Gonorrhœa has its origin in the female, and is possibly developed *de novo* in prostitutes, that is, without infection from the male. It is a highly infective inflammation of the mucous membrane of the vagina generated by the decomposition of retained semen and of foul discharges, the result of repeated acts of indiscriminate intercourse without proper attention to cleanliness. It is impossible to say where urethritis or vaginitis ends, and infective gonorrhœa begins. In the male, gonorrhœa arises in all cases from the application of a peculiar animal poison, generated in the female by impure or indiscriminate sexual intercourse, to the parts which it attacks, and must not be confounded with the various non-specific inflammatory diseases that may affect the parts commonly the seat of gonorrhœa, and which are all characterized by muco-purulent discharges.

The poison of gonorrhoea differs entirely from those of the venereal diseases described in Chapter XXXVI., as has been fully proved by the unerring test of inoculation; these diseases not being capable of reproducing one another in any circumstances. The actual nature of the virus has not been certainly ascertained. The pus from gonorrhoea always contains micrococci, and it has been maintained by Neisser, Bokai, Bockhart, and others, that this organism is the actual virus. Bokai inoculated six students with the organism, which had been cultivated in suitable fluids, and in three gonorrhoea followed. Bockhart also successfully inoculated the organism in the urethra of a man after it had been cultivated to four generations in prepared gelatine. It seems probable, therefore, that the "gonococcus," as it has been termed, is either the actual virus or in some way connected with its development.

The suppurative inflammation which is characteristic of gonorrhoea has these peculiarities: 1. It has a distinct and lengthened period of incubation; 2. It rapidly propagates itself along the mucous tracts that it affects; 3. It is contagious in the highest degree not only when the pus is applied to, and, as it were, rubbed into the mucous surfaces of the generative organs during coitus, but when it simply touches other mucous surfaces; and, 4. It is sometimes attended by remote constitutional phenomena partaking of a pyæmic character.

CHARACTER.—Gonorrhoea is usually looked upon as a purely local affection of the genital organs. Some Surgeons, however, amongst whom may be especially mentioned Travers, seem to consider it as occasionally assuming a constitutional character; in this opinion I entirely agree. Although gonorrhoea in the early stages is doubtless a strictly local affection, yet it is occasionally followed by a particular train of very characteristic phenomena, that can scarcely be looked upon in any other light than as the result of constitutional infection; the more so, as some individuals never have gonorrhoea without the disease being followed by these sequences, whilst others are altogether exempt from them. The parts that are secondarily affected are chiefly the fibrous tissues, the mucous and the cutaneous surfaces. The affections of the *fibrous tissues* give rise to so-called rheumatism and to peculiar forms of inflammation of the testicle and of the sclerotic. The affection of the *mucous membranes* displays itself in specific inflammation of the eyes. The occurrence of these various affections, assuming as they do a specific type so distinctly marked that they can at once be characterized as gonorrhoeal, certainly tends to show that the disease impresses the constitution in some peculiar manner, somewhat analogous to syphilis or pyæmia; though in a far minor degree, and with much less certainty, than these diseases.

SYMPTOMS.—The symptoms of gonorrhoea in the male may be divided into three stages: 1. The Incubative Stage, or the period of Irritation; 2. The Acute Inflammatory Stage; and, 3. The Chronic Stage.

1. **Incubative Stage.**—The first stage, that of irritation, usually comes on from three to five days after connection, when the patient begins to experience some degree of heat, itching, and general irritation about the penis. The lips of the urethra are somewhat red and swollen; its orifice gapes; and, on squeezing it, some mucus exudes. This stage usually continues for three or four days, but sometimes for six or eight, when it terminates in the second stage, which is one of active inflammation.

2. **Acute or Inflammatory Stage.**—The discharge now becomes abundant, thick, and of a greenish-yellow color; there is great pain in making water, with considerable heat and smarting, and the urine, which flows in a diminished stream, is passed with increased frequency. The urethra is swollen, firm, and cord-like to the touch; the whole penis, indeed, looks generally

red and turgescient. As the disease advances, and the bulbous portion of the urethra becomes affected, weight and tension in the perineum will be complained of. If the prostatic portion be the seat of disease, there will be heat and weight about the anus. During the whole of this period there is generally a good deal of constitutional disturbance, restlessness, and fever.

One of the most troublesome symptoms in this stage of the complaint is the occurrence of **Chordee**, which consists in painful erections at night, with a twist in the body of the penis, which is usually curved down towards the scrotum.

3. **Chronic Stage.**—The acute symptoms usually continue for about a fortnight, when the third stage, that of subacute or chronic inflammation, sets in. During this period of the affection the inflammatory symptoms gradually subside, but a thin muco-purulent discharge keeps up, with some degree of heat and irritation about the urethra, and occasional smarting in passing urine. Under proper treatment, this usually subsides in the course of another fortnight or three weeks; but, if neglected, or in certain constitutions, it may last for many months, or even years, then degenerating into a *gleet*. In proportion to the continuance of the affection the inflammatory symptoms subside, though the specific and contagious character does not disappear, and the affection may continue so long as the discharge keeps up. Hunter mentions the case of a girl who had been two years in the Magdalen Hospital, and who infected a person with whom she had connection immediately after she left that institution. The persistence of the contagion of gleet is, it is true, more marked in women than in men. So long, however, as any purulent discharge continues from the male urethra, though it be but a daily drop, the patient must be looked upon as infectious.

The severity and the continuance of gonorrhoea are often opposed to one another. Thus the disease is most severe in young and phthoric persons, and in first attacks; but it is most difficult of cure in strumous and phlegmatic constitutions, more especially if there be a gouty or rheumatic tendency coexisting, and is very troublesome to remove after repeated attacks. I have observed repeatedly that it is very apt to degenerate into a gleet in people who are subject to chronic eczema.

There is a form of chronic gleet which continues very persistently after an attack of gonorrhoeal epididymitis. In these cases the discharge is not so much urethral as testicular. It appears to proceed from the increased exudation from the mucous membrane of the secretory and efferent structures of the testis, during the process of resolution of the inflammation.

The length of time that the infection of gleet will continue in both sexes, but especially in the female, makes it somewhat difficult to say whether the poison of gonorrhoea can be generated *de novo*, as it is not improbable that many individuals communicate the disease, believing themselves to be perfectly cured, though still suffering from slight gleet.

Gleet.—The term *gleet* is applied to any mucous or muco-purulent discharge, which is very small in amount and persists for an indefinite time unaccompanied by any other obvious symptoms. This condition is one which gives rise to great mental uneasiness in many patients, and some varieties are, moreover, liable to terminate in stricture if unrelieved. The correct diagnosis of its nature and source is, therefore, of extreme importance. In the first place, it is necessary to remember that in young men a somewhat copious flow of mucus is apt to accompany an erection of the penis. When, as is frequently the case, an erection occurs just before waking in the morning, the mucus may be found glueing the lips of the urethra together, and may be mistaken by the patient for a gleet. Again, true gonorrhoeal gleet must not be confounded with prostaticorrhoea (see p. 1016). Desormeaux has

shown by means of the endoscope, that a true gonorrhœal gleet is due to the presence of chronically inflamed patches of mucous membrane in the urethra. These patches are purplish or dark red in color, whereas the normal urethra is a pale pink. Sometimes the surface of the mucous membrane is covered with small granulations, like those seen on the conjunctiva in granular lids. This condition Desormeaux calls "granular urethritis." The patches may be multiple, but more often there is only one situated in the bulbous portion of the urethra. The *symptoms* of such a condition are the following: A slight, sometimes almost colorless, sometimes yellowish, discharge will be found glueing the lips of the urethra together in the morning. This discharge is little affected by diet or stimulants, but is usually greatly aggravated by connection. If during micturition the first few drops of urine be passed into a separate vessel, flocculi of mucus and pus are seen floating in it. There is no pain or discomfort in micturition, but the stream may be slightly narrowed, and a few drops of urine may be retained in the urethra, and dribble away afterwards, as in a slight stricture. These inflamed patches may usually be detected without difficulty by the use of the olive-headed bougie. As the sound passes the inflamed spot, the patient will complain of pain, and on withdrawing it a drop of blood may be found upon its bulb. A slight feeling of resistance to the instrument is also felt.

In other cases, the gleet may be due to a chronic inflammatory discharge from the glands and follicles of the urethra. Hill states that it occasionally arises, also, from small vegetations or warts situated immediately inside the meatus.

TREATMENT.—The treatment of gonorrhœa must be conducted with reference to the stage to which the disease has attained, but especially with regard to the amount of inflammatory action accompanying it. It is of two kinds, *rational*, and *specific* or *empirical*. Both plans are useful, and, indeed, usually necessary for a proper cure, but they cannot be adopted indiscriminately. Thus, if specific means be employed during the acute inflammatory stage of the complaint, much mischief may ensue; whilst, if antiphlogistic treatment be persevered in for too long a time, the disease may be kept up indefinitely.

It has been proposed to adopt what has been termed the *abortive* or *revulsive* treatment, during the earliest stages of gonorrhœa: indeed, during the *incubative* period. This method consists either in the injection of a very strong solution of the nitrate of silver into the urethra, or in the application to the inflamed mucous membrane of a strong ointment of that salt by means of a bougie smeared with it; other Surgeons, again, have recommended the administration of very large doses of copaiba at this period. These various plans have, however, deservedly fallen into disrepute. I have on several occasions seen most intense inflammation produced by this mode of treatment, and never, in any case, any good result. Independently of this, it is impossible to know whether the case, in the earliest stage, will prove to be one of simple urethritis or a specific gonorrhœa.

In the *acute inflammatory stage*, attended by heat, swelling of the organ, great ardor urinae, and abundant mucopurulent discharge, the treatment must be entirely antiphlogistic, the activity of the measures being proportioned to the intensity of the inflammation. If this be severe, warm hip-baths, poppy fomentations, or the envelopment of the penis in warm water-dressing, will be of essential service. At the same time, the urine must be diluted, and its acidity lessened, by the patient drinking large quantities of alkaline diluents—barley-water or linseed-tea containing carbonate of potash in solution; and the skin and bowels may be kept in action by the administration, every second night, of a dose of blue pill, and every fourth or sixth

hour, of a powder composed of a drachm of sulphate of magnesia, 5 grains of nitre, and $\frac{1}{12}$ th of a grain of tartar emetic, dissolved in a wine-glass of water. All alcoholic stimulants, spices, salt food, and coffee must be avoided, the diet being restricted to light slops, and perfect rest enjoined. By such means as these, the activity of the inflammation will be gradually lessened, the discharge becoming thinner, the smarting in micturition less severe, and the erections less painful. The patient should also be desired to pass his urine frequently, so as to wash the urethra clean.

During this stage, or earlier if the nature of the disease is recognized, W. W. Cheyne recommends the use of iodoform and eucalyptus bougies. These are composed of iodoform, 5 gr.; oil of eucalyptus, 10 m; oil of theobroma, 35 gr. This is sufficient to make one bougie four inches long. It is thus used: the patient first passes water to clean the urethra, he then dips the bougie in carbolic oil (1 in 20) and passes it quickly into the urethra before it becomes softened by the heat of his fingers. It must be pushed in with a pencil, or some convenient instrument, till it completely disappears. An absorbent pad of iodoform or salicylic wool is then placed over the end of the penis, and covered with oiled-silk or gutta-percha tissue secured by a strip of plaster. The patient then refrains from making water for as long as possible. One bougie may be used daily for two or three days, and in the interval some simple injection, such as chloride of zinc (gr. $\frac{1}{2}$ to $\frac{3}{4}$), or sulpho-carbolate of zinc (gr. ij to $\frac{3}{4}$) may be used. Cheyne states that by these means the inflammation is often cut short and a cure effected in a week or ten days or sooner. If it fails it does no harm. One-twentieth of a grain of perchloride of mercury added to each bougie is said to increase the certainty of their action.

During the second, or, in fact, in all stages of gonorrhoea, much harm is often done by applying lint to the penis. This does not absorb the discharge, but rather shuts it in. It is better to put the penis in a Macintosh gonorrhoea-bag, at the bottom of which a good sized piece of salicylic wool may be placed to absorb the discharge.

When the *third stage* of the disease has been reached, specific treatment may be employed with great advantage; while, if recourse were had to it at an earlier period, it would certainly increase the inflammation and give the patient much distress. Even in this stage the specific remedies, such as copaiba and cubebs, must be cautiously given; the Surgeon feeling his way with them, and being prepared to discontinue them and to return to strictly antiphlogistic measures, if he find that they increase the irritation. Should the disease, however, from the commencement, have assumed a subacute character, the specific treatment may with safety be adopted at a much earlier period.

Copaiba and cubebs are the remedies that are almost universally used in this stage of gonorrhoea. Of these, copaiba is the least irritating, and consequently most generally to be preferred. It may be administered in a variety of ways; in capsule, pill, draught, or extract. The capsule is generally to be preferred, on account of the nauseous taste being thus more completely disguised; but in many cases it acts with more certainty, and with better effect, if given in either of the other forms. When the capsules are given, the patient may take from six to eight or ten in the day, and should at the same time have an alkali mixture, which increases materially the effect of the drug. A very excellent mode of administering copaiba is to rub it down into a mass with burnt magnesia, and to let the patient take about a drachm of this paste three times a day, in a bolus wrapped in water-paper; or if the taste be not much objected to, he may take it most advantageously in mucilage, with liquor potasse and tincture of henbane.

In some relaxed constitutions, and more particularly after frequent claps, cubebs will be found to cure the patient more readily than copaiba, or rather most successfully if given in combination with it. An excellent plan is to put about half an ounce of powdered cubebs into a mortar, and to rub it up with as much copaiba as will form a stiff paste, of which the patient should take a drachm as a bolus thrice daily. The effects of this electuary are often most striking; but it can be used only in the constitutions indicated, and after the more active inflammatory symptoms have subsided. Copaiba in many subjects brings out a red, raised rash, most marked on the backs of the hands and feet, but sometimes extending over the whole body. It is accompanied by considerable itching and often by some rise of temperature. Hill states that a similar eruption, but more papular in character, may follow the administration of cubebs. Hematuria has been occasionally observed as the result of large doses of copaiba. Oil of yellow sandal wood may sometimes be employed with advantage, though its action is somewhat uncertain. It may be given in capsules in doses not exceeding twenty minims three times a day, or the following formula will be found useful; oil of sandal wood, $\mathfrak{z}\text{ij}$, tragacanth in powder $\mathfrak{z}\text{ss}$, water to $\mathfrak{z}\text{viij}$, one ounce to be taken three times a day.

It is during the third stage of gonorrhoea that injections may advantageously be used. Much and very unfounded prejudice exists against their use in the minds of many; but surely it is as safe to apply proper local applications to an inflamed urethra as it is to an inflamed conjunctiva; and the bad consequences, such as stricture and inflamed testicle, which have sometimes been referred to their use, have either been due rather to the long continuance and to the severity of the disease itself than to the remedies employed, or to their application at too early a stage or of too great a strength. It is in long-standing cases of gonorrhoea, in which the discharge continues for months or years, that stricture follows, not in cases of ordinary duration; and it is the result of the chronic inflammatory thickening of the mucous membrane, and has no more to do with the injections than with the copaiba or salines which the patient may have taken. As the ardor urinae subsides, emollient and slightly astringent injections may be used. The best is perhaps chloride of zinc of the strength of two grains to twelve ounces of water, to which two drachms of extract of belladonna may be added. This injection may be used frequently during the day. Acetate of lead, from one to two grains to the ounce of water, is often useful. If this induce irritation, a few grains of the watery extract of opium may advantageously be added. As the disease subsides, a stronger astringent is required, and then one or two grains of the acetate of zinc may be added to each ounce of the injection; or a weak solution of sulphate may be employed, gr. ij to each ounce of water; or an injection of gr. i of the nitrate of silver to the ounce may be used. During the whole of this stage, the diet and habits of life must be carefully regulated, and all stimulants interdicted. The injections should be discontinued as soon as the discharge has ceased; unless this be done, they may reinduce it.

The mode of injection is of importance. A glass syringe should always be used, with a smooth rounded nozzle. The patient sitting on the edge of the chair and holding up the penis, should carefully insert the end of the syringe between the lips of the urethra, and then slowly throw in the injection as far as it will go. Although the inflammation is usually at first confined to the anterior portion of the urethra, yet it in most cases extends to the bulb, and the injection should be applied to the whole length of the inflamed mucous membrane. If any enter the bladder it cannot signify, as it will immediately be decomposed by the salts and mucus of the urine.

Instead of the ordinary glass syringe, the injector (Fig. 918) may be advantageously used. By it, the injection is thrown from behind forwards, so that when passed beyond the inflamed part it washes out the discharge, instead of forcing it further on.

Treatment of Gleet.—In gleet, much difficulty will often be experienced in curing the patient of his discharge. Here much depends not only on the administration of proper remedies, but on care being taken attentively to regulate his habits of life. It will constantly be found that, after the disease

has apparently been cured, excesses at table, and more especially the drinking of beer, or of effervescing or acid wines, will bring back the discharge. It will return also after connection, though it have previously ceased entirely. This is especially the case in strumous, gouty, or rheumatic constitutions, in which all urethral inflammations are with difficulty removed. In these cases, then, abstinence from alcoholic liquids and dietetic stimulants, and a continent life must be strictly enjoined; but the local treatment requires careful attention.

In the early stages of gleet an attempt may be made to cure it by injections. For this purpose somewhat stronger solutions are required than in the more acute period of the disease. Sulphate of copper will often be found useful, commencing with half a grain to the ounce, and gradually increasing it to one or even two grains. Tannic acid in the strength of from two to four grains to the ounce will sometimes check the discharge. Soluble bougies, similar to those already described, but containing tannic acid, sulphate of zinc, or acetate of lead, are often of great service. These, combined with the internal administration of copaiba and cubebs, or the perchloride of iron, may effect a cure. If these do not succeed, the occasional passage of a full sized bougie is of the greatest use. The orifice of the urethra must also be examined for warty growths, which may keep up the discharge.

When the disease has become very chronic, and has assumed the form of granular urethritis, it is difficult of cure: for, as Desormaux has pointed out, no injection, which the healthy portion of the urethra is capable of bearing, will have much effect upon the inflamed patch. He therefore recommends the application of a very

Fig. 918. Teevan's Injector.

Fig. 919.—Guyon's Injector. The Smaller Figure represents the Nozzle.

strong solution of nitrate of silver through the endoscope; but equally satisfactory results may be obtained by the use of Guyon's injector (Fig. 919). This consists of a hollow bulbous sound perforated in the bulb, and fitted with a small syringe. The bulbous sound having been passed first up and

down the urethra till the exact situation of the inflamed spot is found by the tenderness and slight cling before mentioned, the perforated head is held fixed at the diseased spot, and a few drops of a solution of nitrate of silver (ten to twenty grains to the ounce of water) are injected. The patient should pass urine immediately before the injection, and not again for some hours if possible. Berkeley Hill, who has had great experience of this mode of treatment, states that, if the patient keep quiet for some time after, no complications are likely to follow; but neglect of these precautions may be followed by swelled testicle or even perineal abscess. After the operation, a weak astringent injection must be used for a few days, and the passage of bougies for a short time after is usually necessary to complete the cure. Otis, of New York, is of opinion that every prolonged gleet is the result of a narrowing of the canal, and he recommends internal urethrotomy as a cure—cutting the urethra up to its normal size by the method described under the treatment of stricture of the urethra. The operation is somewhat severe, and should never be had resort to till all other means have failed.

The treatment of gleet may therefore be summed up as follows. The patient must be carefully examined, in order to detect, if possible, some constitutional condition, such as struma, gout, or rheumatism, which may serve as a guide to general treatment, diet, and use of stimulants. Change of air and sea-bathing are often of essential service. The orifice of the urethra must be examined for warty growths or suppurating follicles. If these are found, they may be touched with nitrate of silver. If they are not found, the electuary of cubeba and copaiba, or one composed of cubeba and the sesquioxide of iron, may be administered with advantage, and the injections recommended for the chronic stage of gonorrhoea may be persevered with. Should these fail, and should the olive-headed sound give distinct evidence of a tender spot, and perhaps a slight narrowing of the urethra, the passage of a full-sized metallic bougie every second or third day should be tried. If, after a fair trial, this fail also, injection of nitrate of silver by Guyon's injector must next be had recourse to, followed by mild injections and the passage of bougies; and, lastly, if everything else have failed, and a distinct narrowing of the canal be present, internal urethrotomy may be tried as a last resource.

COMPLICATIONS OF GONORRHOEA.—Gonorrhoea, when acute or virulent, seldom runs its course without local complications of some kind, the result of the propagation of the inflammation to neighboring parts, often of considerable severity, and occasionally even hazardous to life,—such as chordee, phimosis, sympathetic bubo, perineal abscess, irritability of the bladder, retention of urine, hemorrhage from the urethra, etc. Many of these complications present no special features, but require to be treated on general principles, without reference to their specific cause. Others demand more special management, and these we may briefly consider here.

Inflammation of the Lymphatics of the Penis may occur, stretching along the sides and dorsum of the penis in the form of hard thread-like lines, with much redness and oedema of the integuments, and general swelling of the organ, the glans in these cases often assuming a turgid aspect and a dull brick-red color. This condition is a very serious one, as it may lead to one of two consequences, or both may ensue, viz., inflammation and suppuration of the inguinal glands, or blood-poisoning. It is the latter result that gives rise to the most serious constitutional effects in gonorrhoea, closely resembling the less severe forms of pyæmia.

Chordee, or painful erection of the penis, with twist of the organ, coming on at night, is often a most distressing and troublesome symptom. It is usually best relieved by the application of cold to the part, by the adminis-

tration at bedtime of a pill composed of gr. j of opium with gr. v of camphor. Ricord recommends a suppository of camphor and opium, gr. x of camphor, and gr. j of the watery extract of opium, to be introduced into the rectum an hour before bedtime, as the best means of removing the tendency to chordee. Full doses of bromide of potassium are sometimes of use.

Acute Prostatitis, presenting all the symptoms described on p. 1013, and in rare cases terminating in abscess, is an occasional complication. It must be treated as there described.

Chronic Prostatitis is rather a sequel of gonorrhoea than a complication. Its symptoms and treatment have been already described (p. 1015).

Inflammation of the Neck of the Bladder with Strangury and Dysuria is not an uncommon complication. It arises from exposure to cold or wet during a clap, and occasionally from the use of too strong injections. The discharge may lessen when the symptoms of the deeper inflammation set in. When the neck of the bladder only is inflamed, the urine remains acid, and contains but a slight excess of mucus. Frequency of micturition, often excessive, and accompanied by the most severe pain, forms the most prominent symptom. Pus and blood may escape with the last few drops of urine. It is distinguished from acute prostatitis by rectal examination, when absence of prostatic swelling and tenderness will be recognized. The inflammation in many cases is less acute, especially when the inflammation comes on at three or four weeks after the commencement of the clap. In the acute form leeches to the perineum, hot baths and fomentations, and full doses of Dover's powder, or of henbane and potash, will afford much relief. If the pain is very severe, a morphia suppository must be inserted into the rectum. In more chronic cases the administration of the perchloride of iron, with belladonna suppositories will be beneficial.

Cystitis, of an acute character, may occur by the extension of the urethral inflammation. The urethral discharge diminishes as the symptoms of cystitis come on, or ceases, just as in epididymitis; the patient is seized with intolerable and frequent dysuria, strangury, and general febrile disturbance. The urine becomes loaded with muco-pus, and may be fetid and alkaline. The condition is perilous. There is danger to life if the constitution be broken, and there is always danger of prolonged or possibly intractable subacute cystitis. Indeed, I believe that many of the cases of chronic subacute cystitis, with muco-pus in the urine, and perhaps atony of the bladder occurring in middle aged men, may be traced back to the influence of a gonorrhoea contracted in early life.

The *Treatment* of this condition consists in the employment of belladonna or opiate suppositories; the frequent use of warm hip-baths; the application of fomentations to the perineum, and of hot poultices to the pubic region. Brodie makes the important practical statement that, if the urine continue acid, the best treatment consists in the administration of calomel and opium. This is entirely in accordance with my experience, and where the patient is moderately young, and the urine acid, with pulse good, calomel with opium, or Dover's powder, will give effectual relief. As the cystitis subsides, the urethral discharge reappears.

Pyelitis and Nephritis are fortunately very rare complications of gonorrhoea. Murchison has recorded two cases in which death rapidly followed extension to the kidney, with coma and delirium. In a case lately in University College Hospital, a slight urethral discharge was followed by pain in the course of the ureter, and the symptoms of pyelitis. The disease assumed a chronic form, the pus in the urine being very abundant. Gonorrhoeal rheumatism of a severe form set in at the same time. After about two years the patient partially regained health, the amount of pus becoming

very small. In another case in the same hospital, a large renal abscess formed some time after an attack of gonorrhoea, to which it seemed to be directly attributable. The abscess was aspirated twice, and the patient recovered, but at his death some years after the kidney was found to be shrivelled to a small mass of fibrous tissue.

Retention of Urine from Gonorrhoea may set in at any period of the acute stage. The obstruction is usually dependent on congestion and inflammation of the mucous membrane of the urethra. Leeches to the perineum, the warm hip-bath, and opiate suppositories, will probably afford relief. It is always desirable to avoid using the catheter, as it is apt to lacerate the swollen and softened mucous membrane, and thus to occasion troublesome bleeding; and will always produce much pain, and increased irritation of the canal. Should, however, the retention have continued twenty-four hours, or longer, it will probably not give way to the means above indicated, and then it will be necessary to use the instrument, when a full sized one should be very carefully introduced; a large instrument entering the bladder as easily as a smaller one, and with less risk of injury to the tender walls of the canal.

When the catheter has been introduced, it is often somewhat difficult to determine whether it should be left in or taken out. If it be left in, inflammation is increased. If it be taken out, the Surgeon may not be able easily to introduce it again. The solution to this question is to be found in the facility with which the instrument is passed. If it have been introduced without much difficulty, it is better to withdraw it after the bladder has been emptied, and to continue the antiphlogistic treatment, when a second introduction may not be required. If, on the other hand, the catheter have been passed with great difficulty, and be firmly grasped by spasm, it should be left in; but very active treatment must be employed to prevent it from exciting too much inflammation.

It must, however, be remembered that the retention may be due to more serious conditions; to prostatitis, to abscess in the prostate or the perineum, or to inflammatory exudation in the tissues about the neck of the bladder. In these circumstances, more active antiphlogistic measures will be required, with the use of the catheter twice in the twenty-four hours, and probably free incisions into the perineum, if there be pus or urine extravasated into that region.

In many cases of gonorrhoeal retention, an old stricture complicates the clap. Here the employment of energetic antiphlogistic measures and the use of the catheter are indicated.

Hemorrhage from the Urethra may occur either as the result of chordee, and consequent rupture of some bloodvessels of the corpus spongiosum, as the consequence of attempts at passing the catheter, or as a kind of exudation from the mucous membrane. Most commonly it may be arrested by the application of ice, and the employment of moderate local antiphlogistic treatment. Should it be abundant, the introduction of a large gum-elastic catheter, and pressure by means of a bandage to the penis or perineum, will arrest it.

Urethral or Peri-urethral Abscess occasionally forms in gonorrhoea. It is supposed to result from inflammation culminating in suppuration, taking place in one of the lacunae or glands of the mucous membrane. An abscess may form at any part of the urethra, but the two most common situations are near the end of the penis and in the region of the bulb. It is possible that in many cases the pus may be discharged into the urethra without being recognized; but if the collection of pus reaches any size it points towards the surface. In the neighborhood of the glans it forms a rounded

swelling, usually projecting under or to one side of the frenum. It is tender on pressure, and the parts round are swollen and oedematous. In this situation it should be opened as early as possible lest it should burst into the urethra, after which, as the aperture is usually insufficient, a second opening will form on the surface, leaving a fistula, which is very troublesome to heal.

When the abscess forms in the region of the bulb, it forms a hard, tender, swelling in the perineum, constituting one of the varieties of *perineal abscess*. In this situation, also, if opened early by a free incision in the middle line, it will be found to have no communication with the urethra, and will quickly heal without leaving a fistula. If it be not opened in time, it may burrow widely beneath the accelerator urinæ, and the expansion from it covering the penis. Under these circumstances it may be felt both at the root of the penis and in the perineum, and there may be considerable swelling of the scrotum. The incision in such a case should be made behind the scrotum only. If left too long, a communication with the urethra may have taken place, but provided the incision is made in the perineum only, it will heal without difficulty.

SEQUENCES OF GONORRHOEA.—The sequences, or more remote complications of gonorrhœa, are partly local and partly constitutional. Amongst the local we find more particularly **Warts** about the prepuce and glans or within the urethral orifice, which require to be treated by excision or caustics; and **Stricture**, the management of which is fully described elsewhere. In some cases, also, in consequence of extravasation of blood, or inflammatory exudation into the corpus spongiosum or the corpora cavernosa, limited and localized **Induration and Thickening of the Penis** may result, attended by chordee, painful erections, and a permanent twist in the organ. In such conditions as these, an attempt may be made to produce absorption of the effused mass, by the administration of small doses of bichloride of mercury, with theunction of iodide of lead ointment.

After the cure of a clap that has been of long continuance, the generative organs are often left in a *weak and irritable state*; the penis, scrotum, and spermatic cords being lax and elongated, with an apparent want of power, and often painful and dragging sensations about the cords and groins.

Besides the strictly local complications of gonorrhœa, certain sequences, to which some constitutions are especially liable, occasionally occur as the result of this disease; viz., inflammation of the testes and of the eyes, and rheumatism. Some of these, as the affections of the eyes and testes, may be either local or constitutional; the others are clearly constitutional. The constitutional effects of gonorrhœa offer characters that have some analogy to those presented by the more chronic and subacute forms of pyæmia. This is more especially the case in monarthritic inflammation of the knee or wrist, leading to disorganization or permanent ankylosis of these joints.

Gonorrhœal Epididymitis is certainly the most common of these sequences. It almost invariably affects only one testis, and commences in the epididymis, whence it extends to the body of the organ. It usually occurs in individuals who have a lax and long scrotum, with very pendulous testes. It seldom sets in before the third week after the occurrence of gonorrhœa, but may occur at any period during the continuance of the discharge, though it is more frequent between the fifth and sixth weeks than at any other time. In cases of gleet, also, it not uncommonly occurs at a later period. In many instances it is referred to some slight injury—a blow, or squeeze, received during the continuance of the gonorrhœa; but in some cases it would appear to rise from extension of the inflammation along the ejaculatory duct. It was formerly believed to arise in some cases from so-called metastasis of in-

inflammation from the urethra to the testis. That the disease commences in the epididymis, may be advanced in support of the first opinion; whilst the fact that the discharge usually ceases when the inflammation of the testicle comes on, and returns as it subsides, has been adduced in support of the doctrine of its metastatic origin. Curling is of opinion that the diminution of discharge is due to counter irritation, as he has seen a case in which the urethral discharge ceased, although the orchitis had been occasioned by a blow. As the symptoms and treatment of gonorrhoeal inflammation of the testicle present nothing peculiar, I shall reserve their consideration until we speak of diseases of this organ. Gonorrhoeal epididymitis is apt to be followed by long continued gleet, consequent on the exudation from the lining membranes of the vas deferens, and the secretory apparatus of the testes.

Gonorrhoeal Inflammation of the Eyes is fortunately not of very common occurrence. It may affect either the conjunctiva or the sclerotics.

Gonorrhoeal Conjunctivitis is one of the most destructive forms of ophthalmia, giving rise not unfrequently, in the course of forty-eight hours, to the most intense chemosis, with opacity and softening of the cornea, followed by staphyloma and a discharge of the humors. In the majority of instances only one eye is affected; but, in some, both are involved to an equal extent. The disease commences with the ordinary symptoms of conjunctival inflammation; itching and swelling of the eyelids, velvety redness of the conjunctiva, mucopurulent discharge, with much lachrymation. The chemosis sets in early, and is very severe; and, unless treatment afford speedy relief, the consequences are most disastrous to vision. Lawrence states that, of 14 cases that fell under his observation, 9 had only one eye affected and 5 both. Of the 9 in whom one eye only was diseased, the organ was lost in 6 cases; of the 5 in whom both eyes were affected, both organs were destroyed in one case; in 2 one eye only was lost; one patient recovered imperfectly; and in only one did complete recovery ensue.

It has been a question with Surgeons, whether gonorrhoeal ophthalmia is the result of the direct application of the specific pus to the conjunctiva, or occurs as a constitutional disorder. There is no doubt that the application of the pus to the surface of the conjunctiva will occasion the disease; and this is now generally acknowledged to be the only mode of origin.

The *Treatment* of this dangerous affection must be of an active character. The violent depleting measures formerly recommended are now universally condemned. General bloodletting is never required; much relief may, however, be given by the extraction of a small amount of blood from the temple by leeches. The patient must be confined to a dark room, the bowels must be kept regular, and a moderate diet allowed. The most active topical agent that we possess is the nitrate of silver. The use of this astringent originally introduced by Little, has been much insisted on by Guthrie, Walker, and others, and is generally adopted at the present day, being certainly the most useful agent that we possess. Surgeons differ somewhat in opinion as to the strength of the application; some, the Germans especially, advise that the solid stick should be used, whilst others employ it in solution, of the strength of a drachm to the ounce of distilled water. Wharton Jones employs a weaker solution, one of four or five grains to the ounce, and I have seen cases very successfully treated by this plan, so much so, indeed, that I am disposed to prefer it to the stronger solution. A few drops must be introduced about twice in the twenty-four hours, into the inner canthus of the eye; the lids in the meantime being kept covered by compresses dipped in weak alum lotion, and the purulent discharge, as it accumulates, carefully washed away by tepid alum injections. Instead of alum, boric acid may be used with great effect, and lately, a very weak solution of bichloride of mercury

(1 in 5000) has been tried with considerable success. In doing this, great care must be taken that none of the discharge comes into contact with the eyes of the Surgeon or nurses, as it is highly contagious, and will almost to a certainty produce the disease; instances are recorded in which, in this way, the attendant's vision has been destroyed. If the chemosis be considerable, it must be incised; and, as the inflammation subsides, belladonna lotions may be employed with advantage, and the use of the nitrate of silver and other lotions gradually discontinued.

Great care must be taken to prevent infection of the other eye when only one is affected. It may be covered with a compress, or, as Dixon recommends, a watch-glass may be placed over it and secured by plaster.

Gonorrhœal Scleritis is by no means of such frequent occurrence as the conjunctival inflammation; when it happens, it will be found to be associated with gonorrhœal rheumatism, and not unfrequently with inflammation of the testicle, occurring apparently in individuals in whom there is a tendency to affection of the fibrous tissues. This disease is evidently of constitutional origin, as it cannot possibly arise from local contagion; it is attended by the ordinary signs of sclerotic inflammation, and is usually accompanied by some degree of iritis.

The constitutional *Treatment* is that for gonorrhœal rheumatism. Locally the eye must be protected from light, and a few drops of atropine solution put in occasionally. If there is much pain, blood may be taken from the temple by cupping or leeches.

Inflammation of the Nose, attended by profuse suppuration, is a complication that I have more than once had occasion to observe in gonorrhœa. The swelling of the organ is considerable, the tenderness great, and the discharge abundant; a condition, indeed, of the Schneiderian membrane that seems analogous to the inflammation of the conjunctiva just described.

The *Treatment* that I have found to succeed best, consists in fomentations, followed by astringent lotions or injections.

Gonorrhœa of the Rectum has been met with in rare cases. In women it may be the result of infection from vaginal discharge, but in men it is usually the result of unnatural vice. The symptoms are pain in the bowel, with a thick muco-purulent discharge. The *Treatment* consists in injections of acetate of lead and opium.

Gonorrhœal Rheumatism principally occurs in young and otherwise healthy persons. The exact nature of the disease is very uncertain. It is supposed by many to be a form of blood-poisoning analogous to pyæmia. Berkeley Hill states that his observations lead him to believe that the disease is met with chiefly in gouty or rheumatic subjects. If the patient have not previously suffered from these affections, a family history indicating a tendency to them will usually be found. In patients who are distinctly rheumatic or gouty, Hutchinson states that any urethral discharge, whether specific or not, may give rise to symptoms identical with those of gonorrhœal rheumatism. The affection is more common in men than in women, and seldom sets in till the third week after the commencement of the discharge, though it may occur as late as the second month. The disease may assume various forms. It may commence insidiously with pain in the joints, quickly followed by considerable effusion. Several joints may be affected, but the knee is attacked with far greater frequency than any other articulation. The febrile disturbance may be slight. The pain and swelling last usually for some weeks, and gradually subside; but relapses are common. In other cases the course of the affection more closely resembles that of acute arthritis; the pain is intense, and the ligaments are early affected. The swelling assumes an oval form, effusion into the articular cavity being slight, or even wanting. The

constitutional disturbance is severe. This variety most commonly ends in ankylosis. In another form occasionally met with, pain forms the chief symptom, without swelling or interference with movement. Other structures beside the joints may be affected, as the fasciæ, the sheaths of tendons, bursæ, and occasionally the nerves. Gonorrhœal scleritis, as already mentioned, is always connected with rheumatism, and orchitis may arise from the same cause. Gonorrhœal may be distinguished from simple acute rheumatism by the attack being less severe, by the affection usually being limited to two or three joints, and often to the knee only, and by the absence of the profuse sweating and the creamy-white tongue. The prognosis is, as a rule, good. Suppuration may occasionally take place, and the disease then merges into that to be immediately described, gonorrhœal pyæmia. Ankylosis is, however, very common, especially in the arthritic form. This arises not so much from destruction of the cartilages, but from shortening and contraction of the inflamed capsule of the joint as recovery takes place. This form of ankylosis is practically incurable.

Treatment.—The first essential point of treatment is to check the urethral discharge as quickly as possible by the means already described. Iodide of potassium, with alkaline tonics, are sometimes of use. Calomel and opium were formerly administered, but are not now believed to be of any value. Salicylate of soda in large doses has been tried with varying effect. Quinine may be given if the temperature is elevated, and in the later stages perchloride of iron is often of material service. The local joint-affection must be treated by absolute rest on splints, blistering, and strapping over mercurial ointment in the later stages. If ankylosis occurs, it must be treated as described on p. 360.

Gonorrhœal Pyæmia.—It is not easy to draw a clear distinction between gonorrhœal rheumatism and pyæmia. The term pyæmia is applied to those aggravated cases, fortunately of very rare occurrence, in which the joint-affection terminates in suppuration, with complete destruction of the articulation. In these cases abscesses are not uncommonly met with in other parts of the body, especially in the subcutaneous tissue. Visceral abscesses are of very rare occurrence. The symptoms are those of chronic pyæmia vol. i. p. 920.

Cutaneous Eruptions. chiefly consisting of roseolæ, with slight pityriasis, and perhaps a few patches of psoriasis, have been described as occurring occasionally in severe cases of gonorrhœa. The description given by Travers of these eruptions makes them correspond so closely to the early manifestations of syphilis that it is probable that they really resulted from an intra-urethral chancre, mistaken for gonorrhœa. If these cases and those in which the rash arises from copaiba and cubeba be excluded, it is doubtful if any truly gonorrhœal skin-eruptions exist.

Gonorrhœa in the Female differs from the same affection in the male in not being so severe, though it is usually more extensive, and of longer duration. The severity is less, on account of the shortness of the female urethra preventing the occurrence of the retention of urine as in the male, and also from the absence of such parts as the prostate, testes, etc., the implication of which constitutes the principal source of difficulty in men. Gonorrhœa in the female may affect the parts to very different degrees; thus, the vulva alone may be implicated, or, as most commonly happens, the inflammation may spread to the whole of the mucous membrane of the vagina. The urethra is less commonly the seat of disease, though occasionally implicated with other parts; and, lastly, the interior of the uterus may become affected by this specific inflammation. In some cases it will even spread along the Fallopian tubes to the ovaries: and ovaritis and fatal peritonitis also may be induced.

The *Symptoms* of gonorrhœa in women are sufficiently well marked in the early stages, when there is an abundant muco-purulent discharge from the parts affected, with a good deal of inflammatory irritation, accompanied with pain in micturition, and a frequent desire to pass urine. As the disease becomes chronic, however, it is more difficult to determine its true character; it being apt to be confounded with some of those accidental and leucorrhœal discharges to which females of all ages are subject.

Diagnosis.—In the majority of cases, gonorrhœa may be distinguished from all other muco-purulent discharges of the female organs, by the presence of inflammation about the external parts, and the mucous membrane of the vagina and urethra. In these cases it will be found, on introducing a speculum (which, however, occasions considerable pain, and is firmly grasped by the contraction of the vagina), that the discharge comes from the vaginal wall, and that the uterine orifice is free from it, or nearly so; whereas in leucorrhœa the discharge proceeds in a great measure from the interior of the uterus, the os and cervix of which will probably also present signs of diseased action. It must, however, be borne in mind that the discharge in gonorrhœa may occasionally be in a great degree uterine; and that that of leucorrhœa may be an exudation from the mucous membrane of the vagina. In such circumstances, when the disease is chronic, it is almost impossible to arrive at a correct conclusion as to the nature of the case from simple inspection; and in these cases of doubt the Surgeon had better give a very guarded opinion, lest he be led into the error of inculpating an innocent woman. The difficulty is increased, and a good deal of obscurity thrown over the case, by the fact that leucorrhœal discharges will occasionally give rise to urethritis in the male, which closely simulates gonorrhœa. Female *Children* also are occasionally subject to an acute inflammation of the vagina and nymphæ as the result of simple irritation, of constitutional disturbance, or of teething; these cases require to be recognized, as they have frequently been the cause of unfounded accusations.

The *Treatment* of gonorrhœa in the female must vary, according as the disease is acute or chronic. In the acute stage, general and local antiphlogistic means—salines, low diet, rest in bed, and emollient sedative fomentations—must be used. As the disease subsides into a chronic condition, astringent injections must be employed; a weak solution of acetate of lead, or the liquor aluminis compositus largely diluted with tepid water, being especially useful. In other cases, a weak solution of nitrate of silver may be used with much advantage. These injections should be employed three or four times a day and in large quantity. After they have been thrown up, a piece of lint well soaked in the lotion should be introduced between the opposed mucous surfaces, so as to prevent their coming into apposition, the discharge being in a great measure kept up by their friction against one another. In order that the injection may be properly given, the woman should lie flat on her back, and pump in the fluid by means of one of Kennedy's elastic bottles. In the treatment of gonorrhœa in women, specifics are of no use unless the urethra be affected, when copaiba may be given, as in the male. The disease is apt to degenerate into a chronic gleet condition, leaving a thin muco-puriform discharge, which will continue to be infectious for a great length of time.

STRICTURE OF THE URETHRA.

Much discrepancy of opinion for a long time existed as to the structure of the urethra, some Surgeons admitting, others denying its muscularity. The presence of muscular fibres in the urethra had been suspected by many in

consequence of the phenomena presented by some forms of stricture being solely explicable in this way, their presence was first actually demonstrated by Kölliker and Hancock, who showed that the tube is surrounded through its entire length with an organic muscular coat. Hancock has demonstrated the course of these fibres. He has pointed out that the fibres of the inner layer of the muscular coat of the bladder pass forwards underneath the mucous membrane of the prostatic portion of the urethra, and those from the outer layer of the muscular coat of the bladder outside the prostate. These two layers join at the membranous portion of the urethra, forming the muscular covering of this portion of the canal. At the bulb, these two layers divide again; the inner lying underneath the mucous membrane, separated from it merely by areolar tissue; the external lying outside the corpus spongiosum, between it and its fibrous investment. At the anterior extremity of the urethra they unite again and form its lips. Thus the urethra is surrounded through its whole length by muscular fibres, a double layer of which invests it at the membranous portion, and again at the external meatus. The prostate and corpus spongiosum are included between planes of these fibres. The vesicles and ducts of the prostate are surrounded by layers of involuntary fibres; those of the ejaculatory ducts coming from the non-striated layer of the vas deferens. These fibres are totally distinct from the common muscular apparatus of the perineum, and their existence proves the urethra to be a musculo-membranous canal.

By **Stricture of the Urethra** is meant a narrowing of the canal at one or more points. These may proceed from three distinct conditions, viz., 1, *Spasmodic Action* of the layer of the involuntary Muscular Fibres situated outside the mucous membrane; 2, *Congestion* of the Mucous Membrane of the canal; or, 3, *Organic Changes* in the Mucous and Submucous Tissues, consisting of thickening, induration, or the deposit of plastic matter within them. According as the disease arises from one or other of these causes, it may be termed a *Spasmodic*, a *Congestive*, or an *Organic* stricture. These different forms of the disease having the one condition—narrowing of the urethra—and its consequences, in common, and in practice being often associated, present so much variety in their symptoms, in the treatment they require, and the constitutions in which they occur, as to require separate description.

Spasmodic Stricture.—The existence of this form of constriction has been much cavilled at. Surgeons, disregarding the evidence of their own senses, and being led away by an imperfect anatomical examination of the urethra, have denied the possibility of spasm of this canal, not being able to demonstrate the existence of any muscular fibres in sufficiently close proximity to the mucous membrane to influence it by their action. The possession of muscular contractility by the urethra is, however, obvious from the facts that a bougie may occasionally be introduced with sufficient ease, but that the Surgeon, on attempting to withdraw it, will find it tightly grasped; so also, occasionally, on introducing the instrument, he will feel it meet with an obstruction, which, on steady pressure, will yield with that species of quivering that is peculiar to spasm of muscular fibre. Again, the fact that a patient will at one time pass his urine with the most perfect freedom, whilst, if it be rendered acrid or acid by drinking spirits, effervescent wines, or other similar beverages, almost complete obstruction will ensue, tends to prove the existence of an occasional spasmodic constriction of the canal. The effect of anaesthetics in facilitating the passage of a catheter must also be attributed to relaxation of spasm. These facts, though sufficiently convincing to many Surgeons, had failed to carry proof of the existence of spasmodic stricture to others, until the researches of Kölliker and Hancock,

which have been referred to, set the question of the muscularity of the urethra finally at rest.

Causes.—The causes of spasmodic stricture are generally such conditions as occasion an irritable state of system, as long residence in bed, climate, especially if conjoined with habitual excesses in drinking, high living, and sexual indulgences. The more immediate causes are usually any circumstances that occasion irritation of the urethral mucous membrane, which, being propagated to the smooth muscular fibres beneath, calls them into activity, and thus gives rise to the spasmodic affection. The most usual of these are those conditions of the system in which the lithates are largely eliminated; as exposure to cold and wet, by which the action of the kidneys is suspended; or too free an indulgence in spirituous and acid liquors—such as red or effervescent wines, beer, or punch—which are well known to give rise to an attack in many constitutions.

Symptoms.—In spasmodic stricture we find evidence of narrowing of the urethra, and consequent impediment to the free flow of urine, rapidly supervening under the influence of certain causes, and as speedily subsiding. A patient, for instance, in his ordinary health and passing urine freely, if he take such food or drink as will give rise to a very acid condition of the fluid, if he be exposed to cold, or get out of health in any way, suddenly finds himself able to pass his urine only in a small stream by drops, and with much straining, or may even be seized with complete retention. Under appropriate treatment these symptoms rapidly subside, recurring, however, on the application of any exciting cause. At the time of the occurrence of this spasm there is often a sensation of weight and uneasiness in the perineum, with evident irritation of the urethral mucous membrane, as shown by reddening of the lips of the orifice; in fact, a tendency to a combination of the congestive with the spasmodic form of stricture. There will often be found to be a very slight organic stricture in cases of the spasmodic form of this disease; so that, when the spasm subsides, the urethra will not be quite so free as natural.

Treatment.—If the patient be suffering from spasmodic difficulty in passing urine, an injection, consisting of half a drachm of laudanum in a pint of starch, should be thrown up the rectum, a morphia suppository given, or a full dose of Dover's powder administered, and the warm hip-bath used. As the opium begins to take effect, the urine will usually be passed without much difficulty. The bowels should then be made to act, when the patient will usually be relieved. If the spasm continue, as it often does, for one day or weeks after this, a full-sized soft bougie should be introduced every second or third day, in order to lessen the irritability of the urethra. In some cases, this is more effectually done by the use of a plated bougie, well warmed and oiled. Whatever instrument is used should be of large size, from No. 8 to 10. A small bougie will often be arrested, and will excite much irritation, when a large one will pass readily. If the use of the instrument cause irritation and increase of spasm, it is better to abstain entirely, and to trust to constitutional treatment. But the Surgeon need not be discouraged, if the first few introductions of the bougie appear to increase the irritation; as the urethra becomes accustomed to the use of the instrument, relaxation of the spasm will take place. At the same time, the patient's general health should be carefully attended to; the bowels must be kept open, and the diet regulated; all acids, stimulants, and sweets being carefully avoided. During the time when the bougie is being used, he should take the citrate of potash well diluted.

As a preventive treatment of these attacks, a careful regulation of the diet

warm clothing with the use of flannel, and keeping the skin in action by means of horsehair gloves and tepid baths, will be found serviceable.

Congestive Stricture.—Many Surgeons look upon *spasmodic stricture* as essentially dependent on congestion of the mucous membrane of the urethra, overlooking altogether the existence of spasm, or considering it as the result of irritation of the perineal muscles, and not of the true organic muscles of the canal. That the two conditions of congestion and spasm are frequently associated in the urethra, in the relation of cause and effect, there can be no doubt; and this is the most frequent condition in which spasmodic strictures are found. Indeed, congestion plays an important part in all forms of stricture; it may, as we have just seen, be connected with the spasmodic variety; it may occur alone; or it may be associated with organic stricture. Some parts of the urethra appear to be more subject to congestion than others; thus, for instance, the membranous and prostatic portions, especially the folds of mucous membrane constituting the verumontanum, are peculiarly liable to become congested.

Causes.—Congestive stricture frequently occurs as the result of chronic and long-continued inflammation of the urethra, or of the passage of urine that has been rendered irritating by being too concentrated, or by an admixture of an undue proportion of lithates. It is especially in gouty or rheumatic subjects who suffer from irritability of the skin and mucous membranes that this condition occurs. In these cases there is no true or permanent obstruction; but the disease is transitory, and due solely to a swollen state of the membrane of the part. But in the majority of cases it complicates, and aggravates seriously, spasmodic and slight organic strictures.

Symptoms.—In congestive stricture we not only find the common symptoms occasioned by an impediment to the free passage of the urine, but some swelling of the lips of the urethra, with reddening and eversion of them. There is also slight gleet exudation, and not unfrequently an abundant puriform discharge, in fact, urethritis of a marked kind, with a sense of weight or fulness in the perineum, pain in micturition, and sometimes uneasiness in defecation. This state of things constitutes a very troublesome affection, intimately connected with the various forms of urethritis, and exceedingly apt to relapse from apparently very trivial circumstances, slight errors of diet, dyspeptic derangements, or any local sources of irritation.

The **Treatment** in these cases should consist in careful regulation of the diet and habits of life, and especially in the administration of the citrate of potash, and the saline aperient mineral waters, as those of Carlsbad or Friedrichshall. If there be much tenderness or weight about the perineum, the application of leeches to this part, together with the use of the warm hip-bath, will be serviceable.

Congestive stricture, though more influenced by constitutional than by local means in many cases, yet is often greatly relieved by the occasional introduction of bougies. In some instances a soft instrument, in others a silver, will be found to answer best. Whatever is used, care should be taken to introduce it slowly and with every possible gentleness. With all care, some hemorrhage usually follows the passage of the instrument; not from deep laceration, but simply as the result of compression of the mucous membrane; and the discharge of blood appears to be beneficial rather than otherwise.

Organic Stricture.—This, the true form of stricture, is the result of the formation of dense fibrous tissue in the mucous membrane and submucous tissue of a portion of the urethra, in many cases extending to the neighboring spongy tissue, or even further. This is produced as the result of chronic inflammation or of the healing of ulcers or wounds, and differs in no respect from the cicatricial fibroid tissue formed in other parts under similar circum-

stances. In its development it shows the tendency to contraction, which forms the characteristic feature of all fibrous tissue produced as a consequence of inflammation, and thus leads to a narrowing of the canal it narrows. The causes of stricture are: 1. Chronic inflammation of the membranous part, resulting from gonorrhoea. Repeated gonorrhoeas and long continued gleet are by far the most fertile causes of this disease. The long continuance of the inflammation is more to be dreaded than its intensity in producing this mischief; hence it is of great importance not to allow gonorrhoea to run on indefinitely, as they will to a certainty be followed by contraction of some portion of the urethra. 2. The healing of an intraurethral chancre always gives rise to a stricture. This is met with within an inch of the orifice, and is a comparatively rare form of the disease. 3. The most inveterate form of stricture arises from transverse laceration of the urethra from blows or kicks in the perineum healing by a contracted scar. Scarcely contusions of other parts of the canal may in the same way cause narrowing of its calibre. A more rare cause is the injury done to the urethra of a horse by the lodgement of a calculus, or in the effort to extract it.

Age.—Stricture of the urethra may be met with at any age after puberty. The causes that usually give rise to it seldom come into operation, however, before the adult age; hence strictures are not very common before 20 years of age. Between that period and the age of 40 they meet commonly, terminate, and may then continue for an indefinite period. The earliest age at which I have seen true organic stricture of the urethra has been in a boy 14 years old, when it had already existed for more than 12 months, it was situated an inch and a half from the meatus, and was so tight as not to admit of No. 1 catheter. It was complicated with and had given rise to a fistula in perineo, through which the greater part of the urine escaped. The boy in whom it occurred could give no explanation of its occurrence, but it was probably traumatic. His attention was first directed to it by a sudden attack of retention. The stricture was hard and gristly, about half an inch long, and required urethrotomy for its relief. There was no calculus.

Seat.—The seat of organic stricture varies considerably; indeed any portion of the urethra may be affected by it, except the prostatic. It was at one time believed that the membranous portion of the canal was the most frequently affected by this disease. This, however, there can be little doubt is an erroneous opinion. H. Smith has examined 98 specimens of strictures contained in the different London museums; of these he found only 21 seated in the membranous portion of the urethra, whilst 77 were anterior to the triangular ligament; the majority of these being either in the bulbous portion of the urethra, or a little in advance of this. Sir H. Thompson in his excellent work on *Stricture*, states that, in an examination of 120 strictures, he found 215 at the junction of the spongy and membranous portions of the urethra; 51 in the spongy portion, from an inch in front of its commencement to within two inches and a half of the external meatus, and 54 at the external orifice, or within two inches and a half of it. The part most frequently affected is the first inch of the spongy portion, in the membranous portion, stricture is extremely rare, being almost invariably of traumatic origin when situated in this part. He says also, "I may confidently assert that there is not a single case of stricture in the prostatic portion of the urethra to be found in any one of the public museums of London, Edinburgh, or Paris." Occasionally strictures are multiple, two frequently occurring, and sometimes as many as four or five.

Pathological Appearances.—In describing the appearances commonly met with in a well-marked case of organic stricture, it will be most convenient to suppose that the whole canal has been laid open along its roof, and to ex-

sider the parts in the following order. 1. The part of the urethra anterior to the stricture. 2. The stricture. 3. The urethra behind the stricture. 4. The bladder. 5. The ureters and kidneys.

1. The *Urethra anterior to the Stricture* is perfectly healthy, unless it has been injured by instruments. If the cut edge of the mucous membrane be taken in a pair of forceps, it will be found to show a considerable degree of elasticity. Its color is pink, and it is semi-transparent. The spaces of the spongy tissue beneath are empty and open, or filled with blood.

2. The *Stricture*.—At the narrowed part the surface of the mucous membrane is of an opaque white color, marked by longitudinal ridges, and often parchment-like in appearance. If its edge be seized in the forceps it will be found to possess but little, if any, elasticity, and to be firmly fixed to the parts beneath. The submucous tissue, instead of forming a delicate areolar layer, is represented by tough rigid fibroid tissue firmly adherent on one side to the mucous membrane, and blending on the other with the cavernous

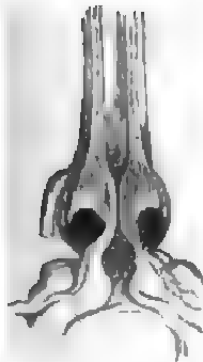

Fig. 920.—Stricture from Consolidation of Corpus Spongiosum.

Fig. 922.—Stricture at the Anterior part of the Urethra.

tissue of the corpus spongiosum. The spaces of the spongy tissue are, in all more advanced specimens, obliterated for a greater or less extent near the stricture, so that the corpus spongiosum at this spot is converted into a dense solid mass. In very extreme cases the chronic inflammatory induration extends even to the areolar tissue beyond. The character of the stricture varies greatly. In some cases it is annular, encircling the whole canal equally for some little distance. When it is elongated, there is usually marked consolidation of the corpus spongiosum, as in Fig. 920. In other cases, again, annular strictures may be narrow and sharp-edged, and are then called "pack-thread" or "bridle" strictures; consisting of bands stretching across the urethra (Fig. 921). Sometimes there are several of these in close proximity to one another, leaving merely narrow passages between or under them. These bands occasionally stretch directly across the canal, but at other times and more commonly they take a somewhat oblique direction (Fig. 922). It is not very clear how these bridles or fræna stretch-

ing across the urethra are formed. It can scarcely be by inflammatory excitation; it is more probable that they are occasioned by perforation of an annular narrowing of the mucous membrane by the point of the catheter. These various kinds of organic stricture are hard and elastic; sometimes when old, almost cartilaginous in their density, feeling gritty and rough to the instrument that passes over them.

The *Amount of Constriction* varies greatly in organic stricture, from slight narrowing of the channel to almost complete obstruction of it. A question has arisen whether the canal of the urethra is ever rendered completely impermeable by a stricture. In answering this, it is necessary to be agreed upon the meaning of the term "impermeable." If by it be meant impenetrable to the passage of a catheter, there can be no doubt that such strictures may occasionally, though very rarely, occur; the channel being so narrow, oblique, or tortuous, that the instrument cannot be passed through it. Strictures, however, of this description may usually be ultimately made permeable to instruments by proper and careful treatment. If by "impermeable" be meant generally impervious to the passage of urine, there can be no doubt that such a condition does not exist. It would clearly be incompatible with life, unless a fistulous opening existed behind the stricture, through which the urine might pass out; and, even with such an aperture existing, I have never heard of or seen a case in which no urine whatever escaped by the meatus, unless, in consequence of injury or disease, a portion of the whole calibre of the urethra had sloughed away; and it is clear that, so long as any urine passes out in this way, a stricture cannot be looked upon as truly impermeable.

3. The **Urethra behind the Stricture** is dilated often, so as to form a considerable pouch, in which in rare cases phosphatic concretions may form. The mucous membrane is more opaque than natural, and its loss of elasticity is indicated by its being thrown into longitudinal folds; it is usually of an ash gray color indicating that it has suffered from chronic congestion or inflammation. The orifices of the lacunae, and of the small glands opening upon it are dilated often to a considerable size. This is also very marked in the floor of the prostatic urethra. These small pits and hollows often cause considerable embarrassment in treatment, the instrument lodging in them after having safely passed the stricture. The cause of these changes is the extreme tension this part of the urethra is exposed to during inflammation, owing to the obstruction in front, and the powerful hypercontracted bladder behind.

4. The **Bladder** in all well-marked cases of stricture shows evidence of chronic cystitis. Its mucous membrane is thickened, rigid, and of an ash-gray color. If from any cause the condition has been aggravated before death, dark red and purple patches will be found upon it. As a rule the cavity of the bladder is diminished, and its muscular coat greatly hypertrophied, giving rise to marked fasciculation of its inner surface. In exceptional cases, especially in old men, it may be dilated as well as thickened, sacculi are very common.

5. The **Ureters** are often more or less dilated. This is not, as was formerly supposed, due to regurgitation of urine, but to obstruction to the orifice of the ureter by the chronic inflammation of the mucous membrane and the hypertrophy of the muscular coat of the bladder; the force that dilates the ureter being the force of secretion from the kidney. The further changes that occur in the pelvis and in the kidneys are fully described in Chapter I, XVII.

Symptoms.—The amount of constitutional disturbance set up by a stricture will vary greatly in different cases. In many, and indeed in most, it is

stances, it is not very great. The extent to which the constitution is influenced will generally be in proportion to the tightness and duration of the stricture; but it is surprising how much constitutional irritation is set up in some systems by a stricture, even though it be not very tight. The interference with the free flow of urine ultimately causes secondary mischief in the kidney, the nature and the symptoms of which have been fully described in Chapter LXII., to which I must refer the reader. In some cases the constitutional symptoms are rather of a nervous character; the patient suffering not only great pain in micturition, but being seized with rigors, followed by nervous prostration, each time the urine flows over the tender and irritable surface.

The *Local Signs* of stricture are always well marked, are very unequivocal, and are dependent simply on the mechanical obstacle presented by the contracted urethra to the free escape of the urine. The disease usually commences with the retention in the urethra of a few drops of urine after evacuation of the contents of the bladder; these escape and wet his clothes. The patient finds that he has to pass urine more frequently than usual, both by night and day; there is some straining, perhaps a slight gleet discharge, and a feeling of weakness about the genital organs. The stream of urine has changes impressed upon it during its passage through the stricture, by which its shape and direction are modified; thus, it may become forked, scattered, twisted, fan-like, or be discharged in a double current—one projected directly forwards, the other dropping perpendicularly downwards. There is usually but little pain in micturition, and such as there is occurs during this act, and ceases as soon as it is completed. As the disease advances, these signs necessarily become more marked, until they may terminate in complete retention; they, however, often come on in a very insidious manner, and when the patient seeks advice he is found to be already the subject of a very tight and intractable stricture: indeed, in some cases, the first circumstance that directs the attention of the patient to his complaint is the sudden occurrence of retention of urine.

Examination of the Patient for Stricture.—In all cases of suspected stricture, the Surgeon should, if possible, see the patient pass water before using an instrument. He will thus be able to judge of the actual amount of obstruction. It sometimes happens that the canal, though not greatly narrowed, is tortuous and indurated, so that an instrument enters with great difficulty, although the patient passes a fair stream of urine. Such a case might readily be mistaken for a very tight stricture if the examination is commenced by attempting to pass an instrument. The existence of a stricture can, however, be determined with certainty only by the introduction of an instrument. In exploring the canal in a suspected case, two points have to be ascertained, the existence of a stricture, and its degree of tightness.

The *Existence of a Stricture* is best determined by passing a soft conical French bougie about No. 8 English scale. It must be slightly warmed and well oiled. This will pass readily, unless the canal be distinctly constricted, when it will be arrested at the narrow point. In this exploration, too small an instrument must not be used, lest it hitch in the fossa of the urethra or against the verumontanum, and this accidental arrest be mistaken for the obstruction produced by a stricture; or it may pass through the stricture, and thus mislead the Surgeon. The existence of a stricture having been ascertained, the next point is to determine its *degree of tightness*. This is best done by withdrawing the instrument previously used, and then introducing a smaller one about the size of the stream of urine that the patient passes. If this fail to enter the stricture, a smaller one still must be used, until that size is reached which can be introduced with but a moderate

degree of force. In this way the existence, the seat, and degree of tightness of the stricture, are ascertained.

A soft instrument should always be used by preference for this preliminary examination, as it causes less pain, and with the most ordinary skill and care it is impossible to do the patient any injury with it. There is no doubt that information as to the length, degree of induration, and form of the narrowing, may be gained by the experienced Surgeon by means of a metal bougie; but the knowledge thus gained is not sufficient to counter-balance the greater ease and safety of a soft instrument.

The slightest narrowings of the urethra are not easily recognized by the means just described. For this purpose the conical or olive-headed bougie (Figs. 923, 924) will be found most useful. The conical shape of this in-

strument enables it to pass readily towards the bladder, but on withdrawing it the shoulder bites on any narrow part. The instrument should be graduated in inches, so that the exact distance of the stricture from the orifice can be readily determined. If it be desired to determine more accurately the seat of the stricture, the distance of the orifice of the bladder from the meatus externus must first be determined by carefully passing a graduated "catheter *à boule*," and noting the exact moment at which the urine commences to flow. The graduated olive-headed sound is then passed, and slowly withdrawn. If the hitch or cling be felt between one inch and one and three quarters, the stricture is in the membranous part. If between one and three-quarters and three inches, it is in the bulbous portion. For the purpose of measuring these slight strictures, Otis, of New York, has invented

an instrument which he calls the "urethrometer" (Fig. 925). It consists of a straight tube, the end of which can be dilated into a sort of fenestrated sphere, and the size to which it is dilated is registered on a small dial on the handle. The instrument can be readily introduced into the bladder, if

Fig. 923.—Conical-headed Sound.

Fig. 924.—Olive-headed Sound.

Fig. 925.—Otis's Urethrometer. A. Open. B. End closed.

necessary, but there is no advantage in so doing. When in the urethra, behind the stricture, the bulb is gradually expanded till it is just held, but not tightly grasped. It is then drawn steadily forward, and when it is stopped the bulb is gradually diminished till it passes the stricture. The exact size of each part is thus registered on the dial.

The employment of soft wax bougies has been recommended with the view of taking a mould of the size, shape, and direction of the stricture, by pressing the end of the instrument into it; but no possible advantage can be

derived from this proceeding, and a Surgeon accustomed to the use of metallic instruments can obtain all this information with more certainty by the finer touch afforded by them.

Treatment.—The treatment of organic stricture of the urethra may be conducted by the following methods: 1, Gradual Mechanical Dilatation; 2, Continuous Dilatation; 3, Caustics; 4, Forceful Expansion or Rupture; 5, Internal Urethrotomy; 6, External Urethrotomy or Perineal Section. Whatever plan of treatment be adopted, the Surgeon must bear in mind that his operations have to be conducted upon a tender canal endowed with exquisite sensibility, which sympathizes closely with the conditions of the general system, and in which improper violence or too active measures may set up a degree of irritation that will readily extend to neighboring structures, and thus jeopardize the life of the patient. But, though it is necessary to recollect all this, he must not run into the opposite and equally dangerous extreme of adopting inefficient measures for the removal of the obstruction. A bad stricture is one of the most serious diseases to which the human frame is liable, and will almost inevitably, if left to itself, terminate fatally by the induction of renal disease, or of serious local complications. We must therefore not hesitate to adopt sufficiently energetic measures for its removal; and if these be properly conducted, there is scarcely any affection in which the Surgeon can afford his patient greater relief than in this. At the same time, however, that local means are being used, constitutional treatment should not be neglected. Organic stricture is often more or less associated with a spasmodic or congestive condition of the urethra, and requires the same constitutional treatment, modified according to circumstance, that is necessary in these affections—proper regulation of diet, avoidance of all articles of food that generate lithates, and care not to allow the urine to become too concentrated. Attention to the maintenance of the healthy action of the liver and skin will also tend much to increase the patient's comfort, and to ward off the more serious consequences of stricture.

In all except the slightest cases of stricture it is advisable, before beginning mechanical treatment, to subject the patient to constitutional remedies to diminish as far as possible the congestion and spasm which may be present. If any serious difficulty be anticipated, and if the circumstances of the patient permit it, he should be confined to bed for a day or more. The bowels should be freely opened, and he should sit for some time in a hot hip-bath, morning and evening. An opium or morphia suppository may be administered at night, and if the signs of congestion be well marked, a few leeches may be applied to the perineum. Occasionally blisters over the seat of stricture, when it can be clearly felt from without, may be of service. By these means alone, a stricture which at first seemed almost impermeable may be so far relieved as to take a No. 4 or 5 catheter.

1. **Gradual Mechanical Dilatation**, as it is erroneously termed, is the usual and certainly the most successful mode of treating ordinary strictures; but it is not the mere stretching or forcible dilatation of the stricture that cures it. The means employed to produce dilatation tend to promote the absorption of chronic inflammatory products in and underneath the mucous membrane, which especially constitute the stricture.

The instruments that are used for dilatation are either metallic, such as silver catheters, steel sounds, or plated bougies; or made of some soft and yielding material, as gum-elastic catheters, catgut, whalebone, or elastic bougies. Though each Surgeon will mostly prefer one kind of instrument to another, it is well not to be too exclusive in the use of any one; for it will be found in particular strictures and certain constitutions that it is advantageous to depart from the ordinary practice, and that the Surgeon may

degree of force. In this way the existence of the stricture, are ascertained.

A soft instrument should always be used in examination, as it causes less pain, and it is impossible to do the patient any harm. Information as to the length, degree of narrowing, may be gained by the experienced hand, but the knowledge thus gained is not the ease and safety of a soft instrument.

The slighter narrowings of the urethra may be dilated by the means just described. For this purpose (Figs. 923, 924) will be found most

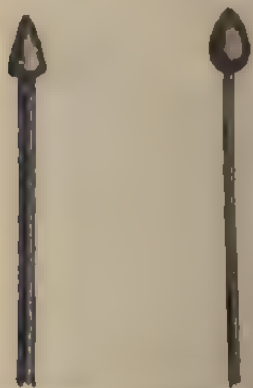

Fig. 923.—Conical-headed Sound.

Fig. 924.—Bulb-headed Sound.

useful in measuring these strictures. An instrument which he can use as a straight tube, the end of which is a sphere, and the size to which it can be introduced. The instrument

Fig. 925.—

necessary, but there is a danger in passing behind the stricture, the instrument must be tightly grasped. It is not until the bulb is gradually introduced that the part is thus reached.

The employment of the instrument in taking a mould of the end of the urethra

is that he adopts the use of soft instruments, and the stricture is tight, it is impossible to introduce a steel bougie or a catheter, then soft instruments are used. At this stage of the disease, a small, conical steel instrument is efficient but quite as

as catheters with bulbous tips, which cause less irritation and excite the mucous mem-

branes of the instruments. In most cases, the safest and most agreeable method is to use a tight irritable catheter, which, if it fails to pass,

of catgut, may sometimes be used. If any other instrument fails, the use of little use in the case of a small instrument, the point of the stricture, can easily be reached by the dilating force with its elastic tip. If the elastic which is the catheter is not stiff enough to enter into the stricture at all, it is not stiff enough to be used to stiffen it, it becomes as hard as a steel bougie, and is

very tight, but twisted, the plan is advantageously employed. The catheter is bent, and bending it, it is introduced an inch from the point, so that it can be introduced more closely. In this way, the impassable may be rendered

passable. The most efficient are conical instruments. The best curve for these is the circumference of a circle 44 inches in diameter, of three sizes between the

point and the thickest part, which corresponds to the bend of the instrument. The point should be well rounded, and the instrument passes more readily if there is a slight constriction immediately beyond it. The instrument should be made of nickel plated steel, and be highly polished. It should have a broad metallic handle, which transmits any sensation communicated to the point more readily than a wooden one. That this instrument will pass much more easily than a catheter is self-evident, and the latter should be used only when it is intended to tie it in. If a catheter be used, it should be made very solid and stiff. The rings should be large, so as to serve for a handle, and the eyes well rounded off and somewhat depressed, so that they may not scrape the urethra. These instruments should be used with every possible care and gentleness; but, though no one recognizes more strongly than I do the necessity of not employing unnecessary violence in their introduction, it is useless to think of passing a catheter through a tight hard stricture without the employment of some degree of force. The catheter will not "find its own way" here as it may in a healthy urethra, but it must be guided and directed by the hand of the Surgeon; and there is scarcely an operation in surgery that requires more tact and delicacy of manipulation than that of passing an instrument through a tight stricture. Here some force must be used, but the skill is shown in proportioning this to the amount of resistance, and in using it in a proper direction. The appearance of force is indeed often greater than the reality; for, though the point of the catheter have passed a tight stricture, it may still require considerable pressure to push the rest of the instrument through it. With a conical steel bougie less force is required than with the catheter, as the stretching is not done with the point which usually passes easily through the stricture, but with the expanded part beyond, which from its conical form passes without much difficulty.

Introduction.—Catheters and sounds are best introduced by laying the patient flat upon his back, with the pelvis somewhat raised, and the head and shoulders low. The Surgeon, standing on the left side, inserts the instrument, well-warmed and oiled with "Lund's oil" or vaseline, into the urethra, with its concavity turned towards the left groin, and passes it down the canal, at the same time drawing the penis upwards with his left hand, so as to put the mucous membrane on the stretch. As the instrument approaches the triangular ligament, the handle is carried to the mesial line, and at the same time raised perpendicularly; and, as its point passes under the pubes, it should be kept well against the upper surface of the urethra, and made to enter the bladder by depressing the handle towards and between the thighs. The surest guide to the bladder is the upper surface of the urethra, which is more fixed than the lower, and less liable to the existence of fistulous openings or false passages. Should difficulty be experienced, the introduction may be facilitated by injecting and slightly distending the urethra with olive oil before passing the instrument.

If difficulty is found in introducing the instrument, and if any doubt exist as to its being in the right passage, the finger must be introduced into the rectum and its position felt for. If the point of the instrument has left the urethra, this may be recognized by its being too thinly covered and too near the gut, or by its being out of the middle line.

Chloroform or ether need be administered only if the stricture be very tight or the patient irritable. Under the influence of an anæsthetic, however, many strictures may be readily passed with metallic instruments that are not pervious any other way.

Results of Introduction of an Instrument.—The introduction of an instrument usually gives rise to a smarting, painful sensation in the urethra; this

is generally most severe as the point approaches the neck of the bladder, and is then sometimes attended by nausea and sudden faintness. As a general rule, the instrument should be passed every second or third day, and when introduced should be left in for about five minutes, or until the spasm of the urethra induced by its introduction has subsided. If, however, the stricture be extremely tight, a very small catheter only having been introduced, the instrument may be left in for twenty-four or forty-eight hours, when it will be found that, however tightly grasped it had been originally, it has become loosened; a slight discharge being at the same time set up from the urethra. It may then be readily withdrawn, and, when the irritation has subsided at the end of a couple of days, a considerably larger one may be introduced.

The augmentation of the size of the instrument should be very gradual. It is fully sufficient to increase it by one number at each time of introduction. Many urethrae will not bear even this, and it becomes necessary to pass the same instrument on two or three successive occasions before a larger size can be introduced. The size of the instrument may be gradually increased until that is reached which the urethral orifice readily admits; beyond this, the Surgeon should not go; but so soon as the full size, usually No. 12 or 14, can be introduced with ease, it should not be passed so frequently as before; once a week or ten days, and gradually with less frequency. But a patient who has once suffered from a tight stricture should pass an instrument at least once a month for the rest of his life.

If the size of the instrument be increased too rapidly, irritation may be set up, and inflammation of the testicles, and abscess in the perineum or prostate, induced. I have more than once had occasion to regret being in too much haste to increase the size of the instrument; and, by augmenting it by two or three numbers at one sitting, have seen the patient thrown back for weeks by the supervention of some of the affections just mentioned.

By gradual dilatation, properly carried out, most strictures may be considerably relieved in the course of a few weeks; and the majority may be brought to the full size by continuing the treatment for a sufficient length of time. Some, however, cannot be cured in this way; it would appear that the tissue of which they are composed is so rigid that, although they may be expanded up to a certain size—say up to No. 5 or 6—it is impossible to go beyond this. In other cases, there is a great tendency to relapse, and to a return of the constriction; the stricture rapidly becoming tighter so soon as the introduction of the instruments is discontinued, even though it be dilated to the full size of the urethra—up to No. 12 catheter, for instance. In some instances the relapse is almost instantaneous, micturition being as difficult as before immediately the catheter is withdrawn. In these cases recourse must be had to other measures, which will be described.

ACCIDENTS ATTENDING CATHETERISM.—The introduction of instruments occasionally gives rise to certain troublesome and even dangerous sequences. Amongst these, syncope and rigors, hemorrhage, and inflammatory irritation about the urethra or testes, are the most common.

Nervous Symptoms, Rigors, and Urethral Fever.—The subject of urethral fever following the use of instruments on the urinary organs in persons affected with chronic subacute interstitial nephritis has already been discussed at p. 886. There is no class of cases in which this untoward complication is more apt to occur than in the treatment of stricture of the urethra, owing no doubt, in a great degree, to the frequency of the occurrence of chronic and possibly unsuspected kidney disease in old cases of stricture.

Various degrees of constitutional disturbance may be produced by the

passage of an instrument through a stricture. In nervous and sensitive individuals, this operation is often attended by a sensation of faintness and chilliness as the instrument enters the bulb or membranous portions of the urethra. This sensation is not due either to pain or to fear. It is purely reflex, and in most cases soon passes off, being less liable to recur as the urethra gets more accustomed to the use of instruments.

If a person liable to these nervous feelings is exposed to a chill, a severe rigor may come on some hours after the passage of the instrument, or the same occurrence may happen when there has been no predisposition to it, the rigor coming on suddenly and without warning. This is more apt to happen when the stricture is tight; when metallic instruments have been used—possibly with some degree of force, and, though during a considerable length of time—perhaps in vain attempts to penetrate the stricture. The rigors in these circumstances are very severe, so much so as to resemble an attack of ague. During the rigor the temperature rises considerably, often to 104° or 105° . The subsidence of the rigor is marked by profuse sweating, and is usually attended by great exhaustion. This occurrence is always very alarming, and, though usually not attended by positive danger, leaves the patient weak and exhausted; and, if he be old, of broken constitution, or the subject of chronic kidney-disease, a fatal result may rapidly ensue. In these distressing cases, death may occur at different periods and in different ways. The earliest period at which I have seen a fatal termination has been in nine hours, usually it takes place in from 24 to 48 hours after the occurrence of the first rigor. The immediate cause of death may be coma, exhaustion, or cardiac syncope.

The cause of these rigors is exceedingly obscure. Constitutional nervousness or timidity has certainly nothing to do with them. They occur in the strongest and most courageous men, and they very rarely follow the use of the catheter in women. I have only once seen these effects in the female; in the person of a young married lady, strong and healthy, who had a stricture of the orifice of the urethra, which I dilated by a two-bladed dilator. Twenty hours after the operation, she had three most intense rigors followed by profuse sweatings. In men, they may occur after dilatation of any part of the urethra, but are much more frequent after dilatation of a stricture seated in the bulb or in the membranous portion of the canal. I have, however, heard of one case in which a fatal rigor followed incision and dilatation of the orifice of the urethra. I doubt whether severe rigors occur unless there have been some traumatic lesion, such as abrasion or rupture of the mucous membrane of the urethra. Rigors certainly follow the use of metallic instruments more frequently than that of the softer kinds, which are less likely to produce such mischief. Rigors are not prevented by the use of anaesthetics. Some of the worst cases that I have seen have occurred after prolonged instrumentation under anaesthetics.

Treatment.—The rigor is best prevented by gentleness in the use of instruments; by the employment of soft, rather than metallic ones; by guarding most carefully against a chill, the patient being kept in a warm room during the whole of the day; and by the administration of a full dose of opium and quinine before the use of the instrument.

When a rigor has set in, the patient should be wrapped up in blankets; a glass of hot spirits and water, or tea, may be given, to be followed up by quinine and opium. The sweating, which is often so profuse as to wet through pillows and bed-clothes, must be encouraged. When it has ceased, the patient should be rubbed dry and laid in dry, warm blankets.

Suppression of Urine is a rare accident after simple dilatation, being more common after the more severe methods of treatment, such as forcible dilata-

tion. The symptoms are at first those just described, the patient suffering from a rigor, with rapid elevation of temperature, dry skin, and vomiting. The secretion of urine entirely ceases, or at most a few drops darkly stained with blood escape. The patient usually dies in from two to three days, unless the secretion returns. In these cases, the kidneys are usually found more or less extensively affected with chronic interstitial inflammation; but cases have been recorded in which the microscope revealed but little change. They are usually gorged with blood. The condition would seem to arise from reflex nervous disturbance of the kidney, but the exact pathology of the process is very obscure.

The *Treatment* consists in dry cupping over the loins and hot-air baths. Large warm-water enemata, with a view of "fomenting the kidneys," have been suggested. The bowels must be freely opened by a compound jalap powder. Possibly in some cases pilocarpine hypodermically, in doses of from $\frac{1}{16}$ to $\frac{1}{8}$ of a grain, might be of use.

Hemorrhage, which is sometimes rather profuse, may follow the introduction of a catheter, especially if the stricture be congestive, and the instrument employed small. It generally ceases of itself; but, if it be troublesome, the application of cold will check it.

The **Inflammation** about the urethra and in the testes that occasionally occurs during the treatment of stricture, is best guarded against by not using too large catheters, and by directing the patient to abstain from much exercise during the time of their introduction.

False Passages are occasioned by the instrument passing out of the urethra through its coats into the surrounding tissues. They are especially apt to occur in tight bridle-strictures, when a small instrument is being used, and more especially if the direction of the constriction be somewhat oblique, so that the point of the sound is thrown against the side of the canal. Fig. 921. The extent and situation of a false passage necessarily vary according to the position of the stricture; and the danger is usually in proportion to its depth. The false passage usually takes a direction downwards and to one side of the urethra. If the stricture be far forward, it may run in the corpus spongiosum; but if it be in the usual situation, it may perforate the lateral lobe of the prostate, or run between this and the rectum, being unable to extend upwards on account of the rigid nature of the structures in this situation. When the false passage merely perforates the corpus spongiosum, running parallel to the urethra, and opening again into the canal, or when perforating a portion of the prostate, it enters the bladder, it is not necessarily attended with much danger; but when it enters the areolar tissue between the bladder and the rectum, breaking up this structure to a great extent, admitting urine into the recto-vesical space and about the neck of the bladder, then the most serious consequences, such as inflammation and abscess in this neighborhood, are apt to ensue, which may not unlikely be followed by the death of the patient.

At the moment when a false passage is made during the introduction of an instrument, by the Surgeon using too much force or pressing in the wrong direction, he feels the point make a sudden slip, which the plane of the handle shows to be to one side of the urethra. The patient complains of severe pain, and is often conscious of a laceration; there is a grating or rough sensation communicated by the tissues against which the instrument has passed; and though it have entered deeply, it will be found not to have reached the bladder. On the Surgeon introducing his finger into the rectum, he probably feels the point of the instrument in the areolar tissue between the gut and the bladder; on withdrawing it, it will be found covered with blood, and there will be free hemorrhage from the urethra.

The Surgeon knows when he has entered an old false passage by the change that takes place in the direction of the instrument, by its not reaching the bladder and by the rough sensation communicated to it, very different from that afforded by the smooth lining of the urethra. The patient is often conscious of the existence and of the entry of the instrument into the false passage, and will warn the Surgeon of it.

If the Surgeon be aware that he has made a false passage, he should, if possible, at the time of the accident pass a catheter into the bladder, and leave it there for a few days until the laceration is healed. If there be an old false passage he must be careful, by keeping the point of the instrument away from it, not to enter it, lest during the introduction of the catheter he raise with the point of the instrument the valvular angle that intervenes between it and the urethra; every time that this is opened up it tends to lessen the chance of closure of the aperture, whilst, overlapping the urethra, it interferes with the onward passage of the instrument into the bladder. By withdrawing the instrument and changing its direction, the false passage may often be avoided, and the bladder reached. Should there have been much difficulty in introducing the catheter, the better plan will be to allow it to remain in the bladder for two or three days, when the false canal may possibly close.

It has already been stated that, in certain forms of stricture, gradual dilatation does not succeed in effecting a permanent cure. In these cases four plans of treatment have been recommended—continuous dilatation, the destruction of the stricture by caustic, forcible dilatation, and its division by the knife. These methods will now be described.

2. **Continuous Dilatation** is merely a modification of the preceding mode of treatment, and is useful only in very tight organic strictures. A small instrument is first passed and tied in. In tying the catheter in, care should be taken that it does not lie too far in the bladder. It should be pushed backwards and forwards until the exact point is found at which the eye is inside sufficiently to allow the water to flow, and be fixed at this point. It is best retained by soft thick silk tied round the corona of the glands, or fixed to the body of the penis by a piece of plaster, care of course being taken not to produce strangulation. In from twelve to twenty-four hours, although it may at first have been tightly grasped the catheter will be found to be quite loose, and urine will escape beside it. It must now be changed for a larger one. In doing this, the fresh instrument should be ready, so that the moment one is removed the other may be introduced. A neglect of this precaution, especially when false passages are present, may seriously increase the difficulty of passing the fresh catheter. By the second day a slight discharge will be found to have been set up from the urethra. The treatment should be continued till the urethra reaches the size of No. 5 or 6, which it will do in a few days at most, after which it is not necessary. The catheter may be closed with a small wooden plug, so that the patient can draw off his own urine, or, better still, an India-rubber tube may be attached so as to drain the bladder. In cases in which a gum-elastic catheter cannot be passed, a small silver one may be tied in, and replaced by a gum-elastic at the first change. When nothing but a filiform whalebone- or catgut-bougie has been passed, it may still be tied in, as the urine will usually find its way beside it even when it seems at first to be tightly grasped; and in twelve hours or a little longer it may, in most cases, be changed for a fine gum-elastic catheter. This plan of treatment is of great use in cases in which considerable difficulty is found in introducing the instrument, but it has the disadvantage of being extremely liable to set up cystitis. If the treatment be continued beyond three days, the urine will almost always be

found to be alkaline; and this is scarcely to be wondered at when we consider the way in which the bladder is, as it were, opened up to the air. The risk of cystitis is much diminished by draining the bladder, for then no urine is left to decompose, and the mere contact of the soft instrument with the walls of the bladder seems to cause but little irritation by itself. In rare cases, sloughing of the urethra may take place at the seat of stricture, leading to perineal abscess. A case of this kind occurred not long ago in University College Hospital.

3. Caustics. In the treatment of stricture by caustics, two objects are endeavored to be attained; the first is the destruction of the stricture; second, the diminution of the sensibility of the surrounding tissues and brane, so that the irritability and spasm of the canal may be lessened. The following is the way in which the caustic is applied. A wax bougie is oiled, is passed down to, but not through, the stricture; the surgeon then with the thumb-nail, makes a notch on that portion of the instrument opposite to the meatus. Another bougie of similar length and size is then armed with a piece of potassa fusa about the size of a small pin's head, placing a depression at its end. A mark is made on it, at a point corresponding to the notch on the first bougie, and it is then passed rapidly down until this mark comes opposite to the meatus, and pressed firmly for two or three minutes against the stricture, upon which the caustic exercises its action. This application, which is followed by a gleet discharge, is to be repeated every second or third day until a bougie of proper size can be introduced; and then dilatation may be proceeded with in the usual way. This practice, stigmatized, not unjustly, by Liston as "most atrocious," has now but few advocates, and, indeed, there appears to be nothing useful effected by it, beyond what can be accomplished much more safely and easily by a catheter or sound in an ordinarily skilful hand.

4. Forceful Expansion or Rupture.—Forceful and rapid dilatation, meaning the expansion and rupture of the stricture, is a method that, originally proposed and practised many years since by Luxmoor, Arnott, and Ross of Glasgow, has of late years been revived in principle, and ingeniously modified in detail, by many Surgeons, amongst whom Richard, Maisonneuve, Perreve, Wakley, Holt, Thompson, and Hall are the most conspicuous. However varied the means by which strictures are thus treated, the instruments employed may be arranged in three groups: *a.* Those that act as sliding tubes; *b.* Those that expand by a screw mechanism; and *c.* Those that act on the principle of a wedge.

a. Sliding Tubes were first employed in the treatment of stricture by Desault at the close of the last century, subsequently by various French Surgeons, and in later years by Hutton, of Dublin, and very extensively and successfully by Wakley. The mode of application of these tubes is as follows: A long conductor is introduced through the stricture into the bladder, and over this a catheter, either of gum or silver, is passed, which in its turn is made to serve as a conductor to a larger one. In Wakley's instrument the conductor, or "urethral guide," consists of a small silver catheter, which, after being passed through the stricture, has a long steel rod screwed into it. Over this a silver tube is passed, which in its turn is made to serve as a conductor; and thus the stricture may be rapidly dilated by passing one tube over another until a full size is reached. The only difficulty in this very ingenious method—which is, however, common to it and every other plan of treating stricture by dilatation—consists in the first introduction of the "urethral guide;" when that has once passed through the stricture, the tubes must follow as a matter of necessity. They cannot possibly go wrong, and, as no laceration of the stricture is, or can be, effected by the instrument, it

appears to be a peculiarly safe means of employing rapid dilatation when circumstances seem to require it.

b. The method of forcibly expanding a stricture by the introduction into it of a small two- or four-bladed instrument, fashioned somewhat like a narrow beaked sound, and which, by *Screw-mechanism* in the handle, admits of being opened out so as to stretch the stricture to an extent corresponding to the distance at which the blades are screwed apart, has many advocates; and various ingenious contrivances have been invented to effect this object. More than half a century ago, Luxmoor attempted it by the use of a four-bladed instrument. Subsequently, Civiale invented a stricture-expander; and of late years two-bladed instruments, having this end in view, have been introduced into practice by Perrève, Lyon, and Sir H. Thompson. The accompanying drawing (Fig. 929) is a representation of the instrument used by

Fig. 929.—Thompson's Stricture expander.

the latter Surgeon; it answers admirably the intended purpose, the expansion of the blades being effected by a screw worked by turning the handle. This should be done very slowly, several seconds being allowed to elapse between each turn of the handle, so that the tissue composing the stricture may be gradually stretched, and the canal of the urethra at the seat of stricture dilated beyond the full size, so as to be overstretched; the extent of dilatation may be carried up to 16 or 18, and is marked on a scale attached to the handle of the instrument. If this operation be done slowly, little if any bleeding results, and there is no evidence of deep laceration of the wall of the urethra at the strictured spot. A large gum-elastic catheter may then be passed, and the urine drawn off. It is not usually necessary to leave the catheter in the bladder, though there can be no objection to doing this for forty-eight hours, after which the patient may have one passed occasionally in order to maintain the dilatation.

c. The rupture or splitting of the stricture by an instrument acting on the principle of a *Wedge*, has been recommended by Reybard, adopted by Holt, and very extensively employed by the latter excellent Surgeon. The instrument used by him is represented in the accompanying figure (Fig. 930). It

Fig. 930.—Holt's Instrument for Splitting Strictures.

consists of two grooved metallic blades joined at the extremity. Between these a tube is slipped along a wire, which in its descent separates the blades at a considerable angle, and thus splits up the stricture. In this way the contracted part of the urethra is at once enlarged to its normal diameter, so as to admit a full-sized catheter, by which the urine is then drawn off. The introduction of the catheter should be had recourse to at first on alternate days, and afterwards at longer intervals. Holt believes that the effects of the dilatation are entirely confined to the morbid contraction, the healthy portion of the urethra not being injuriously disturbed by the expansion of the instrument.

modification of the dilators previously in use. He thus describes it: "The instrument is a straight rod, which equals in calibre a No. 2 or 3 catheter. It is separated by passing between them a wedge. The wedge is prevented, by two dovetail grooves, from leaving the sound which acts as a guide down the urethra." "The advantages of this instrument are: simplicity of construction; the central sound is not needed, hence the split sound can be dispensed with. Next and chiefly, diminution of resistance to the immediate application of the rupturing force, which is to be overcome. The force needed to rupture the stricture is very great, and the attempt has been abandoned, even in skilful hands, from this reason. It is now depended on the continuous friction outside the stricture, and made along the guide. In the wedge-dilator, the instrument is forced to two dovetail grooves, which together do the work. For this, the force required is so small that one can pass the instrument with ease." "The instrument can, if required, be made of any length, such as is described afterwards under In-

struments. It is a most efficient mode of treating stricture: the urethra is restored to its full diameter, and the result is permanent. It is accomplished by simple dilatation, and is a means devoid of danger. The urethra is not injured. A longitudinal rent in the mucous membrane is made along the length of the stricture. The shock produced by so severe a rupture is severe, and suppression of urine has followed. It has also been sometimes followed by urinary pyæmia. What it gains in rapidity it loses in safety. As a universal mode of treating strictures would be a universal mode of treating pyæmia, it is not a means that might have been saved by gentle

Division of Stricture may be practised either from within the urethra, or through the perineum.

The division from within may be performed in two ways: either through the stricture from before backwards, or by passing a lancet through it, and dividing it from behind forwards. The first is performed by passing a lancetted stylet (Fig. 931) into the stric-

Lancetted Stylet for Division of Stricture.

regards the concealed lancet-like knife, attempting to divide the stricture. This plan is necessarily attended by the most dangerous results. An attempt be made to thrust a stylet through the stricture; the probability, indeed almost the certainty, is that the sharp blade will pass by the stricture and divide the urethra. It is, indeed, almost banished from surgery, and is only used with safety only to those strictures that are anterior to the scrotum, where the canal

is straight. In the deeper and more curved parts, any attempt at perforation would obviously be fraught with danger; for, as it would of course be impossible for the Surgeon to guide the stylet exactly in the direction of the urethra, it would be more likely to perforate the walls of this canal than to pass through the stricture. In hard and resisting contractions, however, in the straight portion of the canal anterior to the scrotum, such an instrument may occasionally be used with advantage. A very convenient form of cutting stylet is the one figured here, which has a probe end, that is introduced through the stricture, and serves as a guide to the blade, which is projected and caused to retract into its cylinder by the action of a spring (Fig. 931).

The other mode of dividing strictures within the urethra is by cutting from behind forwards.

During the last few years, great improvement has been made in the instruments employed in this operation, and it has consequently risen much in favor. Cutting from before backwards without a guide proved so dangerous, that it has been finally abandoned. On the other hand, the operation of cutting from behind forwards could not, until recently, be performed unless the stricture was capable of admitting a No. 5 at least. The Surgeons to whom we are most indebted for improvements in the instruments employed, are Van Buren, Gouley, and Otis, of New York, Maisonneuve, of Paris, and Berkeley Hill, of London. The objects which these Surgeons have had in view have been, first, to provide a safe and certain guide for a small cutting instrument, and secondly, so far to diminish the size of the instruments

Fig. 932.—Otis's Dilator and Urethrometer.

as to make them available for strictures not capable of taking more than a No. 1 catheter. Lastly, as it was found that the great mobility of the urethra rendered it difficult in many cases to divide the stricture, a combination of the stretching and cutting was introduced by Otis, which greatly facilitates the operation.

The guide to the bladder may be obtained in two ways. A fine whale-bone bougie having been passed through the stricture, the urethrotome may be so constructed, by being tunnelled for a short distance at its point, as to slide over this into the bladder. But a better plan is the employment of Maisonneuve's *sonde conductrice*, or conducting sound. This is a very fine gum-elastic bougie, provided with a male screw at the end (Fig. 933a). This is first passed on till it is supposed to be in the bladder. A small catheter corresponding to a No. 1, having a female screw at its extremity, is then screwed on to it and passed onwards, while the conducting sound coils up in the bladder. If the urine flow, it is then certain that the conducting sound has passed in the proper direction. It is now withdrawn again, the conducting sound being left in position. The catheter is now replaced by the urethrotome, which screws in the same way. Berkeley Hill has invented a very ingenious urethrotome for cutting from behind forwards, in which a very fine knife can be protruded from an instrument not larger than a No. 2. Another instrument invented by the same Surgeon for cutting from before

backwards is represented in Fig. 933. It combines the principles of several others, and has been found to work most successfully. It is thus employed. The conducting sound having been passed and ascertained to be in the bladder, the female screw *b* is applied to the male screw *a*, and the instrument passed through the stricture. The blades *i* and *h*, when closed, about equal a No. 3 catheter in size. The point *b* is about equal to a No. 1. The instrument having been passed, the wedge *e*, which contains a knife *d* concealed in a shield *c*, is now inserted between the blades and passed steadily down. The blades thus separated stretch and steady the urethra; and when the stricture is reached, the shield *c* stops against it and prevents further progress. The small concealed knife *d* is then protruded by pressing the button at the top of the instrument, and as soon as the finger is removed it is withdrawn again by the spring *j*. The wedge can then be passed on a little further, and if it hitch again the knife can be again protruded. By this means the urethra is cut only at the points of stricture, and no more wound is made than is absolutely necessary. The incision is always made downwards towards the floor of the urethra. This instrument may be employed in almost any stricture that will admit the conducting sound.

In larger strictures Civiale's urethrotome (Fig. 934) may be used. In order to use this instrument, the stricture must be dilated up to about No. 5. The end of the instrument is then passed beyond it, and, the small blade having been made to project, the stricture is divided or notched downwards by firm and steady pressure to the extent usually of about an inch. The blade is then shot into its sheath, and the instrument is withdrawn. As this instrument does not steady the urethra, the penis must be pulled forward so as to put it on the stretch before the division is attempted, and this should be done by a steady pressure or a sawing motion rather than by a sudden effort.

After the operation of internal urethrotomy, a full sized instrument should be immediately passed, but it is not usually necessary to tie it in. It should, however, be passed daily for a few days, and after that every second or third day for three or four weeks. After that, the patient should be taught to pass it for himself, and continue to do so occasionally for the rest of his life.

The operation of internal urethrotomy is, of course, required only in exceptional cases. These

Fig 933.—Herkeley Hall's Dilator and Urethrotome. *a*, Front View, *b*, Side View, *c*, Conducting Sound with small male screw at *a*; *b*, female screw; *c*, sheath for concealed knife; *d*, knife protruded; *e*, wedge for separating the blades *h* and *i*; *f*, the knife is on the posterior aspect of the wedge; *g*, rod for carrying the wedge; *h*, rod for protruding the knife; *i*, screw for regulating the distance to which the knife can be protruded; *j*, spring to draw back the knife and keep it concealed, except when protruded by pressing the button opposite *a* and *b*. (In Fig. *a* the button should have been represented as depressed.)

are chiefly resilient or very irritable, and some very tough strictures. In resilient strictures, dilatation fails because the stricture, though admitting of expansion, immediately relapses. In very irritable strictures, the patient cannot bear the pain of dilatation. In some very tough strictures, simple dilatation fails, and then internal urethrotomy or forcible dilatation is required. In all these cases, the division of the stricture from within removes at once all difficulty in treatment; and I have of late years employed this very simple method in several cases of this kind with the most marked and permanent success. In fact, in strictures of the scrotal or penile portions of the urethra, where one or other of the above conditions—resiliency or irritability—generally prevails, I now very commonly notch the constricted portion of the canal by means of Civiale's urethrotome, and thus at once, and with great ease, obtain most, if not all the space required.

Fig. 934.—Civiale's Urethrotome.

Result.—The risk attending the operation is not great, and diminishes as the stricture approaches the orifice of the urethra. It is not, however, absolutely free from danger. The accidents that may happen are, perineal abscess, extravasation of urine, hemorrhage, and orchitis; and in some rare cases it may be followed by pyæmia. If the kidneys be diseased, it may, like any other operation for stricture, give rise to fatal acute interstitial nephritis. Perineal abscess usually results from cutting too deeply, so that the knife completely divides the corpus spongiosum. Such abscesses most frequently form beneath the accelerator urinis, and burrow forwards, directed by the expansion of that muscle to the root of the penis. They contain a mixture of urine and pus, but it is rare to find general extravasation into the scrotum. Hemorrhage also results from cutting too freely. In rare cases, after the operation, a permanently bent condition of the penis remains during erection. We possess as yet but few trustworthy statistics of the results of internal urethrotomy, and there is every reason to believe that untoward consequences follow this operation more frequently than some of its advocates are willing to admit. Statistics of this operation done in private are worthless; those of cases occurring in hospital practice scarcely exist. In University College Hospital, where the operation has been extensively practised, I find from the Reports of the Surgical Registrar that the results are as follows. In 76 cases operated on during a period of five years, there were 4 deaths, 1 from tubercular disease of kidneys, lungs, etc., 1 from pleurisy, 1 from septicæmia, and 1 from suppurative nephritis. Perineal abscess occurred in 8 cases; extravasation of urine in 1, and epididymitis in 4. There was hemorrhage in 5, and in 2 the patient was left with permanent chordee during erection.

(For the effects produced on the kidneys by splitting strictures and internal urethrotomy, see Chap. LXVII.)

External Urethrotomy.—The division of the stricture from without, by incision through the perineum, may be performed by two distinct operations; the one being applicable only to those strictures that are pervious to an instrument; the other to those which are impermeable. In the first case a grooved staff is passed through the stricture, and the section is made upon this. In the second case, the Surgeon cuts through the stricture, without any guidance except such as his anatomical knowledge may afford.

Operation for Permeable Stricture.—The first of these operations, introduced by Syme as *Urethrotomy*, and commonly called the *Perineal Section* is comparatively a simple procedure. The instruments required for its performance are a staff, a No. 8 silver catheter, a pointed scalpel, and a broad director. The staff should vary in size from No. 1 to No. 6, according to the tightness of the stricture: it should be grooved along its convexity, either the whole of the way, or better, merely for the lower third (Fig. 935). The stem is smooth and of full size, and joins into the lower grooved part by a distinct shoulder, which, being passed down as far as the stricture, forms by its projection a guide to that part of the urethra requiring division. In those cases in which there are false passages, a hollow staff of the same size and shape may be advantageously used; the flow of urine through it indicating with certainty its passage into the posterior part of the urethra.

Fig. 935.—
Shouldered Staff
for Perineal Sec-
tion.

Performance of Perineal Section.—The operation is performed as follows. The staff having been passed well through the stricture, so that the shoulder rests against the upper part of the constriction, the patient is tied up as for lithotomy, and the Surgeon, seating himself in front, pushes the scalpel, with the back of the blade downwards, into the mesial line of the perineum a little above the rectum, and cuts upwards for an inch or more into the raphe. The dissection is carried on very carefully exactly in the median line until the staff is reached, when the knife must be entered into its groove *behind* the stricture, and carried forwards through this. The staff, having been pushed on to ascertain that all is free, must be with-

drawn, and a No. 8 catheter introduced, which is to be kept in for forty-eight hours; it must then be taken out, and at the end of eight or ten days the urethra must be dilated by the introduction every second day of a full-sized silver catheter. Urine escapes for some little time by the perineal incision; but, as this heals by granulation, the flow of fluid gradually lessens and at last ceases entirely.

The principal points to be attended to in this operation are—

1. To see that the staff is fairly through the stricture, and to be especially careful in determining this if false passages exist.

2. To cut carefully in the median line; where, as Syme has observed, a kind of septum exists even in the deeper structures of the perineum, and where there can be no danger whatever of dividing any artery of magnitude, which might happen if any lateral deviation of the knife took place. The only vessel, indeed, which is at all endangered, is the artery of the bulb; and this will of course be avoided by carefully keeping in the raphe.

3. To enter the point of the knife behind the stricture, and to divide that by cutting forwards in the groove of the staff.

4. Much difficulty has occasionally arisen in the introduction of the catheter into the bladder after the division of the stricture. This may be avoided by passing a broad director, with the groove turned up, into the posterior part of the urethra after the stricture has been cut, but before the staff is withdrawn. As the catheter is passed down the canal, its point will infallibly be guided by this onwards into the bladder.

Where there are more strictures than one, the division of the deepest is usually alone necessary; the others may be dilated.

Result.—The result of the perineal section, so far as the life of the patient is concerned, is usually satisfactory; yet cases have not unfrequently occurred in which a fatal termination has been the consequence, and there is every

bistoury, will be found the only really advantageous treatment. It is practically free from danger, as rigors and other constitutional disturbance, scarcely ever follow operations on the anterior extremity of the urethra.

Impermeable Stricture.—In order to perform the perineal section, the stricture must be pervious to a grooved staff, however small this may be; and this, it might be supposed, would limit materially the cases in which the operation can be performed. But complete obliteration of the urethra cannot take place except as the result of sloughing, usually from injury; indeed, "impermeable" strictures, though frequently spoken of, are very rarely met with. Syme, indeed, denied their existence, and stated that, if urine can escape through a stricture, a bougie can be introduced. A Surgeon may often be foiled in his first attempts in passing an instrument through a very tight stricture. But I believe that, with patience, by attention to constitutional treatment, so as to lessen urethral irritation, and especially by the administration of chloroform, he will usually at last succeed in making an instrument of some kind pass through the very worst strictures. In the first case in which I performed the perineal section, almost all the urine had for twelve years been discharged through fistulous openings in the perineum and scrotum; and the principal portion escaped through a large hole on the inside of the left thigh, only a few drops occasionally passing out by the lips of the urethra. No instrument had been passed for four years, though repeated attempts had been made by different Surgeons. Being foiled in introducing a catheter into the bladder the first time I tried, I kept the patient in the Hospital for two or three weeks, attending carefully to his constitutional condition, but without making any further effort. He was then placed under chloroform, when I succeeded in passing No. 1. The urethra was then dilated up to No. 5, beyond which no instrument could be passed, when the perineal section was performed. The patient made an excellent recovery, the fistulous openings closing, and the urine being discharged by the natural channel. In another case, persevering attempts had been made for five years to make an instrument enter the bladder, but without success, the stricture not only being excessively tight, but the urethra acutely sensitive; under chloroform, I succeeded in introducing No. 1 silver catheter into the bladder, and speedily cured the patient.

The influence of *Anæsthetics* in facilitating the passage of instruments through apparently impermeable strictures is very marked. Shortly after the introduction of ether as an anæsthetic agent, Liston was going to cut through a stricture that had resisted all attempts made by his most dexterous hand at introducing an instrument into the bladder; but no sooner was the patient put on the table and rendered insensible, than the No. 8 silver catheter, which had been passed down as far as the stricture, and the point of which was to serve as a guide to the knife, slipped into the bladder, and thus rendered a dangerous operation unnecessary.

Yet no Surgeon can doubt that cases do occasionally, though rarely, occur, in which, in consequence of extravasation of urine and old inflammatory action, the urethra has become so tortuous and narrow, and the perineum so thickened and indurated, that an instrument cannot be passed through, even though the urine pass out readily. It must be borne in mind that a stricture may be permeable to urine, but impermeable to a catheter, even in the most dexterous hands. It does not follow necessarily that, because a fluid will trickle out of a narrow and tortuous channel, a catheter or solid sound can be passed into it from without. In a case of extravasation of urine following stricture, consequent on injury of the perineum, under my care at the hospital, in which no catheter had been introduced for eight years, it was found after death that, although the urethra had been converted into a mass

whenever an instrument is passed, that he cannot bear the repeated introductions that are necessary, more particularly if the stricture be complicated with fistule in perineo or false passages, which render its cure by dilatation tedious and almost impracticable. In such cases as these the Surgeon, being unable to benefit his patient materially by dilatation, must choose between the employment of palliative means or more active measures.

It appears to me that there are four classes of cases, in which more energetic means than simple dilatation may not only be advantageously employed, but are absolutely required.

1. *Very old dense cartilaginous strictures*, often of traumatic origin, which admit an instrument with great difficulty, and cannot be dilated beyond a certain point, owing to the conversion of the urethral structures into a kind of dense, fibrous, almost cicatricial tissue, which neither admits of expansion nor of absorption by the pressure of instruments; and in which a considerable extent—half an inch or more—of the urethra is involved.

2. The same kind of stricture, complicated with *fistula* in the perineum or scrotum, with perhaps considerable plastic infiltration of these parts. In both these classes, I think that the perineal section or external urethrotomy is the preferable operation.

3. *Very tight strictures*, accompanied by *excessive sensitiveness* of the urethra; in which each introduction of the instrument is attended by intense suffering and rigors, so that the patient cannot be induced to submit to a proper course of bougies.

4. *Very elastic*, though perhaps *narrow strictures*, that can be dilated readily enough, even up to the admission of full sized instruments; but which, when the treatment is discontinued, immediately began to contract again, so that the patient is never out of the Surgeon's hands, and sees no prospect of cure.

In these last two classes of cases, I am of opinion that internal urethrotomy or the forcible expansion or rupture of the stricture, is the best method of treatment; the perineal section being too severe and dangerous, whilst simple dilatation is too feeble a means of treatment.

Stricture of the Urethral Orifice is usually the consequence of destruction of tissue by a chancre. It is apt to be extremely tight, and has a great ten-

Fig. 930. — Civiale's Urethrotome for Stricture of the Orifice, modified.

Fig. 935A. — Another form of Bistourie Cachée.

dency to relapse. A tight stricture is not uncommonly met with also within an inch of the orifice as a consequence of an intraurethral chancre, and less commonly of gonorrhoea.

These strictures may be treated by *gradual dilatation* by means of short nail-headed styles of graduated sizes, but this is usually tedious and inefficient. *Division* by Civiale's instrument, introduced shut, and cutting as it is withdrawn (Fig. 930), or in the absence of this, by a common probe pointed

bistoury, will be found the only really advantageous treatment. It is practically free from danger, as rigors and other constitutional disturbance, scarcely ever follow operations on the anterior extremity of the urethra.

Impermeable Stricture.—In order to perform the perineal section, the stricture must be pervious to a grooved staff, however small this may be; and this, it might be supposed, would limit materially the cases in which the operation can be performed. But complete obliteration of the urethra cannot take place except as the result of sloughing, usually from injury; indeed, "impermeable" strictures, though frequently spoken of, are very rarely met with. Syme, indeed, denied their existence, and stated that, if urine can escape through a stricture, a bougie can be introduced. A Surgeon may often be foiled in his first attempts in passing an instrument through a very tight stricture. But I believe that, with patience, by attention to constitutional treatment, so as to lessen urethral irritation, and especially by the administration of chloroform, he will usually at last succeed in making an instrument of some kind pass through the very worst strictures. In the first case in which I performed the perineal section, almost all the urine had for twelve years been discharged through fistulous openings in the perineum and scrotum; and the principal portion escaped through a large hole on the inside of the left thigh, only a few drops occasionally passing out by the tip of the urethra. No instrument had been passed for four years, though repeated attempts had been made by different Surgeons. Being foiled in introducing a catheter into the bladder the first time I tried, I kept the patient in the Hospital for two or three weeks, attending carefully to his constitutional condition, but without making any further effort. He was then placed under chloroform, when I succeeded in passing No. 1. The urethra was then dilated up to No. 5, beyond which no instrument could be passed, when the perineal section was performed. The patient made an excellent recovery, the fistulous openings closing, and the urine being discharged by the natural channel. In another case, persevering attempts had been made for five years to make an instrument enter the bladder, but without success, the stricture not only being excessively tight, but the urethra acutely sensitive; under chloroform, I succeeded in introducing No. 4 silver catheter into the bladder, and speedily cured the patient.

The influence of *Anæsthetics* in facilitating the passage of instruments through apparently impermeable strictures is very marked. Shortly after the introduction of ether as an anæsthetic agent, Liston was going to cut through a stricture that had resisted all attempts made by his most dexterous hand at introducing an instrument into the bladder; but no sooner was the patient put on the table and rendered insensible, than the No. 8 silver catheter, which had been passed down as far as the stricture, and the point of which was to serve as a guide to the knife, slipped into the bladder, and thus rendered a dangerous operation unnecessary.

Yet no Surgeon can doubt that cases do occasionally, though rarely, occur, in which, in consequence of extravasation of urine and old inflammatory action, the urethra has become so tortuous and narrow, and the perineum so thickened and indurated, that an instrument cannot be passed through, even though the urine pass out readily. It must be borne in mind that a stricture may be permeable to urine, but impermeable to a catheter, even in the most dexterous hands. It does not follow necessarily that, because a fluid will trickle out of a narrow and tortuous channel, a catheter or solid sound can be passed into it from without. In a case of extravasation of urine following stricture, consequent on injury of the perineum, under my cure at the hospital, in which no catheter had been introduced for eight years, it was found after death that, although the urethra had been converted into a mass

of cicatricial tissue at the part injured, it was yet permeated by a narrow, tortuous passage, through which the urine had escaped.

Hence, cases will occasionally occur, in which the perineal section is not practicable. In the event, therefore, of a stricture being so tight and tortuous that no instrument will pass through it, or where, a portion of the urethra having sloughed away, its canal is obliterated, neither the cure by dilatation nor urethrotomy can be performed, and it may then be necessary to have recourse to incision of the stricture without a guide.

Operations for Impermeable Stricture.—In operating for the relief of impermeable stricture various means have been adopted, the chief of which are: 1, opening the urethra behind the stricture; 2, opening the urethra behind the stricture and cutting forwards through the constriction; 3, opening the urethra in front and dividing the stricture from before backwards.

1. **Opening the Urethra behind the Stricture**, or, as it is often called in this country, Cock's operation, is thus performed: The patient having been prepared as for lithotomy, the operator introduces his left forefinger into the rectum. He then takes a broad, sharp-pointed knife, which Cock advised should be double-edged, and passes it towards the apex of the prostate, guiding its course by the finger in the rectum. The knife must be passed at one thrust to the apex of the prostate, and great care must be taken that it keeps accurately to the middle line. The external wound is then enlarged somewhat by moving the knife up and down, till the lower angle reaches to about half an inch from the anus. The knife is then withdrawn and a large probe-pointed director with a handle is passed through the prostatic urethra from the wound, and along this a female catheter, or an instrument of that shape fitted with rings by which it can be securely tied in, is guided into the bladder. The essential points of the operation are to keep accurately to the middle line and to open the urethra as it emerges from the prostate gland. Should the prostate itself be notched, no harm will result. The instrument having been passed as above described, is tied in and retained for some days or weeks, as may be required. In a very large proportion of cases, after the irritation of the passage of urine through the narrow stricture has been removed, a certain degree of relaxation will take place, and a few days after the operation it frequently happens that a catheter will pass through the stricture which was formerly "impermeable." If this does not take place, an effort may subsequently be made by some further operative procedure to open up a way in the natural line of the urethra; and, should this fail, the patient may pass his urine permanently through the fistulous opening in the perineum. This can be kept readily open by the occasional passage of a flexible bougie, which must be left in situ for a few hours. Cock records cases in which the patient passed his water in this way for twenty years or more. The opening being well in front of the prostate, the control over the escape of urine is perfect, and the patient's mode of micturition is assimilated to that of the other sex.

This operation is best adapted to those cases in which the patient is suffering from actual retention at the time the Surgeon is called upon to operate. The objection to it is that it does nothing to relieve the stricture, unless this should happen to yield after the irritation of the passage of urine is cut off.

2. **Opening the Urethra behind the Stricture and cutting forwards.**—This operation may be regarded as an extension of the preceding method. It is thus performed: A No. 8 silver catheter is passed down to the stricture; the patient is then tied up as if for lithotomy; and the Surgeon, sitting in front, pushes a bistoury with the back turned towards the rectum into the raphe of the perineum as far as the apex of the prostate, so as, if possible, to open the dilated urethra *behind* the stricture. He then cuts *forwards* through

the stricture on to the point of the catheter, and, having thus opened a passage, endeavors to pass that instrument on into the bladder. This operation, I have no hesitation in saying, is one of the most troublesome in surgery. I have more than once seen the most skilful operators foiled in their endeavors to accomplish it, and compelled to relinquish the operation without consenting it, or succeed only after prolonged and most painful attempts. The difficulty consists in finding the posterior part of the urethra. When the tissues of the perineum are hard and gristly from repeated attacks of inflammation and the presence of fistulae, it is a most difficult matter to dissect through such an altered mass and hit the urethra beyond it, and the difficulty is still further increased by the bleeding, which is often very profuse. Moreover, should the Surgeon find the posterior part of the urethra, and cut forwards from it to the catheter in the urethra, the chances are that his incision will not follow the line of the urethra, and the fistulous track he establishes between the part of the urethra in front of the stricture and that behind it will almost to a certainty contract, as the wound heals, to such an extent as to leave the patient little better for the operation.

3. **Opening the Urethra in Front of the Stricture and dividing from before backwards.**—This operation, though difficult of performance in some cases, gives better results than any other. Wheelhouse has lately invented some ingenious instruments which greatly facilitate its performance.

The operation is thus performed. The patient having been secured in the lithotomy position, Wheelhouse's staff is passed down to the stricture. The end of this is about the size of a No. 8 catheter; on one side it is flattened and grooved, and on the other it forms a small blunt hook, with which the upper end of the "button-hole" incision in the urethra may be drawn upwards. The staff being passed and held with the grooved side forwards, the Surgeon cuts down upon it by an incision about 1½ inch long in the median line and opens the urethra just above the stricture. The staff is now pushed out at the wound and turned round, so that the small hook is forwards; it is then drawn upwards so as to catch in the upper angle of the opening, and in this way the urethra is put on the stretch and steadied. If the special staff be not at hand, the end of a catheter can be cut down on with almost equal ease. The edges of the slit in the urethra are then seized in artery-forceps and held apart so as to expose the interior of the canal, which can be readily recognized by its smooth shining surface. It will often be found to be convenient to pass a silk suture through each side by which the edges may be held apart, as the forceps are rather apt to get in the way. Oozing having been allowed to cease, the aperture leading to the stricture will usually be found without very great difficulty. The chief trouble in many cases arises from the constant trickling of blood from the upper part of the wound. This may be arrested by plugging it with a small sponge, or by the application of water, at a temperature of about 140° F., which is usually more efficient than ice. Another difficulty may arise from the urethra having been opened too far above the stricture, under which circumstances the incision must be prolonged downwards. If a false passage have been opened instead of the urethra, it is recognized by the absence of the smooth pink mucous membrane. The orifice of the stricture must be sought for with a fine probe. Wheelhouse uses a small probe-pointed director. In some cases the small director used in sitting up the canaliculus will be found to pass when other instruments have failed. In seeking the true orifice of the stricture every depression must be carefully explored without force. Pressure above the pubes will often cause a slight escape of urine by which the proper orifice may be recognized. When the opening is found and the probe passed, the stricture must be divided along it with a fine knife or tenotome. Wheelhouse

then passes a small gorget through the stricture and along this a full sized catheter can be easily guided into the bladder. It must be tied in and retained for a few days. The wound may be wiped out with a strong solution of chloride of zinc and afterwards sprinkled with iodoform and filled with iodoform-wool, which may be left undisturbed till the third day when healthy granulation will usually be found to have commenced. This operation requires care and patience, but it is easier and safer than any other.

General Results of the Treatment of Stricture.—Whether it is or is not possible permanently to cure a stricture, is a question which has been much debated. The advocates of the various modes of treatment, whether forcible dilatation, interna. urethrotomy, external urethrotomy, or caustics, have often asserted that by the means they adopt a stricture can be really cured, so that the patient is rid of his disease forever, and need fear no return. The general opinion, however, of those who have studied this question carefully, is that although a patient can be put into a position in which his stricture need never be a source of danger to him if he occasionally passes an instrument, he cannot be really cured—that is to say, by no means of treatment can a strictured urethra be restored to its normal condition. Every patient, therefore, who has once suffered from a definite organic stricture, should continue for the rest of his life to pass a full-sized instrument not less than once a month; otherwise, gradual contraction is almost certain to take place, and the whole treatment will have to be commenced again.

COMPLICATIONS AND RESULTS OF STRICTURE.

RETENTION OF URINE has already been several times described as arising from different causes. Thus, in boys, it arises from the impaction of a calculus in the urethra; in girls it is usually hysterical; in old men it is almost invariably the consequence of atony of the bladder or enlarged prostate, alone or combined. In those of middle age, stricture of the urethra is the occasioning cause in the vast majority of cases. Retention of urine has a tendency to occur in all tight strictures from the gradual and progressive contraction of the canal. It most usually, however, takes place in consequence of a congestive spasmodic condition being superadded to the organic constriction. It commonly happens that a patient having a moderately tight organic stricture commits an excess, or becomes exposed to cold and wet, and thus gets such a congested condition superadded, that the urine will not pass at all, or only in such small quantity by drops, and with so much pain and straining, that the bladder cannot be completely emptied. In these cases the retention always eventually becomes complete; the bladder speedily fills, and rises above the pubes; there is much distress and constitutional disturbance; and, if relief be not afforded, the distended portion of the urethra behind the stricture will ultimately give way, and extravasation of urine ensue. In these circumstances it becomes imperatively necessary to empty the patient's bladder as speedily as possible.

Treatment.—This varies with the severity of the symptoms and irritability of the patient. If the retention have not continued very long, and if the patient be not very irritable, an endeavor might be made at once to give relief by passing a small catheter into the bladder. In this the Surgeon may often succeed more readily than might have been expected, the stricture frequently yielding before an instrument more easily when there is retention, than when this condition does not exist. Even if the catheter do not enter the bladder, its point or that of a catgut bougie merely being introduced well into the stricture, it will generally happen, as Brodie has pointed out, that, on the withdrawal of the instrument, the urine will follow in a full stream;

but if a sufficiently small catheter be used (in many cases not larger than half of No. 1 is admissible), the instrument may usually be made fairly to enter the bladder. If the patient be very irritable, it is better, before attempting the introduction of the instrument, to give him an opiate enema of a drachm of laudanum in about two ounces of starch, and to put him into a warm hip-bath; the introduction of the catheter may now be attempted, and will generally succeed. Should it still fail, the effect of an anæsthetic should be tried, when it almost invariably may be made to pass without the employment of any great or dangerous degree of force. There are no cases in surgery in which anæsthesia is of more value than in these; under its influence it is seldom, indeed, that the catheter will not pass. After the instrument has been passed into the bladder it should be left there, being tied in by means of tapes passing from its rings under the patient's thighs, to a bandage that is passed round his waist. A free purge may be administered on the following day, and the patient should be confined to bed. The catheter will be found to be loosened at the end of forty-eight hours, when it should be withdrawn, and the cure by dilatation proceeded with in the usual way.

There are two conditions which in retention of urine may eventually call for operative interference. The first is the necessity for very frequent introduction of the catheter, owing to an irritable state of the bladder. In these cases, it may eventually be thought safer to puncture the bladder and to establish a direct opening, either through the rectum or above the pubes, rather than subject the patient to the constant terror of repeated catheterism, which will end by exhausting him. Every act of catheterism inflicts a certain shock to the system, greater in some, less in others; and if this have to be repeated every three or four hours, less danger will probably result from puncture of the bladder than from the frequent use of the instrument. In these cases the patient cannot allow it to be tied in for the same reason, that of extreme irritability, that necessitates its repeated introduction.

The second condition that calls for operation is a different one, viz., the necessity of relieving retention of urine. For if the Surgeon be unable to introduce a catheter in the ordinary way through the stricture, relief must be given to the over-distended bladder in some other way, lest it or the urethra burst, and extravasation of urine occur. The bladder may be emptied in five ways: 1, by Forceful Catheterism; 2, by making an Opening into the Urethra behind and through the Stricture; 3, by Puncturing the Viscus itself through the Rectum; 4, by Puncturing it above the Pubes; and, 5, by Aspiration.

1. **Forceful Catheterism** is a most unsurgical and dangerous procedure. Nothing can surely be more improper than to take a small, stiff, silver catheter, pass it down to the stricture, and then, by main force, attempt to drive it on into the bladder. In these cases the Surgeon usually fails in his attempt at reaching the viscus, but pushes the point of the instrument into the tissues around the neck of the bladder or into the prostate, and thus induces great, and perhaps even fatal, mischief in these regions. If he should, by some fortunate accident, reach the bladder, it is not by any skilful though forcible expansion of the stricture, but rather by perforating the urethra, and burrowing through the corpus spongiosum and prostate—"tunnelling," as it has been termed—until he again enter that canal, or in some such way reach the neck of the bladder.

2. **Opening the Urethra behind and through the Stricture.**—In the kind of retention of urine that we are now discussing, the safest, though by no means the easiest mode of affording relief after the failure of the catheter, is to make an incision into the middle line of the perineum, and to open the urethra behind or through the stricture. In many cases the simple opening

of the distended sinus beyond the stricture will be found the most convenient mode of treatment, especially if the operation has to be done in a hurry and without all the conveniences which surround the Surgeon in hospital practice. If, however, it is practicable, it is better to perform the operation *per se* before the stricture, and thus to relieve the disease at the same time as the retention. Simple puncture of the dilated pouch behind the stricture—as has been already pointed out, easier in cases of retention, as it is more tensely distended and may attain a considerable magnitude. The mode of performing these operations have already been sufficiently described, pp. 1068-1070.

Another advantage of the perineal incision in these cases is, that it not unfrequently happens that urinary abscess has begun to form, or the extravasation of a few drops of urine has taken place sooner than the Surgeon may have had any idea of; and if so, the incision through the perineum will afford an exit for any extravasated matters, at the same time that it relieves the patient from the distress and danger of the retention. Should any mischief of this kind have taken place, it is not necessary to be particular about opening the urethra with the knife, for, an aperture having already been established in it, the urine will readily flow through the artificial channel thus formed by free incision into the inflamed or suppurating perineum.

3. Puncture of the Bladder through the Rectum.—After emptying the bowel by means of an enema, the Surgeon passes the left index-finger well

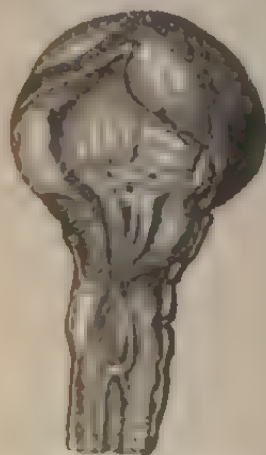

Fig. 937.—Seat of Puncture through Rectum in a case of Stricture.

into the gut, feeling for the posterior margin of the prostate; he then carries the trocar and canula, which are long and somewhat curved upon this as a guide, and, when the extremity of the instrument has reached the posterior edge of the prostate, he pushes it upwards into the bladder (Fig. 937). The seat of the puncture between but in front of the ureters is well shown in Fig. 937, which represents the bladder and strictured urethra of a man who died some days after the operation had been performed for retention from stricture. In performing this operation, the Surgeon perforates the bladder in that portion of its fundus which is uncovered by peritonæum, being bounded behind by the reflection of the serous membrane, anteriorly by the prostate, and on each side by the vesiculi seminales. In order to avoid wounding any of these structures, he should keep strictly in the mesial line, and puncture immediately behind the prostate. In introducing the instrument into the rectum, the Surgeon should withdraw the point of the trocar into the canula, so as to avoid wounding the gut, and not

push it forwards until he has the end of the canula fixed against the spot where he intends to make the perforation. In making the puncture the instrument must be directed forwards towards the umbilicus. After withdrawing the stylet and emptying the bladder, the canula should be tied in by means of tapes. It is often difficult to prevent the canula from slipping out of the wound when only tied in, and thus exposing the patient to the danger of urinary infiltration. It may be securely retained by means of a strip of silver wire passed on either side through the slit in the guard and the contiguous skin of the nates. The canula should be retained for a few days—

until urine begins to pass by the urethra, or until a catheter has been passed through the stricture:—when it must be withdrawn and the aperture left to close. The irritation of the passage of the urine having been removed from the urethra, a catheter may often be passed a few days after the operation; and the stricture will readily yield to dilatation in the ordinary way.

This operation has the advantage of being far easier of performance than the last, and may, doubtless, occasionally be required in those very rare cases of retention from stricture in which there is no sign of abscess or extravasation in the perineum, in which the urethra appears not to be dilated behind the stricture, in which the prostate is not enlarged, and in which, under chloroform, and with patience, a catheter cannot be passed into the bladder; a combination of circumstances that will but very rarely indeed occur to a surgeon skilled in the use of his instruments.

The operation of puncture through the rectum is not devoid of danger; peritonitis, urinary infiltration, and pelvic inflammation and abscess, may result from it.

The recto-vesical pouch of the peritoneum will sometimes descend so abnormally low as to cover the *bas fond* of the bladder as far as the prostate, leaving no space for a puncture to be safely made. This condition necessarily cannot be determined during life, hence its great danger. I have known two instances in which a double puncture was in this way made through the fold of the recto-vesical pouch, half an inch beyond an unenlarged prostate, for relief of retention. In both cases, death from peritonitis occurred. The preparations are in University College Museum.

In a remarkable case that was under my care at the Hospital (in 1859), a sequence occurred which I have never seen noticed, viz., the diffusion of rectal flatus through the areolar tissue of the pelvis and down the thighs and nates, producing an emphysematous condition of these parts and the death of the patient. The case was briefly as follows: A middle-aged man had suffered from traumatic stricture for very many years—indeed, from childhood. He was admitted with retention. As no catheter ever had been or could be passed, I punctured the bladder by the rectum in the usual way. The canula was removed on the fifth day. He then passed urine *per urethram*, and continued to do so up to the time of his death. The day after the withdrawal of the canula he felt very ill, but without any positive or tangible complaint. The next day it was found that the back and inner part of both thighs were emphysematous and crackling, evidently distended with gas. The emphysema extended downwards and also up the flanks, and appeared even in the right arm. There was no pain or discoloration. He died on the following day, the eighth after the puncture. After death, no trace of pelvic inflammation, suppuration, or urinary extravasation was found; but there was much infiltration of gas under the pelvic peritoneum, and in the areolar tissue between the bladder and rectum. The gas had probably passed through the sciatic notches into the posterior parts of the thighs. It was fetid, like intestinal flatus.

4. **Puncture of the Bladder above the Pubes**, in cases of retention from stricture, is but seldom resorted to; although some Surgeons of eminence, more especially Paget, of Leicester, have strongly recommended and often practised it. This operation, which has been discussed at p. 1024, is undoubtedly easy of performance, and sufficiently safe, though not free from the danger of infiltration of urine into the tissues around the puncture, and of the inconvenience of a fistulous opening being left. There is one class of cases to which it appears to be especially applicable, and in which I have had occasion to practise it, viz., those cases of retention from impassable stricture in which there coexists an enlargement of the prostate, rendering

puncture through the rectum impossible, the Surgeon's finger not being able to reach beyond the enlarged prostate; and here undoubtedly the safest, if not the only course to pursue, is the suprapubic puncture. In some cases of impermeable stricture, Paget has established a permanent fistulous opening above the pubes, the patient wearing a tube, through which he passes his water. Sir Henry Thompson also has adopted a similar proceeding in some cases of disease of the bladder with painful and frequent micturition, in which catheterism could not be carried out.

Brainard has suggested that, after tapping above the pubes, especially if the cause of difficulty in passing an instrument has been in great part the presence of false passages, an attempt may be made to pass instruments from the bladder down the urethra.

5. The Employment of the Aspirator for the purpose of emptying an over-distended bladder is, however, upon the whole the simplest method of treatment, and should be preferred to any of the preceding plans, in the first instance at all events. The perforating trocar of the aspirator should be passed directly into the bladder above the pubes. The operation is a simple one, and with a little care is perfectly safe. The chief points are not to thrust the needle too deeply, to direct it well behind the pubes, and gently to withdraw it before the whole of the urine has escaped, so as to prevent the emptied bladder from collapsing upon and being wounded by its point (see p. 883, vol. ii.).

After the bladder has been punctured, either through the rectum or above the pubes, means must be taken to restore the calibre of the urethra, so as to prevent the orifice of the puncture from degenerating into a permanent fistulous opening. With this view, the canula should be left in the bladder, and the urine allowed to discharge through it for from four to six days. At the expiration of this time, should no urine have passed by the urethra, the stricture in the canal will be found to be relaxed, and a small instrument may usually without much difficulty be introduced into the bladder, where it should be retained, the canula being withdrawn. The cure of the stricture by dilatation may then be proceeded with in the usual way.

In connection with this subject, it may be stated that *Puncture of the Bladder* may be required for the following conditions:

1. Impermeable stricture (through rectum).
2. Complete rupture of urethra (through rectum).
3. Enlarged prostate (above pubes).

Extravasation of Urine is one of the most dangerous and fatal results of unrelieved retention. This accident may occur in consequence of rupture of the dilated portion of the urethra which is immediately behind the stricture. It then occurs suddenly, the patient, while suffering from retention, feeling something give way during a violent effort at micturition, and at the same time there is a sense of some relief, as if he were emptying the bladder, followed after a time by a hot and burning throbbing pain in the perineum.

In other cases the process is more gradual, and is preceded by the formation of an abscess in the immediate neighborhood of the urethra, most probably commencing in one of the lacunae or glands opening into it. The abscess bursts into the urethra, and its cavity is subsequently distended with urine at each act of micturition; finally its walls give way, and general extravasation takes place. In some cases it is probable that the abscess arises from a very limited extravasation of urine into the tissues in the immediate neighborhood of the urethra, consequent upon ulceration of the mucous membrane behind the stricture. In these cases the signs of perineal abscess, to be presently described, precede the extravasation often for some days.

The part of the urethra that gives way is almost invariably the membranous portion of the canal, just between the layers of the triangular ligament, where it is weak, being least supported by surrounding structures, and usually most dilated and attenuated by the pressure to which it has been subjected. The extravasated urine afterwards finds its way through the anterior layer of the triangular ligament, where it is perforated by the urethra, and so beneath the deep layer of the superficial fascia of the perineum, by which its course is afterwards directed. This fascia is firmly attached across the perineum to the free border of the triangular ligament and, along each side, to the rami of the ischium and pubes, as far upwards as the pubic spine, from which point its attachments are continued outwards along Poupart's ligament to the crest of the ilium. The extravasated urine, therefore, uniformly takes a course forward into the perineum and scrotum, and upwards upon the external organ of generation, the groins, and the anterior abdominal wall: so that it ascends contrary to gravity rather than soaks back into the more dependent parts of the body, as it would do, were it not for the particular connections of the fascia that has just been alluded to. I have, however, known the superficial fascia to give way, and the urine, then gravitating backward, to give rise to extensive sloughing in the ischio-rectal fosse and about the nates, denuding the rectum.

The *Local Effects of Extravasated Urine* that has become acrid, decomposed, and concentrated by long retention, are most deleterious upon the tissues with which it comes into contact. It acts as a most intense irritant on all that it touches. The vitality of whatever portion of areolar tissue it infiltrates is quickly destroyed; the tissue becoming converted into a kind of putrid stringy slough, intermixed with and softened by a quantity of fetid dark-colored acrid pus and urine. The ravages of extravasated urine are often extensive; the urethra giving way suddenly behind the stricture, the fluid is driven with all the force of the vital and physical contractility of the over-distended bladder into the perineum, and thence rapidly finds its way through the scrotum upwards. Rapid swelling and infiltration, partly urinous, partly inflammatory, take place in the scrotum and penis; these parts become enormously distended, oedematous, cracking, and emphysematous. The skin is speedily affected, becoming of a dusky-red or purple color, and then falling into a state of gangrene. In this way the testes may become denuded, and the cords exposed. It is remarkable, however, if the patient survive these destructive effects, with what rapidity repair goes on in this region. It is seldom that infiltration extends higher than the groins, or the anterior portion of the abdominal wall; but it may reach the costal cartilages before proving fatal.

The *Constitutional Disturbance* is always very great. At first there is high fever, with a rapid full pulse; but the symptoms speedily assume the form met with in acute septic poisoning. The tongue becomes brown and dry; there may be vomiting; the pulse becomes small and very rapid; muttering delirium sets in, ending in insensibility, and death quickly follows.

The *Treatment* consists in making a free and ready outlet for the urine as early as possible. This should be done, as soon as extravasation is known to have occurred, by a deep incision into the middle of the perineum. So soon as any pain and throbbing, with diffused swelling, occur in the perineum, with redness and more or less oedema of the scrotum, the patient should be drawn to the end of the bed and placed in the position for lithotomy. The Surgeon should next introduce his left index-finger into the rectum, so that the gut may not be wounded and then pushing a long sharp-pointed bistoury deeply in the raphe of the perineum, cut upward to a sufficient extent into the extravasation, and in the direction of the urethra.

A catheter should then, if possible, be introduced, secured in the bladder, and left unplugged, with an India-rubber tube attached; in this way no further extravasation can occur, an outlet will be afforded to matters already effused, and the greater part of the urine will commonly be found to escape after a time by the aperture thus made. Should the case not be seen until extravasation has spread widely, a free incision should be made not only into the perineum, extending to the aperture in the urethra, but also into the scrotum on each side of the septum, into the penis, and wherever else swelling is observed. The sole chance of safety for the patient lies in making these free incisions, through which the parts may, to a certain extent, empty themselves. However extensive the infiltration and serious the mischief may be, we need not despair of the patient if a free outlet can be obtained for the acrid and putrescent urine; and in order to secure this, the infiltration must be followed by incisions as high as it extends. The parts must, at the same time, be covered with some warm and moist antiseptic dressing. The best is boracic acid lint moistened with warm boracic acid lotion. If this be not at hand, the surface may be greased with carbolic oil (1 in 10), or terebene and oil and fomentations made of oakum wrung out of boiling water may be applied. These applications are cleaner than poultices, and should always be preferred. The patient will often experience great relief from frequent hot hip-baths, Cond's fluid or boracic acid being added to the water. In this way the parts can be most thoroughly cleaned without pain to the patient.

If the patient survive the immediate impression upon the system produced by the gangrene and the urinary infiltration, he must be prepared to go through a severe trial to his constitutional powers, in the separation of the sloughs, the profuse discharge, and other sources of irritation that are set up. During this period he will require abundant support—the brandy-and-egg mixture, ammonia and bark, with any nourishment that he can take; and much attention should be paid to the removal of the sloughs, to providing a ready outlet for discharges, and to keeping the patient as clean and as free from all local irritation as possible.

Perineal Abscess.—By perineal abscess is meant a collection of pus in the perineum situated under the deep layer of the superficial fascia of this region. It is the confinement of the pus by the fascia which gives these abscesses their special character. Owing to the attachments of the deep fascia which have just been described, the pus formed in connection with the urethra is shut off from the ischio-rectal fossa, just as extravasated urine is. If the abscess be left unrelieved, it may burrow widely around the bulb and along the urethra before it reaches the surface by perforating the fascia. It is very important, therefore, that such abscesses should be opened early.

The chief forms of perineal abscess met with are the following:

1. *Abscesses arising from Suppuration in a Lacuna or Follicular Gland.*—These have already been described as an occasional complication of gonorrhœa. They are met with also in stricture. They may point slowly towards the surface, without actually communicating with the urethral canal. In other cases they open into the urethra, and then run the same course as abscesses commencing from the canal.

2. *Abscesses commencing from Ulceration in the Urethra behind a Stricture.*—These arise in the dilated pouch behind a tight stricture. As before stated, the mucous membrane at this part is thickened and opaque, and often pigmented, showing evidence of chronic inflammation. The openings of the ducts are dilated, sometimes giving the whole surface a reticulated appearance. The ulceration commences in one of the hollows thus formed. The inflammatory consolidation of the surrounding tissues prevents general extra-

vasation; but the pressure during micturition and the constant presence of retained urine cause gradual extension of the cavity till a distinct abscess is formed discharging imperfectly into the urethra. Such an abscess slowly extends till it reaches the surface. It then bursts its cavity, contracts to a narrow channel, and thus a urinary fistula is formed. At any period before it bursts superficially, its wall may be ruptured during a violent effort at micturition, and diffuse extravasation of urine may result.

3. *Abscesses from Injuries by Instruments*.—These occasionally arise from false passages made with a catheter or bougie; they may also follow forcible dilatation or internal urethrotomy. More rarely they result from inflammation and ulceration of the mucous membrane around an instrument tied into a tight stricture. These abscesses usually form rapidly. If resulting from a false passage behind a tight stricture, they may lead to extravasation of urine; but under other circumstances, as there is a free passage through the urethra, this is not likely to occur. If the injury is in the bulbous or spongy portion, the pus may burrow forwards along the urethra under the accelerator urine, and appear at the root of the penis in front of the scrotum.

4. *Suppuration of Cowper's Gland* is an occasional cause of a perineal abscess. It may occur from the irritation of a stricture, but far more commonly it is met with during the acute stage of gonorrhœa. The gland can at first be felt as a tender knot on one side of the middle line near the bulb. This gradually increases and becomes more tender, and at last fluctuation is felt. This form of abscess can be recognized if seen early by its situation, and by the fact that it is distinctly on one side of the middle line. At a later period it may burrow widely round the bulb and in the perineum, so that its exact origin cannot be determined. It usually causes some difficulty in micturition.

5. *Prostatic Abscesses* may, as before stated (p. 1014), occasionally point in the perineum.

It will be seen that there are two distinct classes of perineal abscesses: those that communicate with the urethra, and those that do not. The former usually end in urinary fistula, the latter do not.

The *Characters* of a perineal abscess are those of a hard, rounded, elongated or oviform mass, situated in front of the anus, extending along the urethra, or perhaps occupying, to some extent, one side of the perineum. Fluctuation is not to be felt so long as it is bound down by the superficial fascia; when it bursts beyond its limits, then that sign may be met with. But so long as it is under the fascia the abscess will be found to be surrounded by so dense a mass of indurated tissue, and so tightly bound down, that fluctuation, or even elasticity, is not appreciable by the most practised finger.

Treatment.—The usual routine treatment of local sedatives, fomentations, and poultices, are of no avail in these cases. When once pus has formed in this situation it must be freely evacuated. No good can possibly come of delay, and every possible harm may result from the infiltration of pus among the important tissues of this region. The Surgeon must not wait for fluctuation, but when once the hard mass has fully formed must make a free incision into it. For this purpose he must keep in the mesial line, or as close to it as possible; for in all perineal incisions "*medio tutissimus*" must be his motto.

Urinary Fistulæ commonly form in the perineum and scrotum, as the result of abscess in these regions communicating with the urethra; occasionally, however, they are met with in other situations, as in the groin, the anterior abdominal wall, or the inside of the thigh. They usually commu-

nicate with the membranous portion of the urethra, but occasionally occur anterior to this. In number they vary considerably; when occurring in the scrotal and penile portions of the urethra, they are usually single; but when in the perineum, they are often rather numerous, several apertures being occasionally met with about the perineum, scrotum, and nates. In one case Civiale found as many as fifty-two. Their size also differs considerably; some admitting only the finest probe, whilst others are large cloacæ. In a case under my care, the patient had a tunnel of this kind in the groin that would readily admit three fingers. They are usually tortuous, elongated, and narrow; sometimes constricted externally and more widely dilated behind. The surrounding parts are greatly condensed; the whole of the scrotum and penis is enormously enlarged, indurated, and almost cartilaginous in structure. The urine may escape almost entirely through the fistulae, scarcely any being discharged through the urethral orifice; or there may be but a slight exudation from the fistulous openings.

The *Treatment* of urinary fistula varies according as it is complicated with stricture, and as it is situated in the anterior or the posterior part of the canal.

If there be a stricture, this, as the cause of the fistula, will require removal either by dilatation or by the perineal section. If the stricture be not very tight and hard, dilatation commonly succeeds; the instrument being introduced every second or third day, until the urethra is dilated to its normal size, when the fistulous tracks will in most cases close. In some instances, however, the frequent introduction and withdrawal of the catheter is a source of irritation, and then it had better be left in. When this practice is adopted, a moderate sized elastic catheter should be used. If this be too small, the urine will flow between it and the sides of the urethra, and thus escape through the fistulae; if too large, it stretches the urethral orifice of the fistula injuriously.

If the stricture be very tough and irritable, the better plan is to perform urethrotomy at once, as much time and pain are thus saved. In the majority of instances, internal urethrotomy with Civiale's instrument appears to me to be the safest and simplest procedure, and I have very advantageously practised it in such cases. But if the fistulae be very numerous, so as to riddle the perineum and scrotum in all directions, perhaps the better plan is to perform the perineal section. In this way we not only divide the stricture, and thus at once remove all obstruction, but give a free exit to the urine, which, instead of escaping by tortuous and sinuous passages, finds its way out readily through the new aperture that has been made, and this will eventually granulate and heal by the second intention.

The fistulae, especially if small and recent, will sometimes heal kindly enough after the removal of the obstruction; but if extensive, old, and cartilaginous, they are, of course, little disposed to take on reparative action; and although the cause that in the first instance gave rise to them may be removed, yet they constitute an independent affection which requires special treatment.

The special treatment for urinary fistula must vary according to the size of the canal, but more particularly with regard to the part of the urethra with which it communicates; whether it be a *Perineal*, a *Scrotal*, or a *Penile* fistula. But in all cases, and wherever it be situated, there is one most important point to be attended to, viz., never to let the fistula be disturbed or irritated by the passage of urine over or through it, or it will never heal. Hence the urine must always be drawn off with the catheter, which the patient should be taught to pass for himself.

If the fistula be *Perineal*, and of small size, a probe coated with melted nitrate of silver, or a wire made red-hot in the ordinary way, or by the gal-

vanic current, and passed down it occasionally, may cause its contraction. If it be large, the edges of the fistula may be freely rubbed with the nitrate of silver, or deeply pared and brought together by quilled sutures, after which the urine should be drawn off, whenever required, by a catheter. If the fistulæ be large and very numerous, it will be better to pass a grooved director down the principal ones, and slit them up so as to throw the several sinuses into the larger one.

When the fistula is *Scrotal*, it often requires to be laid open, and to be made to granulate from the bottom, when it may be found to communicate with large sloughy and ill-conditioned cavities in this situation.

When *Penile*, the fistula is usually much more troublesome to heal; its edges are thin, and the track is short and shallow.

Urethroplasty may in such cases be advantageously practised. Operations of this kind require for their success very careful management and minute attention to detail; they very commonly fail in consequence of a small quantity of urine or of mucus escaping through the wound, and thus interfering with union of its lips.

In order to prevent this accident, which is fatal to the success of the operation, the patient should be taught to pass a catheter, and thus to draw off his own urine after the operation as often as necessary; or an assistant must do this every third or fourth hour. Should this, however, not be practicable, a full-sized gum-catheter should be passed into the bladder and properly secured there. It should be left without a plug, so that no distention of the bladder and consequent likelihood of escape of urine between the urethra and the instrument may take place. In order to prevent urinous effusion over the integuments of the penis and scrotum, a vulcanized India-rubber tube should be attached to the end of the catheter, by which means the flow of the urine is directed away from the patient.

Urethroplastic operations may be varied according to the seat and extent of the fistulous opening.

If the fistula be in the *perineum*, the parts around being thickened and indurated, its closure may often be attained by freely and deeply paring the edges, and then bringing them together with the quilled suture, or by Sims's button.

When the fistula is *scrotal*, the edges should be freely pared, and the parts around widely dissected up so as to form large and thick flaps of cellulocutaneous tissue, which may be brought and held together by metallic sutures or shotted clamps. In this way, if union be not obtained throughout the whole length of the fistula, it may be to a partial extent; and, after a time, a second or a third operation will complete the cure.

When the fistula is *penile*, the difficulties in effecting closure become immensely increased. This is owing to the thinness of the integumental structures and the absence of subcutaneous areolar tissue in this region, so that there is not sufficient thickness of the parts for ready plastic union. In these cases, the Surgeon has a choice of four operations.

1. Nélaton has recommended the following procedure: The edges of the fistula having been pared, the skin around, to the extent of about an inch, should be dissected up subcutaneously through an opening made below the fistula, the edges of which must then be brought together by a few points of suture. The displacement of the skin covers in the aperture in the urethra and causes granulations to spring up, by which the fistula is closed (Fig. 938).

2. The edges of the fistula having been pared and the skin separated widely, lateral incisions may be made so as to take off all tension, and a slip

of India-rubber may then be passed underneath the flaps of skin, in order to prevent contact with urine from disturbing the adhesions (Fig. 939).

3. Ricord, recognizing the fact that the occasional intrusion of a drop of urine between the freshened edges of the integuments brought together to

Fig. 938.—Urethroplasty. Nelaton's operation: First Method.

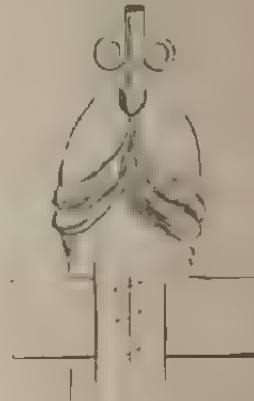

Fig. 939.—Urethroplasty. Nelaton's Operation: Second Method.

close the fistula is the most common cause of disunion, recommended that, in those cases in which a perineal or a scrotal fistula happens to coexist with a penile one, a catheter should be passed through the former into the bladder, and left there during the whole of the operative procedures that are adopted

Fig. 940.—Urethroplasty. Clark's Operation: First Stage.

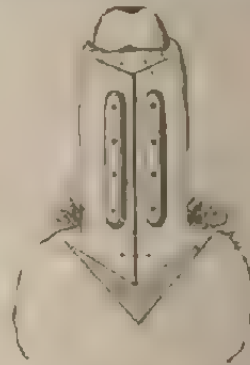

Fig. 941.—Urethroplasty. Clark's Operation: Second Stage.

for the closure of the penile fistula. Should no fistula exist in the perineum, he has proposed, though I believe the operation has never yet been practised, to puncture the bladder—which would most conveniently and safely be done

through the rectum—and to keep it emptied in this way until the penile fistula has been closed by one of the preceding operations, and then to allow the lower aperture to close spontaneously; or, if it were situated in the perineum, to adopt surgical means for its occlusion.

4. Le Gros Clark has recommended and successfully practised the following operation. Having paired the edges of the fistula, he makes a transverse cut through the integuments of the penis, about an inch in length, above and below it. He then dissects up the flaps of skin so bounded, and brings them together by means of clamps or the quilled suture. By this operation a wide raw surface from each side is brought into contact, instead of a mere raw edge of cut integument, and there is consequently a greater chance of successful union resulting (Figs. 940, 941).

In all operations of this kind union will be promoted by keeping the part constantly bathed with a concentrated cold solution of boracic acid. In this way all decomposition of any mucus or urine that may accidentally find its way to the wound is prevented, and at the same time the lotion is so un-irritating that it does not interfere with union. The lotion is best applied by means of a piece of boracic acid lint, which must be frequently wetted and changed. If the urine can be efficiently kept from the wound, a dry dressing of iodoform or salicylic wool will be found the best.

Stricture of the Female Urethra is rare. When it occurs, it is seated at the external orifice, which will be found to be narrowed and sharp-edged. The disease is usually the result of gonorrhœa, but may be caused by a chancre at the orifice. The symptoms are the ordinary one of irritability of the bladder, frequent desire to micturate, and some difficulty or delay in doing so.

The *Treatment* consists in the dilatation of the orifice by means of a two-bladed dilator.

URINARY VAGINAL FISTULÆ.

Preternatural communications between the urinary passages and the vagina commonly arise from injurious pressure upon and consequent sloughing of the anterior wall of this canal, to a greater or less extent, during parturition. They may, however, occur from idiopathic abscess, or from malignant disease involving those parts.

VARIETIES.—Urinary vaginal fistulæ are essentially of two kinds, according as the communication is established between the urethra or the fundus of the bladder and the vagina. Hence they may be divided into *Urethral* and *Vesical*.

Urethro-vaginal Fistulæ are, so far as my observation goes, of most common occurrence; and this is readily explained by the fact that the urethra lies between the vagina and pubes and is therefore exposed to the most severe pressure. These fistulæ are usually of small size and linear. **Vesico-vaginal Fistulæ** establish a communication between the neck or fundus of the bladder and the vagina. They are consequently situated further back than the other and are usually larger and more ragged.

RESULTS.—The existence of a urinary fistula in the vagina is always a source of the greatest discomfort and distress to the patient. The dribbling of urine through the preternatural aperture is generally continuous; although if this be situated far back it may be somewhat intermittent, a flow taking place as the lower portion of the bladder fills. The incontinence of urine thus produced gives rise to irritation and excoriation about the external parts, and occasions a strong ammoniacal odor to hang about the patient.

The precise seat and extent of the fistulous opening may be ascertained by

placing the patient on her knees opposite a good light, and holding aside the posterior and lateral walls of the vagina with bent spatulae; when the anterior aspect of that canal will have a tendency to protrude, and thus to expose the fistula, at the same time that the introduction of a bent probe or of a female catheter, into the urethra, will guide the Surgeon to the actual opening in the urinary passage. By means of the duck-bill speculum (Fig. 942), the fistula can be brought into view equally well if the patient be placed in the lithotomy position.

TREATMENT.—When the aperture is small, about a line or two in diameter, and more especially if urethral, its closure may best be effected by touching the edges of the aperture with the galvanic cautery or a red-hot wire, and repeating this application once a fortnight or three weeks, until a cure is effected by their gradual contraction. This little operation is most conveniently effected by placing the patient in a kneeling posture, and then touching aside the posterior and lateral vaginal walls by means of the duck-bill speculum, when the opening will be fairly brought into view.

When the fistula is larger, and especially when vesical, its cure can be accomplished only by paring the edges, and bringing them together with sutures, and thus attempting to procure union by the first intention. In effecting this, however, two difficulties present themselves—the sutures either cutting their way out too soon, or the trickling of urine between the separated edges interfering with adhesion. In order to overcome these difficulties, a variety of ingenious contrivances have been introduced by different Surgeons: amongst which may be especially mentioned the clamps of Marion Sims and Baker Brown, and the button-suture of Bozemann. To some especially, is due the great merit of having substituted silver wires for silk suture in this operation, by which the probabilities of a successful result have been very greatly increased.

Fig. 942. — Duck-billed speculum.

Before the operation, the bowels should have been freely opened by castor oil and an enema. It was formerly recommended that no anæsthetic should be given, as its administration makes it difficult to place the patient in the most convenient position—on the knees and elbows, with the buttocks well raised and the head low. As, however, the operation is tedious and painful, it is better to give an anæsthetic, and no difficulty will be found in performing the operation with the patient lying on her back in the lithotomy position, if the pelvis be well raised on a pillow. It is of great moment that the parts should be freely exposed. This is best done by means of the "duck-bill" speculum (Fig. 942), by which the posterior wall of the vagina is well drawn up and out of the way of the operator, and light is reflected on the fistulous opening.

The edges of the aperture are now to be freely pared. This is best done by seizing them with a hook, forceps, or a double hook, and dissecting off the vaginal mucous membrane to the extent of about a quarter of an inch all round, by means of a fine, small scalpel or angularly set knives (Figs. 943, 944) and scissors properly curved. The dissection should be carried towards the fissure, and especial care taken that the angles are well cleared of mucous membrane.

After the edges of the fistula have been freely pared, and all cicatricial constrictions divided, sutures of silver are passed across the top of the wound. These wires may most conveniently be passed by means of the hollow needle (Fig. 945); or, if this be not at hand, a silk thread may

be passed by a *nævus* or corkscrew needle, a full half inch from the freshened edge of the fistula, and brought out through a corresponding point on the other side of the fistula, without having transixed the mucous membrane of the bladder. As many threads as necessary having been passed in this way, a piece of silver wire about eighteen inches long is attached to the silk,

Figs. 943 and 944.—Angularly Curved Knives.

which is then drawn out, leaving the wire to occupy its place, so that its centre corresponds to the fissure, and both ends hang out of the vagina. Sims then passes the uppermost free ends through holes made in a narrow leaden bar, on which they are clamped by having split shot fixed upon them

Fig. 945.—Hollow Suture Needle.

in the same way as is done on a fishing line. The unclamped wires are now drawn down until the bar is pulled close to the upper suture holes; and a second clamp is then fixed to these ends and is pushed up against the lower suture apertures. In this way, the edges of the fistula are brought and held together on each side by a clamp, which may be allowed to remain in from seven to ten days. The clamps may then be removed by clipping off the flattened shots from the anterior one, which is thus detached from its bed. The posterior one, with the wires attached, may then be hooked up, pushed backwards, and lifted out of the vagina with forceps. Instead of a clamp, Simpson used a splint made of annealed iron wire, which surrounds and supports the tissues around the fistula. In many cases, however, where the fistula is of but moderate size, the clamp and splint may be dispensed with, and the edges of the opening brought together with the suture-wires only.

In the after-treatment, especial attention is required; and here the great point is to prevent contact of urine with the edges of the fistula. With this view, a catheter should be introduced, and worn in the bladder, so that no urine may collect in this organ. For this purpose, Sims has invented a very ingenious catheter, represented in the annexed cut (Fig. 946), which may be worn with more comfort, and with less chance of slipping, than the ordinary instrument. After the patient has been put to bed, and the catheter introduced, a full opiate should be given, and continued throughout the treatment, with a view of preventing the action of the bowels, a point on which Sims lays much stress, and to which the success of his operations may

Fig. 946.—Sims's Catheter.

be in a great measure attributed. It is very seldom that they require to be opened for ten or fifteen days, provided the patient be kept on a solid diet. During this treatment, the catheter may be removed once or twice a day, in order to be cleansed and to be kept free from phosphate or mucous accumulations; and free ablutions of the external genitals by syringe and warm water should be practised during the whole of the treatment. After the removal of the sutures, Sims advises that the catheter should be continued, and great care taken that the patient do not move too soon, lest the weak cicatrix be strained.

A very simple and successful mode of closing these fistulae has been invented by Bozeman, by what he terms the "button-suture." After joining the edges of the fistula, and passing silver wires across in the usual way, he draws the parts together by passing both ends of the wires through an aperture in a steel rod, which being carried along them closes the opening. A thin leaden plate, "the button," properly perforated down the middle is then slipped along the wires so as to cover the fistula (Fig. 947); and each shot having been pushed along, their free extremities are pressed tightly

Bozeman's Apparatus for Button Suture

Fig. 947.—Application of Plate.

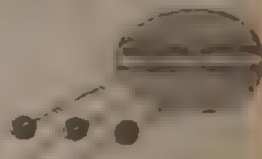

Fig. 948.—Application of Shot.

against the button, the wires are then properly nipped, and the apparatus left on for about ten days (Fig. 948); the shot are then cut off, the leaden plate is carefully lifted off, and the suture wires, having been attracted out, are withdrawn.

Whatever kind of suture may be employed, it is always of great importance that the edges of the fistula be brought together *transversely* to the axis of the vagina. Should the abnormal aperture be close to, or even complicate, the cervix uteri, this part may be drawn down and transfixed by the sutures, thus adding materially to the support of the posterior lip of the fissure.

TUMORS IN THE URETHRA.

Small Polypoid Tumors are not unfrequently met with inside the urethral orifice. They have occasionally a gonorrhoeal origin, though they commonly arise irrespectively of such disease. They are always very vascular, and are most frequently met with in or around the female urethra, where they are of a bright red color, have a florid hue, bleed freely when touched, and are composed of extremely vascular papillae; they are commonly conical or oval, bordering the urethral orifice on one side, or even encircling it. They grow slowly, and seldom attain a larger size than that of a raspberry.

These vascular tumors are far less frequent in the male than in the female urethra. When they occur in men, they usually constitute a small granular florid mass inside the orifice of the canal.

When seated in or around the female urethra, these tumors not unfrequently give rise to very great and continuous irritation; much pain occurs, and after micturition radiating through the whole pelvic region, attended by an admixture of mucus and a little blood in the urine, and, in fact, many

of the symptoms of stone; so that patients laboring under this affection are often sounded on the supposition of the existence of calculus.

TREATMENT.—Vascular urethral tumors may be removed in four ways: by **Excision**, **Ligature**, **Caustics**, or the **Actual Cautery**.

1. **Excision.** When situated within the male urethra, the tumors should be snipped off by a fine pair of curved scissors. When situated in or around the female urethra, if of small size and pedunculated, they may readily enough be removed by the scissors or dissected away; the canal of the urethra being encroached on as little as possible. This operation is, however, always attended or followed by very considerable and continuous arterial hemorrhage, which has even been fatal. Hence, when the tumor is large, and the patient weakly, excision should be practised with much caution. If it be done, the hemorrhage may be arrested by the introduction of a catheter into the urethra, and by firm pressure on the bleeding surface by means of a pad of lint, supported by a T-bandage.

2. **Ligature** is not a convenient mode of removing these growths; its application is difficult, very painful, and tedious.

3. **Caustics**, particularly strong nitric acid or potassa cum calce, may be very conveniently employed where the tumor is of small size and very vascular. In applying them, the upper wall of the canal must be protected by a broad director introduced along it.

4. The **Actual** or **Galvanic Cautery** is the most convenient agent for the removal of vascular tumors from the female urethra. By it they are at once destroyed without hemorrhage; and the eschar that is formed protects the subjacent raw surface from the irritation of the urine. If they be situated deeply within the urethra, and of small size, the galvanic cautery or a red-hot wire will most easily reach them; but if they be at or around the orifice, I employ a small olive-shaped cautery. During its application, the surrounding parts may be protected from the action of heat by a wooden spoon having a hole cut in the middle through which the application is made, and the upper wall of the urethra by a director or silver catheter, which should be retained after the operation. Care must be taken not to destroy more tissue than is absolutely necessary, lest a stricture of the orifice be left.

CHAPTER LXVIII.

DISEASES OF THE PENIS AND SCROTUM.

DISEASES OF THE PENIS.

Complete Arrest of the Development of the Male Sexual Organs must be of very rare occurrence. I have seen only one instance of it. This was the case of a man *æt.* 22, in whom the penis and scrotum were perfectly formed, but not larger than the organs of an infant a few months old. No distinct testes could be felt, but there was some thickened structure in the scrotum which felt like an unravelled testis. The prepuce was long. There was some hair, but very little, on the pubes. This person had sexual desires, and, in fact, had engaged himself to be married when his condition led to

a surgical examination. He told me that he had erections, when the organ became about an inch or an inch and a half long, and that there was occasionally emission of a glairy fluid. He was fair, fresh-colored, round-faced, fat, and had smooth, rounded limbs more like those of a stout girl than of a young man. His voice was weak and feminine in tone. He led a sedentary indoors life, but said that he was strong and capable of ordinary physical exertion.

CONGENITAL MALFORMATIONS. Adhesion of Penis to Scrotum.—I have once, and once only, met with a very curious malformation of the genital organs, the penis being tied down by its under surface to the scrotum, so as to lie in a deep sulcus between the testes. In these cases the raphé of the scrotum appeared to be continued in a narrow rather firm band upwards to the under surface of the penis, so that this organ was always bent or bowed downwards. The patient, a man of 30, passed his urine downwards, apparently from the under surface of the scrotum; during erection the penis curved up in a semicircular form, the convexity upwards, the glans being tightly tied down to the scrotum by the narrow tense band continued up from the raphé. In fact, the condition of this organ was very like that which is met with in the tongue when "tongue-tied." This malformation was remedied by cutting through the frænum which tied the penis down, and thus liberating the organ.

Hypospadias consists in a cleft condition of the under surface of the penis. Up to the tenth week of intrauterine life the external organs of generation are alike in the male and female. At this time the urogenital aperture forms a narrow slit wider behind than before, at the anterior extremity of which is a small eminence representing the rudimentary penis or clitoris. In the female the urogenital aperture remains unclosed and the external folds of integument forming its lateral boundaries enlarge, forming the labia majora, which contain the vascular bulbs corresponding to the corpus spongiosum of the male. These remain separate and distinct, but a small isolated portion becomes united in the middle line, forming the glans of the clitoris. In the male the two sides of the urogenital aperture unite in the middle line, forming the scrotum, and the bulbous and spongy portions of the urethra. At the same time the small eminence, which in the female becomes the clitoris, develops into the penis. The vascular bulbs, which in the female remain separate in the labia, unite along the middle line in the male, forming the bulb of the corpus spongiosum. In the female no corpus spongiosum exists in the clitoris, the glans being an isolated nodule of erectile tissue. In the male the erectile tissue is continuous around the urethra from the bulb forwards.

Hypospadias consists in an arrest of the union along the middle line, and in proportion to the degree of the malformation the male organs come more closely to resemble the female in appearance. Hypospadias appears in three degrees. In the simplest form the glans is cleft along its under surface, the foreskin also showing a corresponding gap. In the second degree the corpora cavernosa and glans are well developed, but the urethra is cleft to the root of the penis and the corpus spongiosum is wanting between the bulb and the glans. The penis thus resembles a large clitoris. The under surface shows a furrow in the line of the urethra usually covered by a moist mucous membrane. Between the glans penis and the point at which the urethra terminates, in the place of the absent corpus spongiosum a firm dense band of fibrous tissue is often present, somewhat resembling in hardness and tension the matrix of a burn. In these cases when erection takes place, the organ assumes a crescentic shape, with the convexity upwards, the tense hard cord that has just been mentioned stretching across its arc like the string of a bow, thus rendering connection impossible, and the sufferer practically impotent.

The third and most extreme form of hypospadias is when the scrotum also is cleft and the urethra opens in the perineum. This is usually accompanied by imperfect development of the penis, and most commonly by retained testicles. It is this malformation that has been erroneously considered to be an example of hermaphroditism. The cleft empty scrotum resembles the labia of the female, and the diminutive penis might readily be taken for a large clitoris.

Hypospadias affects only the parts in front of the membranous portion of the urethra, and consequently never leads to incontinence.

Treatment.—The first degree of hypospadias requires no treatment, the cleft glans being not even an inconvenience. Intermediate degrees between the first and second require treatment only if the urethra is so short that the seminal fluid will not enter the vagina during connection, or if there is a tight band beneath.

In the second degree of hypospadias, the first step is to dissect away the firm fibrous band which prevents complete erection. Some months after this has been successfully accomplished, and when the scars have become supple, the attempt may be made to close the urethra. In order to do this successfully, it is necessary to provide an epithelium-covered lining for the new urethra. Many methods have been suggested for doing this, but by far the best is that adopted by Anger, which is an adaptation to hypospadias of Thiersch's operation for epispadias. It is thus performed. An incision is made parallel to the groove representing the urethra, and half an inch from its right margin, a transverse incision from each end of this is made up to the edge of the urethral groove. The flap thus marked, which we will call the right flap, is then dissected up, leaving it attached along the margin of the urethral groove. A similar flap is then raised on the left side, but on this side the incision is carried along the left margin of the urethral groove, and the flap turned outwards, its attached edge being in the position corresponding to the free edge of the right flap. The right flap is now turned over so that its skin surface forms the lining of the new urethra. A number of fine stitches are then inserted in the following way. The needle is first passed through the base of the left flap from the skin surface, then through the free edge of the right flap from the raw surface towards the skin, then it is made to catch the left edge of the urethral groove, and finally passed again through the base of the left flap. In this way the edge of the right flap is held in position, and the stitches can be removed from the surface. When these have all been passed, they may be tightened. A similar number of stitches are then passed through the free edge of the left flap, by which it is attached to the skin of the penis at the outer edge of the raw surface from which the right flap was raised. The raw surfaces of the two flaps are thus brought closely into contact, and an epithelial lining formed for the new urethra. During the healing, a catheter must be tied in, and the bladder drained. A small fistulous opening will usually be left at the lower end, which must be closed by a subsequent plastic operation. Several successful cases of this operation have been recorded, and it seems to be by far the most efficient of the many methods suggested. The third degree of hypospadias admits of no treatment.

Epispadias.—The upper surface of the penis is less frequently fissured; only, I believe, in cases of extroversion of the bladder. This condition, termed *epispadias*, may be remedied to some extent by Wood's operation, described at p. 992.

PHIMOSIS.—The prepuce is not unfrequently the seat of malformation or disease. The condition of it in which it is so much elongated that it extends beyond the glans, and at the same time it is so much contracted that it pre-

vents the proper exposure of this portion of the organ, is termed *phimosis*. This may be either congenital, or acquired as the result of inflammation and disease.

In **Congenital Phimosis**, the penis is usually somewhat atrophied and the development of the glans is prevented by the pressure of the narrow prepuce. The skin is abundant and lax; but the mucous lining of the prepuce is short, contracted, and undeveloped. The constricting band which prevents the retraction of the foreskin is always situated at the junction of the skin and the mucous membrane. In the majority of cases a long foreskin is simply a source of local inconvenience; but it may become a source of disease from a variety of causes. Thus, in children, retention of the sebaceous secretion—"smegma preputi"—under an elongated and tight foreskin, comes a source of local irritation and inflammation from desquamation. The irritation thus kept up (Fig. 949), leads to local excitement and to

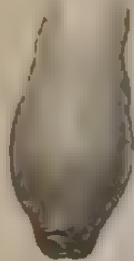

Fig. 949—Irritated Congenital Phimosis.

the development of the habit of early masturbation. In some cases the preputial orifice is so tight as to interfere materially with the discharge of the urine which passes from the urethra into a kind of pouch between the glans and prepuce, distends this stricture, and is then expelled in a fine jet or in a scattered sprinkling stream through the narrowed preputial orifice; and irritations of the bladder, often presenting symptoms simulating calculi, may thus be set up. Calculous concretions may form between the glans and the prepuce in such cases as do and have been known to do so in enormous numbers. V. Shaw, of Fyzabad, removed no fewer than 426 calculi varying in size from a pin's head to a small bean, from the situation in the person of a native of India, 50 years of age, who came under treatment for what appeared to be a large tumor of the end of the penis, the true nature of which was not detected until in removing it the irritated against the contained calculi. Various affections of the genito-urinary organs in children, such as incontinence, intermittent flow of hæmaturia, priapism, etc., have been shown by Bryant to be owing to congenital phimosis. The straining in micturition may give rise also to hæmorrhoids. Hydrocele of young children will also be found to be very frequently associated with phimosis. Sayre has pointed out the important fact that paralysis and various forms of spastic contractions chiefly of the lower limbs are due to the same cause, being readily curable by circumcision. In addition to these I have seen general spasmodic affections in children resemble chorea, resulting from congenital phimosis. At more advanced periods of life I have known it to be a cause of impotence, or rather as interfering with conception in the wife, the semen after emission being retained under the tight and narrow prepuce until erection had completely subsided. Congenital phimosis especially becomes a source of inconvenience in after life if gonorrhœal or venereal disease be contracted, as it renders exposure of the diseased part difficult or impossible, and interferes with the necessary treatment. In the opinion of some surgeons, cancer of the penis, if not occasionally, is at all events predisposed to, by congenital phimosis.

Acquired Phimosis usually results from repeated attacks of inflammation or of specific disease in the part, giving rise to solid œdema, or to the hypertrophy of the prepuce.

In elderly men, phimosis will sometimes slowly come on as a consequence of the irritation set up by cracks, fissures, or superficial ulcerations forming round the preputial orifice, which becomes narrowed, so as to prevent

glans from being uncovered. It is not uncommon in gouty subjects from repeated attacks of herpes preputialis. The preputial mucous membrane becomes thickened, and can be felt like a broad band under the loose and possibly slightly oedematous integument of the prepuce. This condition is a source of much irritation and annoyance, and requires relief by dilatation or by circumcision.

Treatment.—Every child who has a congenital phimosis ought to be circumcised; and even those who, without having phimosis, have an abnormally long and lax prepuce, would be improved greatly in cleanliness, health, and morals by being subjected to the same operation; and it would be well if the custom of Eastern nations, whether it be regarded as a religious rite or only as a time-honored observance, were more frequent among us. Phimosis, when not congenital, must be treated in accordance with its cause; thus, if it have resulted from inflammation, that must be subdued; if from venereal disease, that must be remedied, when perhaps the contraction and elongation will gradually subside. If, however, the phimosis, though acquired, be permanent, it should be subjected to operation.

A long foreskin without actual phimosis, if a source of annoyance to an adult, may easily be remedied by keeping it constantly drawn back. At first the tendency for the prepuce to slip forwards must be overcome by wrapping a piece of dry lint round it, and securing it by an elastic band, which must be just tight enough to keep it in position. After a few weeks the foreskin will retain the retracted position, and after a year or so will be found to have undergone considerable diminution in size.

Operations for Phimosis may be conducted on three plans; the elongated and contracted prepuce may be dilated, or slit up, or circumcision may be performed.

1. *Dilatation of the Phimosis* may be effected by putting the patient under chloroform, introducing a pair of forceps, and opening them widely, tearing through the narrow preputial orifice and tight funnel-shaped mucous membrane; or this may be slit up with a narrow tenotome on each side, and then dilatation practised. This procedure may be usefully adopted if the prepuce be not very long and tight, or if any objection exist to circumcision as too severe an operation.

In the acquired phimosis of old men, consequent upon contraction following cracks of the preputial margin, I have found that dilatation may safely and speedily be effected by the introduction of a two-bladed dilator, such as is used for the female urethra, which, being gradually screwed open, causes the indurated circle to yield.

2. *Slitting up of the Prepuce*, whether upon its upper or under surface, is, I think, an objectionable procedure, leaving the prepuce of its abnormal length, and more or less fissured and knobbed. In all cases I prefer circumcision as the simplest and speediest operation, and as leaving the most satisfactory result.

3. *Circumcision for Congenital Phimosis in Infants.*—It may be gathered from what has already been stated with respect to the evil effects resulting from congenital phimosis, that circumcision in this condition may be required to remove an elongated and possibly adherent prepuce, which occasions much local irritation, or which is the exciting cause of reflex and distant nervous disturbance of a paralytic or spastic character. So great are the evils resulting not only from congenital phimosis, but from an abnormally long, though not phimotic prepuce, that it is only humane and right from a moral point of view, to practise early circumcision in all such cases. This operation is easily and safely performed according to the Hebrew rite, which I have several times had an opportunity of witnessing, and which is done as

follows: The child being held on the lap of an assistant, the operator draws the foreskin slightly forwards, and then grasps it just in front of the glans by drawing it through a slit in a silver guard. This is not held perpendicularly downwards, but is inclined from above slightly forwards and downwards so as to avoid cutting the frenum as much as possible, and to cut the prepuce in an oblique or quilled manner. This is done by one stroke of a broad, round-ended knife. The mucous membrane is then torn open between the finger and thumb along the dorsum of the penis, and is turned back so as to be brought into contact with the cut edge of the skin. A strip of lint is then twisted round the organ in the sulcus behind the glans, to keep back the mucous membrane, and also to restrain hemorrhage from pressure. Union is perfect in a few days. This operation, which is performed on the eighth day after birth, is very rarely attended by any ill consequences. I have, however, seen it in one case followed by fatal erysipelas, and have heard of another instance in which death occurred from hemorrhage.

Circumcision in Boys or Adults may be most conveniently performed in the following way. The Surgeon restrains hemorrhage during the operation

Fig. 950. — Clover's Circumcision Tourniquet (open).

Fig. 951. — Clover's Circumcision Tourniquet (shut).

by tying a tape tightly round the root of the penis, or by compressing the organ in Clover's circumcision tourniquet (Figs. 950, 951), a most useful instrument, which can be slackened or tightened at any time. He next draws

Fig. 952. — Instrument for holding the Prepuce in Circumcision.

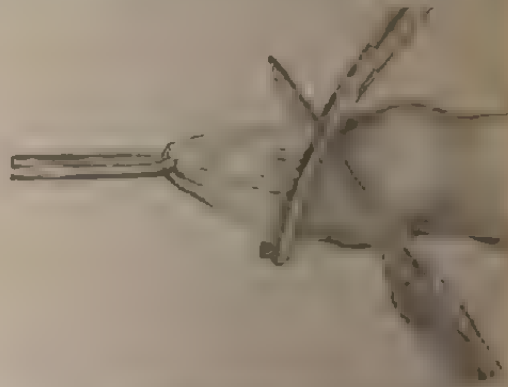

Fig. 953. — Circumcision in the Adult.

the elongated prepuce slightly forwards, until the portion of it which corresponds to the back of the glans is brought just in front of that structure. He then seizes the projecting prepuce immediately in front of the glans with

a pair of narrow-bladed polypus forceps, which he gives to an assistant, who must hold them tightly; or he grasps it and protects the glans by means of a plate (Fig. 952), which I have had constructed for this purpose. With one sweep of the bistoury he cuts off all that portion of the integument which projects beyond the forceps, which are then taken away (Fig. 953). It will now be found that he has removed only a circle of skin, but that the mucous membrane lining it still tightly embraces the glans; this he slits up, by introducing the point of a pair of scissors at the preputial orifice; and then, trimming off the angles of the flaps, he turns back the mucous membrane, and attaches it to the edge of the cutaneous incision by a sufficient number of fine catgut sutures. Before introducing these, he will generally find it necessary to ligature a small artery on each side of the penis, and one or two in the frænum. The best dressing in children will be some simple ointment, such as boracic acid ointment, or the glans may be simply smeared with a little vaseline. After every act of micturition, the parts should be well sponged with boracic acid lotion or Condyl's fluid and water. In the adult, union by first intention may often be obtained by a dry dressing of iodoform-wool thickly covered with collodion, so as to protect it from the urine. This may be left unchanged for four or five days. There is usually a good deal of swelling of the mucous membrane about the frænum, and some solid œdema usually remains for some weeks after the operation. This gradually subsides, and a linear cicatrix remains, which causes the patient no inconvenience. In some cases I have found adhesions between the prepuce and the glans; these require to be torn or dissected through, but no inconvenience results from this slight addition to the operation.

If sloughing of the prepuce have occurred, allowing the glans to protrude, as in Fig. 954, circumcision must be practised.

The chief points to be attended to in the performance of this operation, and on which its after success is most dependent, are—1, That too much skin be not removed; 2, That the mucous membrane be slit up to the base of the glans; 3, That too much of it be not removed; 4, That all bleeding vessels be tied with catgut ligatures, which must be cut short; 5, That the mucous membrane be well turned back, so as to cover the gap left by the retracted skin; 6, That all sutures be of catgut, which will be absorbed, and thus save the pain of taking them out.

Paraphimosis.—In *paraphimosis* the prepuce has been forcibly drawn back behind the glans, which becomes strangled by the pressure exercised by the preputial orifice, so that the parts cannot be replaced in proper relation to one another. This accident principally occurs in boys, or in individuals who have naturally a tight prepuce, and who, on uncovering the glans, find it difficult to get this part of the organ back. This difficulty is speedily and greatly increased by the swelling from congestion that is set up in the constricted glans.

Treatment.—This is sufficiently simple. The Surgeon should first try to reduce the swollen organ. He may often succeed in doing this by seizing the body of the penis between the index and middle fingers of each hand, and then endeavoring to draw the prepuce forwards, at the same time that he compresses the glans between the two thumbs and pushes it back (Fig. 955). Should reduction not be effected in this way, the constricted and

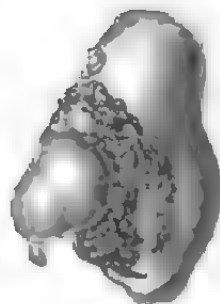

Fig. 954.—Sloughing of the Prepuce, and Protrusion of the Glans.

strangling preputial orifice must be divided. In doing this, the surgeon will observe that the glans is separated from the body of the penis by a deep and narrow sulcus, which is especially evident on the upper part of the organ. This sulcus, which is overlapped on one side by the glans, and on the other by a fold of integument—the swollen mucous layer of the prepuce—corresponds to the inner margin of the preputial orifice; and it is by the division of this, in which the stricture is situated, that immediate relief will be given. This operation may readily be done by drawing the glans forward, and passing the point of a narrow-bladed scalpel into the sulcus on the dorsum of the penis, and making a perpendicular incision about one third of an inch in length through the integuments at the bottom of the groove directly across

Fig. 955.—Reduction of paraphimosis.

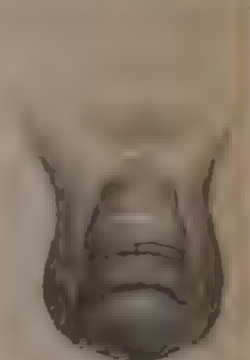

Fig. 956.—The result of the operation.
The result of the operation.

it (Fig. 956). In consequence of the great stretching of the parts the division will immediately gape widely; so that, instead of being longitudinal, it will appear to be transverse; and then reduction of the glans may readily be effected.

Balanitis.—Inflammation of the prepuce commonly occurs as the result of local irritation from want of cleanliness, not unfrequently set up by a gonorrhoea. When confined to the prepuce, and constituting *balanitis*, that structure is much swollen, infiltrated, and reddened, and, while the inflammation lasts, continues in a state of phimosis. When the mucous membrane of the glans is affected as well, constituting *posthitis* there is a good deal of irritation and smarting, together with mucopurulent discharge.

Treatment.—The disease requires to be treated on ordinary principles. The continued application of lead lotion, with the internal administration of salines, will generally remove it; but in many instances the most efficient plan will be found to consist in rapidly sweeping the inflamed surfaces with a stick of nitrate of silver passed down between them on one side of the frenum, and carried round to the opposite side. If the patient is liable to repeated attacks, circumcision should be performed.

Herpes of the Glans and Prepuce is characterized by the formation of small vesicles or excoriated points upon the mucous membrane of this organ, attended by much smarting and itching, and occurring chiefly in persons of a gouty habit of body, with an irritable mucous membrane.

Treatment.—This slight affection is often very rebellious to treatment. In many instances, local means alone will not suffice; for, though relief may be obtained by powdering the part with the oxide of zinc, or by using slightly astringent and cooling lotions, yet no permanent benefit will be derived from

constitutional treatment be adopted, modified according to the circumstances of the case.

Hypertrophy of the Prepuce not unfrequently occurs as the result of chronic irritation or disease; it is usually of limited extent, and requires no special interference on the part of the Surgeon; but in some instances it may become so extensive as to require operative interference. The hypertrophy is due to solid edema of the areolar tissue of the prepuce and of the sub-integumental structures of the body of the penis, the organ being very greatly enlarged and becoming club-shaped. In these cases circumcision, with the excision of a V-shaped piece from the dorsum of the penis, will usually be found to leave a good and satisfactory result. But a greater magnitude than this may be attained. Thus Vidal has related and figured a case that had attained such an enormous size, that the organ reached to below the knees, and was as large as a thigh. This monstrous growth was successfully excised.

Warts on the penis have already been described. They may attain a very large size, as in Fig. 957, and are best treated by being snipped off with curved scissors.

Horny Excrescences have been observed to spring from the glans penis. The most remarkable case of this kind on record is one by Jewett, of Connecticut. It was that of a young man, in whom, after operation for congenital phimosis and the removal of warts, a horn grew from the left side of the glans penis, and attained a size of three and a half inches in length by three-fourth of an inch in diameter at the base. It could be handled and cut without pain, and the patient "was accustomed to amuse the inmates of the ward by lighting the end of the horn and allowing it to burn." It did not return.

Persistent Priapism, lasting for many days, is occasionally met with, as the result in most cases of excessive venery, and more especially of violent coitus during intoxication. The erection of the penis is not accompanied by any sexual desire, but is attended with great pain, a sense of weight about the perineum, much anxiety, and constitutional disturbance. The organ is singularly hard and unyielding. The pathology of this condition is obscure. By some it has been considered as the result of extravasation of blood into the corpora cavernosa; by others, as dependent on sympathetic or reflex nervous irritation. The effect of treatment would lead to the inference that the latter view was correct. Incisions into the corpora cavernosa to let out the blood supposed to be extravasated have been productive of no good result, whilst the erection has rapidly subsided under full doses of the bromide of potassium.

Gangrene of the Penis.—Sloughing of the integuments of the penis, to a greater or lesser extent, not unfrequently occurs in persons of broken constitution as the result of inflammatory phimosis, simple or gonorrhoeal (Fig. 954); or in consequence of the invasion of syphilitic phagedena, and, indeed, the glans and body of the organ may often be extensively destroyed by the latter cause. These various forms of the disease have been described in different parts of this work.

The true *idiopathic gangrene* of the penis is, however, a very rare disease; and Demarquay, who has specially directed attention to it, finds but few

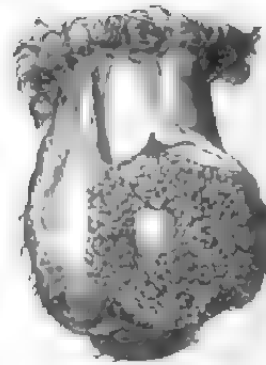

Fig. 957.—Wart on the Glans and inner surface of Prepuce, which is slit up.

It was excised, and did

instances of it in the records of surgery. It has chiefly been met with people of advanced age or of broken constitution, who, whilst suffering from some local affection of the organ, have been attacked by acute general disease, such as typhoid or smallpox, or have become the subjects of gangrene. In some cases it is probably embolic. The disease, when affecting the body of the penis, is often fatal—possibly by hemorrhage on the separating of slough. When the glans only is attacked, the prospect is better. In either case—especially the former—mutilation of the organ to a great extent will result.

The *Treatment* of gangrene of the penis presents nothing special, with exception of restraining hemorrhage by means of the actual cautery, and preventing or repairing loss of substance in the urethral wall, if it be much by the disease and involved in the destruction resulting.

Fibrous Tumor of the Penis.—The penis may be the seat of fibroid and other tumors. The accompanying drawing (Fig. 958) is an illustration

Fig. 958.—Fibroid Tumor of the Penis, Successfully Removed.

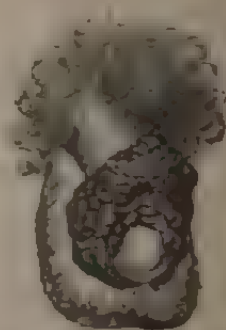

Fig. 959.—Epithelioma of the Penis.

one springing from the fibrous tissue of the corpora cavernosa which was removed some years ago from the under surface of the organ.

Cancer of the Penis.—The form of cancer met with in the penis is *Squamous Epithelioma*. It usually springs from the sulcus behind the glans and thence invades the neighboring portion of the organ. It always commences in the anterior extremity of the penis, affecting the body of the organ only by extension from the original starting point. It appears in two forms, either as a flat tubercle or as a distinctly papillary growth. When it commences as a tubercle it appears as a hard, pale, reddish-white mass situated on the glans or between the prepuce and the glans. This increases in size and extends deeply into the organ. At last a crack forms and a serous discharge to exude which usually becomes very fetid. Ulceration rapidly takes place. Sometimes the disease appears to be very distinctly localized; but after its removal it will usually be found to infiltrate the organ for a considerable distance.

The papillary form at first presents the appearance of ordinary warts (Fig. 959). It grows rapidly, and a deep-seated indurated base can be felt beneath it. Ulceration soon sets in with abundant foul discharge. At first the distinction from a simple growth is not easy to make, but the flat hard infiltrating the glans will usually indicate its nature.

Cancer of the penis occurring under a long foreskin soon leads to such enlargement of the glans that the prepuce cannot be drawn back. It then causes a globular enlargement over which the skin of the prepuce is tightly stretched, and a foul serous discharge often tinged with blood escapes from the orifice. Finally the distended foreskin may give way and the fungating cancerous growth project through an ulcerating aperture in it. The glands in the groin are early affected.

Causes.—It has been supposed and with some show of reason, that congenital phimosis predisposes to the affection; probably by confining the secretions, and thus keeping up irritation of the part. Hey found that, of 12 patients with this disease who came under his observation, 9 had congenital phimosis; and Travers states that Jews, who are circumcised, are seldom subject to this affection. But as they are a limited community in this country, and as the disease is rare, we cannot draw any conclusive inference from this observation. It is, however, very probable that the papillary form of the disease often arises from the local irritation resulting from the accumulation of the secretion under a long foreskin. The nodular form of the affection, however, may occur frequently in individuals who have not suffered from this source of irritation; of this I have seen several instances at University College Hospital.

Diagnosis.—Epithelioma of the penis requires to be diagnosed from *fungoid warts*. This may usually be done readily enough, by comparing the indurated state of the malignant with the soft and lax condition of the non-malignant affection. From *chancreous induration* of the glans, the history of the case and the way in which it is influenced by treatment will enable the Surgeon to effect the diagnosis.

Treatment.—The treatment of cancer of the penis will vary according to the nature and extent of the malignant affection. If the growth is limited in extent and especially if it is papillary in form the Surgeon may, if he see the case early, content himself with dissecting off the affected patch. Should the growth be more extensive and extend deeply into the substance of the penis the treatment must be conducted on the principles that guide us in the management of malignant affections wherever situated; viz., to remove the diseased organ at as early a stage as possible, whilst the affection is localized, before the glands are implicated and the constitution poisoned. In the penis, this may readily be done by an operation that is simple in its execution and nearly devoid of danger. In many cases a return may take place, and that speedily, either in the part itself or in the neighboring lymphatic glands; yet, even if this occur, it is clearly the duty of the Surgeon to rid the patient of a loathsome disease, and to put him in a state of comparative comfort for some time; the more so, as there is reason to believe that, in some instances, the disease may be entirely extirpated from the system, evincing no tendency to return. Indeed, I believe that amputation of the penis for cancer is more successful in its results than is the extirpation of malignant growths from most other situations. In some of Hey's cases, which continued under his observation, there was no recurrence of the disease for several years. I have seen several patients who, after a lapse of six or eight years, have continued free from a recurrence of the disease; and I have also seen a gentleman who had his penis amputated for cancer more than twenty-five years ago, and in whom no return has taken place. The fact is, that we see and hear of those cases in which a recurrence takes place; but those patients who remain free from a return of the affection do not divulge their infirmity; and it is exceedingly rare in hospital practice to find a patient come back with recurrent cancer in the stump of the penis, which he would certainly do if relapse took place. In those cases in which the operation is not successful,

it has usually been delayed too long, the disease having already impaired the lymphatic glands in the groin, and thus contaminated the patient's constitution.

Amputation of the Penis is best performed with the knife, though the écarateur may be used if preferred. The operation should always be performed towards the root of the organ, so as to be well clear of the disease. Before proceeding to operate means must be taken to restrain undue hemorrhage. This is best done by tying a narrow tape tightly round the root of the penis, or by encircling this part by Cloyer's tourniquet. The operation may be done in various ways, but the following is perhaps as efficient as any. The penis being drawn well forward a circular incision is made in it with a bistoury dividing the skin only. The corpora cavernosa are cut carefully through from the dorsal aspect, care being taken not to cut the corpus spongiosum. If necessary a full sized catheter may be introduced to define more clearly the limits of the urethra. The part of the penis beyond the section of the corpora cavernosa being drawn well forward, difficulty will be found in separating these from the corpus spongiosum. Finally the corpus spongiosum is cut through half to three-quarters of an inch nearer the glans than the incision through the corpora cavernosa. Bleeding is then arrested. There are usually five arteries requiring ligation, the dorsales penis, one in each corpus cavernosum, and one in the corpus spongiosum. In securing these, trouble is not unfrequently experienced in consequence of the retraction of the stump that is left. The danger of hemorrhage does not exist if the tape or the tourniquet have been properly applied before the operation, as every artery should be secured before the compression is removed. The projecting corpus spongiosum and urethra are then slit up with a pair of scissors along the dorsal aspect. It is then spread out and attached by catgut sutures to the skin below and to the corpora cavernosa above. In this way the contraction of the urethral orifice, which is often a most serious source of inconvenience and even of danger to the patient after amputation of the penis, may with certainty be prevented. Hilton, who first pointed out the necessity of providing against this accident, recommended that the urethra should be slit along its under aspect, but if this be done the urine is directed downwards between the legs during micturition, while if the slit be made towards the dorsal aspect it is often projected somewhat forward, and the patient can thus make water with less inconvenience. In performing the operation care must be taken that the skin is not dragged too much forward, lest sufficient covering be not left. After the operation is finished the spongy tissue should be wiped over with a solution of chloride of zinc (40 to 50), and the stump must be covered with a piece of lint moistened with boracic acid or some other antiseptic. After passing water the parts must be well bathed with some antiseptic solution. In this way septic infection, which may readily occur in so spongy and vascular an organ, may be prevented.

If the amputation be performed too high up, infiltration of urine may take place into the scrotum, and to prevent this, it may be easier to introduce an elastic catheter after the operation, and leave it in for a few days.

When the écarateur is used, it is better to divide the skin and the corpus spongiosum with the knife, the corpora cavernosa only being cut through with the wire. There is, however, little if any advantage to be gained by the use of this instrument, unless there is any special reason for avoiding too much blood, as hemorrhage is not usually a serious trouble in the operation.

If the glands in the groin are distinctly, but not too greatly, enlarged,

attempt should be made to remove them at the same time as the amputation of the penis is performed.

In a case extending too far back to allow the performance of the ordinary operation, Pearce Gould successfully removed the disease by dividing the scrotum and dissecting away the whole organ as far back as the crura, leaving an opening in the perineum through which the patient subsequently passed water.

If, after amputation of the penis, much inconvenience arises from the urine being passed downwards between the legs, it may best be avoided by following Ambrose Paré's advice of adapting a funnel, which may be made of metal, or ivory, to the pubes over the stump, and thus carrying the urine clear of the person.

Other Tumors besides cancer are occasionally met with in the penis. I have seen *Cysts* and *Nævi* situated under the prepuce; and *Fibrous Tumors* may occur in the corpora cavernosa. Such morbid growths, if small, can readily be removed without injury to the rest of the organ; if large, they may require its amputation.

DISEASES OF THE SCROTUM.

Inflammatory Œdema of the scrotum is an erysipelatous inflammation of this region, and derives its chief peculiarity from the circumstance of its giving rise to great effusion into and swelling of the areolar tissue of this part and of the penis, with a tendency to the rapid formation of slough in it, by which the integument may likewise become affected to such an extent that the testes and cords speedily become denuded. This disease usually originates from some local source of irritation, as fissures, cracks, or urinary extravasation. There is a peculiar and specific form of "inflammatory œdema" of the scrotum and penis, which is apt to occur as a sequence of smallpox and scarlet fever. In this form of the disease rapid and extensive infiltration of the parts occurs, with a tendency to speedy gangrenous disorganization of the areolar tissue and skin covering the organs of generation.

Treatment.—This consists in elevating the scrotum, fomenting it well, and making early and free incisions into it, particularly at the posterior and dependent parts of the scrotum and penis, with the view of relieving the tension to which the tissue is subjected by the effusion into its meshes, and thus preventing the liability to slough. Should this occur, the case must be treated on ordinary principles, when cicatrization will speedily ensue, however extensive the denudation of parts may be. The constitutional management must always be conducted in accordance with those principles laid down in the first division of this work, and with special attention to the maintenance of the patient's strength.

Hypertrophy of the scrotum seldom occurs in this country, though Liston once had occasion to remove such a mass, weighing 44 lbs.; but in some tropical regions, particularly India and China, it is of frequent occurrence, and may go on until it attains an enormous bulk, forming a tumor nearly as large as the trunk, and perhaps weighing 70 or 80 lbs., or even, as in one case recorded by Larrey, 200 lbs. These enormous growths are of simple character, and constitute the disease termed *Elephantiasis Arabum of the scrotum*. (See vol. i. p. 944.) Fig. 960 represents a tumor of this kind, weighing 40 lbs., which was successfully removed by Rogers, of the Mauritius. It is taken from a photograph of the case, kindly sent to me by that gentleman.

it has usually been delayed too long, the disease has reached the lymphatic glands in the groin, and thus constitutes a permanent disfigurement.

Amputation of the Penis is best performed with the *écraseur* may be used if preferred. The operation is performed towards the root of the organ, so as to avoid the urethra. Before proceeding to operate means must be taken to prevent hemorrhage. This is best done by tying a ligature around the penis, or by encircling this part by a bandage, as in circumcision, only nearer to the root. The operation may be done in various ways, but the most common is any. The penis being drawn well out, it is cut with a bistoury dividing the skin and the *corpus spongiosum*. If necessary, the dissection may be done more clearly the day after the operation. The difficulty will be found in the removal of the *corpus spongiosum* inch nearer the glans. Finally the *corpus spongiosum* is then secured by the *dorsales penis*, or by the *perineal*. In securing these, the retraction of the penis exists if the operation, as a rule, is performed off. The penis is then cut off by a pair of scissors. The patient lying on his back and having the penis raised above the level of the body for an hour before the operation, this way may at the same time be bled so as to empty the source of the hemorrhage. This method does not prevent the possibility of the hemorrhage may be prevented by one of the following methods:

Fig. 900 — Elephantiasis of the Scrotum.

1. The application of the aortic compressor. 2. The application of a screw-compressor to the root of the tumor. The use of the other methods may be combined. The use of the compressor is especially advocated by Dr. Turner, a medical officer at Samoa, who has had vast experience in this operation, having treated no fewer than 138 of these tumors. The clamp used by Dr. Turner consists of two parallel bars of sufficient length, united by two long upright screws worked by nuts. After the tumor has been raised and emptied of its blood, the compressor is applied to the neck and screwed down tight, and the operation is proceeded with.

The directions given by Dr. Turner for the safe performance of the operation are as follows: The patient having been anesthetized, the clamp is applied to the tumor and the tumor emptied of its blood by pressure, the clamp must be removed. The tumor, if small, may then be raised by the hands; if large, large hooks should be passed deeply into the leathery skin at the base and being attached to a block and tackle fixed to the ceiling, the whole must be raised so that its posterior part is brought into view. A couple of skin-flaps, about 14 inch long, are then made here at its neck. The tumor is then lowered and allowed to fall forward. Two or three skin-flaps are now to be made from the front and sides of the tumor, the front flap be-

penis when dissected out; one should be of sufficient lateral flaps are intended to cover in the testes. for. In small tumors, where it lies superficial ones, where deeply buried, it is best through which the urine escapes, going dissecting out the organ, which should be now to be sought for by they must be cleared and the if this mass is now removed. —may require ligature in the usually loosened. The skin-flaps are and testis, and the wound treated on this object to the formation of skin-flaps on penis and testis, as tending to favor recurrence. As Dr. Turner very truly remarks, the skin on is generally healthy, being merely dragged down from the scrotum. occasionally affects the scrotum; and, as it occurs principally in the scrotum, it has been appropriately enough termed *Chimney-sweep's scrotum*. This affection appears to arise from the irritation of the folds in the folds of the scrotum (vide vol. i. p. 976). It commonly presents as a tubercle or wart, which after a time cracks or ulcerates, wanting the ordinary characters of a cancerous ulceration. It rapidly spreads, involving at last the greater part of the scrotum, and perhaps invading the testis. After a time, the inguinal and pelvic glands will be affected; and the patient, if deprived of his covering of soot, will be found to be cachectic-looking.

The *Treatment* consists in excising widely the diseased portion of the scrotum, provided the inguinal glands be not involved, or the patient's constitution poisoned. The disease has a great tendency to return, and it is seldom that the patient long escapes with life when once he has been affected by it.

CHAPTER LXXIV.

DISEASES OF THE TESTIS AND CORD.

MALPOSITION OF THE TESTIS.

THE testes are, in the fetus, lumbar organs lying below the kidneys, and in the normal condition descend into the scrotum a short time before birth. From some arrest of development, this descent may be retarded on one or both sides; and in other instances it is never completed. An undescended testis may continue to lie within the cavity of the abdomen; or it may find its way into the internal ring; or may become engaged in the inguinal canal, lying above the external abdominal ring, or it may project just beyond this, not passing into the scrotum. In these several situations it may remain quiescent; but it may become the seat of inflammation or of new growths, simple or malignant. It may also, when undescended, as has been stated at

Treatment.—Tumors of this kind necessarily require extirpation. In performing this operation, two points imperatively demand attention. The first is the avoidance of hemorrhage, which in so vascular a region might easily be fatal. The other is the preservation of the penis and testes.

The avoidance of hemorrhage may be effected by four methods, which may be employed singly or combined. These are, 1, by position, as originally

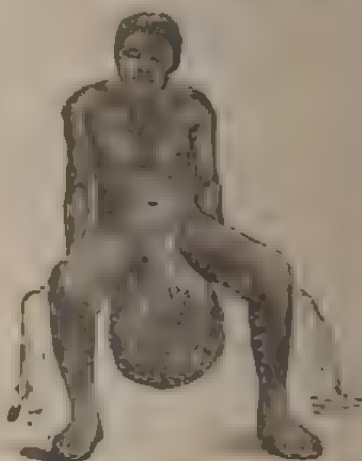

Fig. 260 — Elephantiasis of the Scrotum.

advocated by O'Ferrall in 1844. The patient lying on his back and having the tumor raised above the level of the body for an hour before the operation. The tumor may at the same time be bandaged so as to compress the vessels, and thus empty them. This method does not prevent the proximal hemorrhage.

This proximal hemorrhage may be prevented by one of the following methods:

1. The application of the aortic compressor.
2. Esmarch's bandage.
3. The application of a screw-compressor to the root of the tumor. The first and either of the other methods may be conjoined.

The use of the compressor is especially advocated by Dr. Turner, a medical missionary at Samoa, who has had vast experience in this operation, having removed no fewer than 138 of these tumors. The clamp used by Dr. Turner consists of two parallel bars of sufficient length, united by two long upright screws worked by nuts. After the tumor has been raised and emptied of blood, the compressor is applied to the neck and screwed down tight, when the operation is proceeded with.

The directions given by Dr. Turner for the safe performance of the operation are as follows: The patient having been anesthetized, the clamp applied, and the tumor emptied of its blood by pressure, the clamp must be screwed home. The tumor, if small, may then be raised by the hands; if large, two large hooks should be passed deeply into the leathery skin at the bottom and being attached to a block and tackle fixed to the ceiling, the whole must be raised so that its posterior part is brought into view. A couple of skin-flaps, about 1½ inch long, are then made here at its neck. The tumor is then lowered and allowed to fall forward. Two or three skin-flaps are now to be made from the front and sides of the tumor, the front flap being

intended to cover in the penis when dissected out; one should be of sufficient size for this purpose. The lateral flaps are intended to cover in the testes. The penis must next be sought for. In small tumors, where it lies superficially, it is easily found. In larger ones, where deeply buried, it is best reached by slitting up the aperture through which the urine escapes, going in search of the glans penis, and then dissecting out the organ, which should be held up against the abdomen. The testes are now to be sought for by cutting diagonally, and with finger and knife they must be cleared and the cords followed up. By a few strokes of the knife this mass is now removed. A large number of vessels—from 30 to 40—may require ligature in the stump; they are tied as the clamp is gradually loosened. The skin-flaps are then brought together over the penis and testis, and the wound treated on ordinary principles. Some Surgeons object to the formation of skin-flaps with the view of covering in the penis and testis, as tending to favor recurrence of the disease. But, as Dr. Turner very truly remarks, the skin on the neck of the tumor is generally healthy, being merely dragged down from the parts above the scrotum.

Epithelioma occasionally affects the scrotum; and, as it occurs principally in chimney-sweepers, it has been appropriately enough termed *Chimney-sweeper's Cancer*. This affection appears to arise from the irritation of the soot lodging in the folds of the scrotum (vide vol. i. p. 976). It commonly commences as a tubercle or wart, which after a time cracks or ulcerates, presenting the ordinary characters of a cancerous ulceration. It rapidly spreads, involving at last the greater part of the scrotum, and perhaps invading the testis. After a time, the inguinal and pelvic glands will be affected; and the patient, if deprived of his covering of soot, will be found to be cachectic-looking.

The *Treatment* consists in excising widely the diseased portion of the scrotum, provided the inguinal glands be not involved, or the patient's constitution poisoned. The disease has a great tendency to return, and it is seldom that the patient long escapes with life when once he has been affected by it.

CHAPTER LXXIV.

DISEASES OF THE TESTIS AND CORD.

MALPOSITION OF THE TESTIS.

THE testes are, in the fetus, lumbar organs lying below the kidneys, and in the normal condition descend into the scrotum a short time before birth. From some arrest of development, this descent may be retarded on one or both sides; and in other instances it is never completed. An undescended testis may continue to lie within the cavity of the abdomen; or it may find its way into the internal ring; or may become engaged in the inguinal canal, lying above the external abdominal ring, or it may project just beyond this, not passing into the scrotum. In these several situations it may remain quiescent; but it may become the seat of inflammation or of new growths, simple or malignant. It may also, when undescended, as has been stated at

p. 791, vol. ii., become complicated with or mistaken for a hernia, and may present many diagnostic difficulties. Inflammation of the testis retained in the canal will be considered at p. 1104. When an undescended testis becomes painful or the seat of structural disease, it may require removal from the canal. The testis may be met with in other abnormal situations; thus, some time ago I saw a case in which one of these organs was situated in the perineum, close by the anus, having apparently missed the scrotum; and cases have occurred in which they have been met with in the interior of the pelvis. The organ may sometimes be turned hindside forwards, being retroverted, so that the epididymis is placed in front. In a case of this kind which I had an opportunity of examining after death, a few years ago, the epididymis and vas deferens were considerably larger than natural. If a hydrocele form in such a case, it will be seated behind the testis.

There is a very important question connected with malposition of the testis, viz., Is the organ when undescended prolific? There is reason to believe that it is not. Such testes are small, hard, and granular in structure; and, when they are examined under the microscope, spermatozoa are not found in them. When only one testis is undescended, the other one, being in its proper position, carries on the functions of the two organs; but when both testes are retained in the canal or in the abdomen, being undescended, the individual who is the subject of such malposition will most probably be sterile. He may have the usual erotic feelings, full power of erection, and of emission of a spermatic fluid; but the secretion will probably have no fecundating power. In the event of it being necessary to determine this point with certainty, the examination of a drop of this fluid under the microscope will demonstrate the presence or not of spermatozoa, and so decide it.

Treatment.—In most cases, a misplaced testis calls for no treatment. In children, the application of a horseshoe truss above it may aid in its descent when it lies immediately outside the ring, but its effect is somewhat doubtful. Any attempt to bring the testicle down into the scrotum would be ineffectual, for in these cases it will be found that, although the vas deferens is usually long and lax, the vessels are too short to allow of any further displacement of the gland downwards. A testicle in the groin may, however, be so serious a source of inconvenience, as to call for some operation for its relief. This most commonly arises when it lies in the inguinal canal. In these cases the gland may occasionally be forced into the external ring and partly strangulated, causing intense pain till it is reduced. Under these circumstances, the ring may be closed by suture, as in the radical cure of hernia, or the gland may be removed. The latter is, perhaps, the preferable operation, as being the more certain.

When the testicle has missed the scrotum and passed into the perineum, it may be a great source of pain from the frequent injuries to which it is exposed in sitting. As in these cases the cord is of sufficient length, the testicle may be put into its proper position without great difficulty. It must be dissected out, and left attached by the cord only. An incision is then made into the scrotum, the testicle placed in its proper position, and secured by a catgut suture. The details of the operation must necessarily vary with the abnormal position from which the gland has to be removed.

NEURALGIA OF THE TESTIS.

A painful or irritable condition of the testicle may occur without any actual disease of the organ; the pain being seated either in the epididymis, which is the part naturally the most tender, in the body of the testis, or stretching along the cord to the loins and groins. It is usually paroxysmal.

and is accompanied by great tenderness, and commonly by some fulness of the organ, which feels soft and flaccid; but it is difficult to make a proper examination, on account of the agony that is induced by touching the part. This disease occurs chiefly in young men of a nervous and excitable temperament, and is frequently associated with great mental disquietude and despondency, often amounting to a suicidal tendency.

The *Causes* are obscure; in many cases the disease appears to be connected with a neuralgic temperament, but in others it is associated with some dyspeptic disorder, or may be dependent upon local irritation; thus external piles, or the pressure of a varicocele, will often give rise to it.

The disease is usually of a very chronic character. In some instances, however, it ceases spontaneously, after having lasted for weeks or months.

Treatment.—When the neuralgia is dependent upon constitutional causes, the treatment is extremely unsatisfactory. The administration of tonics, such as iron, zinc, or quinine, the local application of sedatives, as of atropine ointment or the tincture of aconite, may be of service. In other cases, cold bathing or douching will be beneficial; and, in all, keeping the part supported with a suspensory bandage will be advantageous. In the event of there being any local irritation, that should be removed; thus I have known the disease to cease after the excision of external piles; and when it is connected with varicocele, proper measures must be adopted for the relief of that affection.

In extreme cases, Sir A. Cooper recommends castration; but such a proceeding is altogether unjustifiable in a disease that is either constitutional, or dependent on local causes which are readily removable.

INFLAMMATION OF THE TESTIS.

Inflammation of the Testicle, considering the organ as a whole, may be of two distinct kinds, varying as to seat and as to cause. Thus it may be seated in the body of the organ, constituting *Orchitis*; or the epididymis may alone be affected, constituting *Epididymitis*. As to cause, it may be rheumatic, traumatic, or gonorrhœal, or may occur as a sequela of mumps.

Acute Inflammation.—The *Seat* of the inflammation, at the commencement of the disease, depends greatly upon the cause, which may be in the urinary passages or elsewhere. Irritation in any part of the urethra, occasioned by the passage of instruments, by the lodgement of calculi, or by gonorrhœal inflammation, usually causes the epididymis to be primarily affected, and the body of the organ to be inflamed in a secondary manner. When, on the other hand, the inflammation comes on from injuries, blows, strains, or other causes acting on the testis as a whole, the body is usually first affected. To all this, however, exceptions will often occur; and orchitis may supervene as the result of gonorrhœa, or epididymitis from a blow. The orchitis in such cases is in all probability a kind of constitutional affection, intimately associated with inflammation of other fibrous tissues, especially with gonorrhœal rheumatism; the inflammation of the epididymis, arising from gonorrhœa or other irritation of the urinary passage, appearing to result from direct extension of the morbid process along the vas deferens.

Symptoms.—These necessarily vary to a certain extent, not only according as the disease is of an acute or of a chronic character, but as it primarily affects the body of the testis or the epididymis. When it commences in the latter structure, it is the inferior globus that is commonly first affected, which becomes swollen, hard, and tender. The disease may be confined throughout to this part; but most frequently it invades the whole of the organ, which becomes uniformly enlarged and somewhat ovoid; it is frequently accompanied

by a good deal of effusion into the tunica vaginalis, then constituting the *Acute Hydrocele* of Velpeau. As the inflammation subsides, the different characters presented by the enlargement of the two constituents of the organ again become apparent. The swelling is therefore due partly to general enlargement of the organ, but in some cases to inflammatory effusion into the tunica vaginalis; and this exudation may either be purely serous or partly coagulable.

The pain is always very severe, with much tenderness and a sensation of weight, and commonly extends up the cord into the groin and loin. It is generally greatest when the body of the testis is affected, owing probably to the enveloping fibrous tunic preventing the expansion of the organ. Hence it is often spasmodic and paroxysmal, extending up the course of the cord. There are usually considerable swelling and redness of the scrotum, with turgescence of the scrotal veins, and a congested state of the cord, with sharp pyrexia, nausea, and perhaps occasional vomiting.

As the disease subsides, the body of the testis first resumes its normal character and shape, the epididymis often continuing hardened and enlarged for a considerable period. In fact, the induration that forms in the epididymis may be permanent, implicating the whole or a portion of its convolutions.

Gosselin has shown that this induration of the epididymis following inflammation frequently causes complete obstruction of the canal, and if occurring on both sides produces sterility. In 19 such cases he found spermatozoa absent from the semen, and the patients consequently incapable of procreation, although the appearance of the testes and of their secretion was scarcely altered, and the virile powers of the patients remained unimpaired. Curling also mentions several such cases, and points out the necessity of continuing the treatment of epididymitis until the last trace of induration has disappeared. At a later period, treatment is almost useless.

Subacute Orchitis usually comes on with the same symptoms, though in a less marked form than in the acute variety. The swelling, however, is considerable, though of a softer kind. When the disease is chronic, the testis often becomes permanently enlarged and hardened, assuming an oval shape, being smooth, heavy, and uniformly expanded, with a sensation of weight, dragging, and severe pain, and a good deal of tenderness on pressure. This form of orchitis occasionally occurs in old people.

Orchitis may occur idiopathically, without any assignable cause in the way of external injury or local irritation in the urethra or prostate. This form of the disease is most common in middle-aged men, and more especially in those who are gouty. In fact the disease is in all probability one of the many local forms of gouty inflammation. It is not very acute but lingering, liable to recurrence, and to be followed either by hydrocele or chronic indurations of the epididymis.

Atrophy of the Testis as a consequence of Inflammation is more liable to follow the orchitis of mumps in young men above the age of puberty than any other inflammatory affection of the organ. It is remarkable how rapid and how complete the wasting of the testis will be in these cases. A few weeks after the subsidence of the inflammation the testis will be found to be shrunk away, so as to form a small soft mass not larger than a filbert.

Atrophy of the testis may sometimes gradually ensue also as a result of chronic epididymitis, and the consequent induration of this structure. Strangulation of the vascular supply to the testis occurs, and the whole organ at last wastes so as to leave nothing but a small hardened mass in the scrotum.

Treatment.—The treatment of *Acutely Inflamed Testicle*, whether local or constitutional, is essentially antiphlogistic. The patient should be kept in

bed with the testis raised on a small pillow between the thighs, and hot fomentations diligently applied. At the same time the swollen gland may be painted with an ointment composed of equal parts of glycerine and belladonna. This treatment will usually be found to give the patient most relief; but if the case be seen very early, before much swelling has taken place, the application of cold by means of Leiter's tubes (vol. i. p. 216) or Ott's coil may sometimes cut the inflammation short and give immediate relief. Local blood-letting is often of great service when there is much pain. It is best carried out by puncturing the veins of the scrotum—a far better method than applying leeches, the bites of which are apt to become irritated. This little operation may be very effectually done by directing the patient to stand up, and to foment the scrotum for a few minutes with a hot sponge, so as to distend the veins; these may then be punctured at various points with a fine lancet, and the parts well fomented afterwards, so as to encourage the flow of blood. In this way six or eight ounces may be taken in the course of a few minutes; when enough has escaped, the further flow may be arrested by laying the patient down and elevating the part.

If there be much effusion into the tunica vaginalis, constituting acute hydrocele, relief may be afforded by puncturing this sac with the point of a lancet. Puncture of the testis itself, which has been recommended, is a needless and dangerous proceeding. I have known of a case in which it was followed by abscess in the gland, ending in its complete destruction.

The *Constitutional Treatment* during the acute stage consists in the administration of salines and antimony, with henbane in full doses, so as to give an aperient, a diaphoretic, and a sedative together; when this begins to act, great relief is usually afforded.

As the inflammation subsides, the treatment must be changed. When there is merely swelling and hardness left, with but little pain or tenderness, the testis may advantageously be strapped with adhesive plaster, so as to give good support and to promote absorption of plastic matter. Fricke, of Hamburg, has strongly recommended strapping in the acute stage; but I cannot say that I have ever seen any advantage derived from it at this period of the disease, though I have many times seen it tried; it has usually appeared to me to increase, sometimes very considerably, the pain in the part, and the general uneasiness.

In *Subacute Orchitis* much benefit is usually derived from a short course of Dover's powder and calomel, with early strapping of the testis. When the organ has become enlarged and indurated, as the result of chronic inflammation, it may be advantageously strapped either with simple plaster, or with one composed of equal parts of the *emplastrum ammoniacum hydrargyro* and soap-plaster; mercury in small doses, more especially the bichloride, being continued for some length of time, until the inflammatory products are absorbed and the hardness disappears.

In *Strapping a Testicle*, the scrotum should be shaved, and then drawn tightly upwards on the affected side. The Surgeon should next pass a long strip of plaster, at least an inch broad, above the enlarged testicle and round the corresponding side of the scrotum, so as to isolate it, as it were. Another strip is now passed from behind, in a longitudinal direction, over the lower end of the testis, and upwards upon the anterior part of the scrotum; and then, by a succession of horizontal and vertical strips, neatly overlapping and drawn tightly, the organ is completely enveloped and compressed. To be of any service, the strapping must be tightly and evenly applied; but at the same time care must be taken not to strangle the scrotum by drawing down the upper strips of plaster too forcibly. In a case of syphilitic disease of the testis, in which I was obliged to have recourse to castration,

the whole of the side of the scrotum had sloughed away, leaving the testis exposed and fungating, in consequence of the tight strapping which had been employed before the case came into my hands.

After the swelling has subsided, the patient must wear a suspensory bandage for some months.

The *Induration about the Epididymis*, which usually remains after epididymitis, must be treated by prolonged counter-irritation with tincture of iodine, or by the application of the iodide of lead or iodine-ointment. So long as any induration is left, it is doubtful whether the secretion is able to find its way through the thickened epididymis.

Abscess, as the result of inflammation of the testis, is of rare occurrence. Sometimes the scrotum inflames at one point, where fluctuation becomes apparent, with thinned skin and evident signs of suppuration; a puncture should here be made, and the pus let out as soon as formed. In true abscess of the testicle the pus forms under the tunica albuginea, adhesion takes place between the testis and the scrotum, the fibrous coat gives way, and the pus gets vent externally through the integuments. Into the aperture that necessarily results a portion of the secreting tissue of the gland sometimes projects, and, becoming inflamed, forms a red, granular, and fungous mass, protruding through and overlapping the edges of the aperture. The treatment of this condition will be considered when we come to speak of the scrofulous testicle.

Inflammation of the Testis in the Inguinal Canal may sometimes take place, even in adults, when the organ has not descended through the external ring; giving rise to a train of somewhat puzzling symptoms which closely resemble those of strangulated incomplete hernia; with which, however, it must be borne in mind that it may be associated (p. 791, vol. ii.). On examination, a large irregular tumor, in some parts hard, in others soft, very tender to the touch, and occasioning a sickening sensation when pressed, will be found in one of the groins, in the situation of the inguinal canal. There are usually a tendency to vomiting and some constipation, with colicky pains in the abdomen. On examining the scrotum, it will be found that the testis on the affected side is absent; and, on passing the finger into the external ring, the organ can be felt to be lodged in the canal. In consequence of the proximity of the peritoneum to the inflamed testis, this membrane occasionally becomes involved in the morbid process; and, as the result of the constriction of the tendinous and aponeurotic tissues in this situation, sloughing has occasionally occurred. Either of these conditions may lead to a fatal termination.

The *Treatment* should be actively antiphlogistic. Leeches must be freely applied over the part; salines with antimony being at the same time administered, and fomentations diligently persevered in.

Inflammation and Abscess of the Cord.—In some cases the inflammation of the testis may extend, or the disease may, from the first, be limited to the areolar tissue of the cord, giving rise to tumefaction, with a good deal of pain and tenderness along it, and eventually abscess, accompanied by the usual signs of suppuration. The *Treatment* of such a case must be conducted on ordinary principles, early discharge for the pus being secured.

Chronic Orchitis of a persistent character constitutes a distinct disease of the testis, so closely allied to some forms of tumor of this organ in its character and pathology, that it will be more convenient to consider it with the *Sarcomas*.

HYDROCELE AND HEMATOCELE.

By **Hydrocele** is meant an accumulation of serous fluid, formed in connection with the testis or cord. Most frequently the fluid occupies the sac of the tunica vaginalis, constituting a true dropsy of it; in other instances, it appears to be formed in distinct cysts, situated either in connection with the testis, or upon the cord. Hence hydroceles are commonly divided into those that affect the *Tunica Vaginalis* and the *Encysted* variety.

HYDROCELE OF THE TUNICA VAGINALIS may occur as the result of acute orchitis; the inflammation of the testis causing the effusion of a quantity of fluid into its serous investment (p. 1102). This, however, is not the kind of hydrocele that is commonly met with; the fluid so poured out as the result of active inflammation becoming absorbed as the parts recover their normal condition. The ordinary hydrocele occurs as a chronic disease, without any signs of inflammation of the testicle, or, at most, with but slight tenderness of that organ. It is most frequently met with in individuals about the middle period of life, commonly without any evident exciting cause, either constitutional or local. It is very common in men who have lived long in warm climates, and Sir J. Fayer considers it in some cases to have a malarial origin.

In young infants, hydrocele is not unfrequently seen, and in them it may affect two forms: either the ordinary one, similar to that which occurs in adults in whom the tunica vaginalis constitutes a closed sac filled with fluid; or a less common variety, in which the accumulation of fluid in the tunica vaginalis communicates, by the persistence of a canal in the funicular prolongation of the peritoneum investing the cord, with the general cavity of that membrane. This form of hydrocele is *Congenital*; and the fluid in it occupies the same position that intestine does in a congenital hernia. It may readily be recognized by the fluid being made to flow back into the general peritoneal cavity, on raising or squeezing the tumor. But, although this may be considered to be the true congenital form of hydrocele in infants, the other variety of the disease also occurs in them when but a few days old, and very possibly even at the time of birth.

Symptoms.—The symptoms of hydrocele are tolerably evident. The disease begins with a degree of swelling and weight about the testis: the swelling may at first be soft, but after a while becomes hard and tense; or it may be so from the commencement. There is no impulse in it when the patient coughs. Whatever its original condition, the tumor soon becomes oval or pyriform in shape, being narrowed above, rounded and broad below: it is smooth and uniformly tense and hard; it usually fluctuates distinctly, but may have merely a semielastic feel. It reaches upwards along the cord, towards the external abdominal ring, which may in some rare cases be (Fig. 961) invaded by it, but the cord is usually distinctly to be felt above the upper margin of the tumor.

Most commonly the size varies from that of a hen's egg to a small cocoon; but sometimes it may attain a

Fig. 961.—Double Hydrocele Constricted Opposite External Abdominal Ring and this Simulating Inguinal Hernia.

considerably greater magnitude than this, and will then cause much inconvenience, as it reaches up close to the external ring, and drags over the penis, causing that organ to be buried in it, so as to interfere with micturition. Gibbon, the historian, had an enormous hydrocele, which was tapped by Cline, who drew off six quarts of fluid.

The most characteristic sign of hydrocele is its translucency by transmitted light. This may always be detected by the Surgeon grasping the posterior part of the tumor with one hand, so as to put the integuments of the forepart on the stretch, then placing the edge of the other hand along the most prominent part of the swelling, and having a lighted candle held close behind. On making this examination, the tumor will appear translucent; if, however, the walls of the sac be thick, or the fluid dark, the transmission of light through it may not be perceived unless the examination be conducted in a darkened room. Another very simple and efficient method of determining the translucency is by putting the end of a stethoscope against the tumor, and looking down the tube against the light. It must not be forgotten that in infants a hernia may be translucent on account of the thinness of the structures at that age.

We have already seen that the ordinary hydrocele of the tunica vaginalis may vary as to size: it may also differ as to shape; in some cases being globular, in others constricted in the middle, or of an hour-glass shape (Fig. 961).

The quantity of liquid varies considerably; there are usually from six to twelve or twenty ounces, but I have known a hydrocele to contain more than one hundred and twenty ounces. The fluid is generally clear and limpid, and of a straw-color; but in very large and old hydroceles it may become of a dark-brownish or chocolate hue, owing to the admixture of disintegrated blood; and it will then be found to contain flakes of cholesterine. The sac is usually thin; but in some old cases it becomes thick and dense, lined by a kind of false membrane, and divided by septa or bands, occasionally to such an extent as almost to separate it into distinct compartments. When the sac is thick, and the fluid opaque and turbid, there may be considerable difficulty in detecting the translucency.

The testis is often somewhat enlarged, especially about the epididymis, and frequently slightly tender, more particularly in the early stages of the complaint. It is almost invariably situated in the posterior part of the sac (Fig. 962), but may sometimes be found towards its anterior part. When this is the case, the epididymis will be found turned towards the front, owing to the organ being retroverted. If the hydrocele is of any size and tense, the testicle is lost in it. Its situation can then be recognized by some pain elicited by pressing on it, and by the opacity of the tumor at that point.

A peculiar form of hydrocele is occasionally met with which extends through the external abdominal ring forming a large tumor in the region of the inguinal canal, between which and the scrotal swelling fluctuation can be felt. There is in this form a distinct impulse on coughing. It occurs in those cases in which the processus vaginalis testis has been obliterated only at the internal abdominal ring, remaining patent below. Such cases are very rare and may resemble hernia, but they are easily distinguished by their translucency, their irreducibility, their absolute dulness on percussion, and their distinct fluctuation.

The *Coverings* of a hydrocele are the same as those of the testis. Besides the integumental structures, aponeurotic prolongations from the inter-columnar and cremasteric fasciæ may be traced over the surface of the swelling (Fig. 963).

Treatment.—The treatment of hydrocele is divided into the *Palliative* and *Curative*. By the *palliative* treatment the Surgeon seeks simply to relieve the patient of the annoyance induced by the bulk or weight of the tumor; but the *curative* has for its object the permanent removal of the disease.

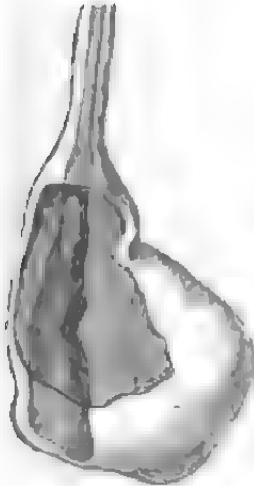

Fig. 962.—Hydrocele of the Tunica Vaginalis laid open.

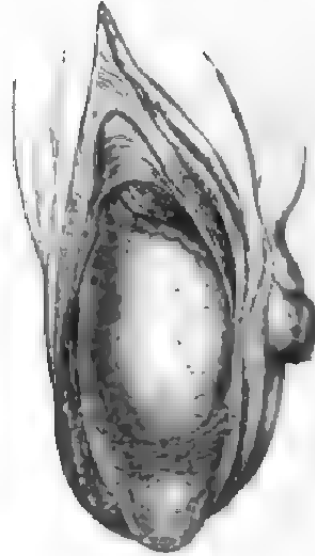

Fig. 963.—Dissection of a Hydrocele, showing its coverings.

The **Palliative Treatment** consists in the use of a suspensory bandage and cooling lotion, or in tapping with a fine trocar. These simple means, however, will sometimes succeed in effecting a radical cure. Thus, in infants it will happen that the application of evaporating and discutient lotions may remove the effused fluid; and indeed it is seldom that any other plan of treatment than this is required in young children. The best lotion for the purpose consists of one composed of \mathfrak{zj} of chloride of ammonium, \mathfrak{zj} of spirits of wine, and \mathfrak{zviij} of water; with this the scrotum should be kept constantly wetted; and, if there be a communication with the peritoneum, a truss should be kept applied over the external ring. In adults it occasionally happens that simple tapping of the tumor has effected a radical cure. Some years ago, a gentleman from Cuba consulted me for a small hydrocele which had been forming for several months; I tapped it with a fine trocar, and drew off about five ounces of fluid. This was followed by a radical cure. This case bears out a remark made by Brodie, that the few instances in which he had known simple tapping to produce a radical cure occurred in West Indians. I have, however, several times seen hydroceles disappear after having been tapped a few times, without any other treatment, in persons who had never been in hot climates. This simple operation is not altogether, however, destitute of danger; I have known an old man to die from inflammatory œdema of the scrotum after having been tapped, and tetanus also has followed this operation. After tapping, it usually happens that the hydrocele slowly forms again, attaining its former bulk at the end of about three months. Occasionally it will be found that the hydrocele returns more and more slowly after each tapping; so that by repeating this simple process at intervals of three, then six, then twelve months, the disease will finally

cavity should be obliterated by adhesions between its opposite sides, though these not unfrequently form. The means by which the Surgeon sets up this inflammation are either throwing a stimulating injection into that cavity after tapping it, or the introduction of a small seton into the tunica vaginalis. Whichever plan is adopted, a certain amount of inflammation ought to be set up. This is always attended by considerable swelling of the testis, and by the effusion of a fresh quantity of fluid into the tunica vaginalis. As this is absorbed, the part gradually resumes its normal bulk, and the disease will probably not return.

In order that the radical cure, in whichever way undertaken, should be safe and efficient, it is necessary, in the first instance, that the disease should have been allowed to attain a chronic condition, more particularly if the hydrocele have been of rapid growth. In order to prevent its attaining too large a size, it will be well to adopt palliative tapping once or twice before attempting the radical cure. Care must be taken to remove all inflammation and tenderness about the testis also, before having recourse to this means of treatment. If attention be not paid to this, recurrence of the hydrocele will probably ensue. After the proper amount of inflammation has been set up, it will be well to treat the patient as if he were suffering under an ordinary attack of orchitis, confining him to the bed or couch for a few days; indeed, care in the after-treatment is of very considerable importance in securing a favorable result.

The treatment by *Injection* is that which is commonly employed. It consists in tapping the tumor in the usual way, and then throwing a sufficient quantity of stimulating fluid into the tunica vaginalis through the canula, so as to excite a proper amount of inflammation in it. Port wine, or a solution of the sulphate of zinc of the strength of $\mathfrak{z}\text{j}$ to $\mathfrak{z}\text{xij}$, were formerly employed, but their use has been entirely abandoned since the introduction of iodine for the purpose.

Injection of Iodine.—The injection of tincture of iodine, originally introduced by Sir J. R. Martin, whilst practising at Calcutta, is now always preferred as a more certain and safer mode of treatment than any other. Many Surgeons prefer the liquor iodi to the tincture, believing it to be more certain in its effect. The quantity of tincture of iodine injected should vary from two drachms to half an ounce, according to the size of the tumor. It may be used pure or diluted with an equal quantity of water. After injection, the Surgeon should rub the scrotum gently over the testis, so as to diffuse the injection equally over the surface of the sac. One half the quantity thrown in should then be allowed to escape, the canula removed, and the puncture closed with a piece of plaster. The canula used for this purpose should be made of platinum and not of silver, which is apt to become corroded and made brittle by the action of the iodine. A good deal of inflammation, with fresh effusion into the sac, will usually be set up, on the subsidence of which a cure will be found to have been effected.

Useful as the iodine injection is, it sometimes fails in producing a radical cure of hydrocele. This is attributable to two causes: the first is, that in some cases sufficient inflammation is not set up to induce that condition of the tunica vaginalis which is necessary for a radical cure. It is well known that, when a hydrocele is radically cured by injection, it is so, not by any adhesion taking place between the two opposite surfaces of the tunica vaginalis and a consequent obliteration of its cavity, but by the inflammation that is artificially induced exciting such a modification of this membrane as to restore the balance between the secretion and absorption of the fluid by which it is naturally lubricated. Now, in some cases, sufficient inflammation is not induced by the introduction of the irritating fluid to restore the natural

balance between these two functions of the membrane; and the tunica vaginalis gradually fills again after the injection, as it would after the simple operation of tapping. It occasionally happens that the patient may suffer excruciating agony at the time of the injection, from the contact of the stimulating fluid with the surface of the testis, and yet little or no inflammation may be excited. The amount of suffering, therefore, at the time of the operation is by no means proportionate to the amount of consecutive inflammation which follows. Indeed, the reverse would appear to be the case in many instances; and I have often observed that, in those cases which progress most steadily to a radical cure, there is but a moderate amount of pain experienced at the time of the injection.

There is a second way in which injections would appear to fail; a considerable amount of inflammation is excited, and effusion takes place into the tunica vaginalis, which, in the course of three or four days, becomes distended to, or almost to, the same size that it had previously to the operation; but this effused fluid, instead of being absorbed by the end of the second or third week, remains unchanged in bulk, or absorption goes on to a certain point, and then seems to be arrested; the tunica vaginalis remaining distended with a certain quantity of fluid.

A third way in which the failure arises, is in consequence of the walls of the sac being so thickened that they cannot collapse.

The proportion of cases in which the iodine injection fails to bring about a radical cure of the hydrocele is variously estimated by different Surgeons. Thus, Sir J. R. Martin states that in India the failures scarcely amount to 1 per cent.; Velpeau calculates them at 3 per cent. I am not aware that any statistics of this mode of treatment in this country have been collected, but the general opinion of Surgeons would appear to be decidedly in its favor, as being the most successful as well as the safest plan of treatment that has yet been introduced. In this opinion I fully coincide; yet it is by no means improbable that the success of the iodine injection in this country would prove to be not quite so great as is generally believed. I have seen a considerable number of cases of simple hydrocele of the tunica vaginalis, both in hospital and in private practice, in which a radical cure had not been effected, although recourse had been had to the iodine injection by some of the most careful and skilful Surgeons of the day, as well as by myself. It is especially apt to fail in men advanced in years. In them there is either not sufficient inflammation excited, or, if it be, the fluid that is as a consequence effused into the tunica vaginalis is not reabsorbed.

Seton.—The cure by the introduction of a seton, though formerly much employed, is seldom practised at the present day, chiefly on account of the danger of exciting too much inflammation. It may, however, conveniently be employed in the true hydroceles of children, and in some of those cases in which the injection fails, if practised in the manner that will immediately be described. There can be no doubt that, as a first remedy, iodine injection is preferable to the seton, in the treatment of hydrocele; but when injection has failed, and this from no want of care on the part of the Surgeon, or of attention to the after-treatment of the case, but apparently from insufficient inflammation having been set up in the tunica vaginalis, the seton will, I think, be found to be the most certain means of accomplishing our object. It is true that several objections may be urged to the use of the seton; it requires much watching and care, and is occasionally apt to excite a dangerous amount of inflammation in the areolar tissue of the scrotum; and these objections are, to my mind, sufficiently valid to prevent our employing it as the ordinary treatment for the radical cure of hydrocele. But it must be remembered, that the particular cases to which I am now alluding are those

in which ordinary means have proved insufficient to excite proper action, and in which, consequently, it would appear as if a greater amount of irritation could safely be borne. Indeed, nothing is more remarkable than the difference in the intensity of the inflammation that is set up in different individuals by the means that are commonly employed in the treatment of hydrocele. In some cases the most irritating injections may be thrown into the tunica vaginalis, or a seton may be drawn through the scrotum and left there for days, not only without giving rise to any injurious inflammation, but without setting up sufficient to bring about a cure of the disease; whilst in other instances simple tapping may effect a radical cure, or may give rise to such an amount of irritation as to terminate in a fatal sloughing of the scrotum.

The seton that I employ in these cases is composed of one or two threads of dentist's silk. It may be introduced by means of a *navus* needle, the fluid of the hydrocele being allowed to drain away through the punctures thus made; or, far better, by tapping the hydrocele, and then passing a needle, about six inches long, armed with the seton, up the canula, drawing it through the upper part of the scrotum, and then removing the canula, cutting off the needle, and knotting the thread loosely (Fig. 96, vol. i.). The thread should not be removed until the scrotum swells and becomes red, with some tenderness of the testis and effusion into the tunica vaginalis. When these effects have been produced, it may be cut and withdrawn, and the case treated in the same way as when the radical cure has been attempted by iodine injection, viz., by rest and antiphlogistic treatment. The length of time during which the seton must be left in before sufficient, or even any inflammation is produced, varies very considerably. In most instances, the proper amount of inflammation is excited in from twenty-four to thirty hours; but in other cases the seton may be left in for ten or twelve days, giving rise to but little inflammation, although a radical cure may result.

The **Antiseptic Method** has been successfully applied to the treatment of hydrocele by Volkmann, and Reyher, of Dorpat. The sac is incised along its anterior aspect, and the fluid evacuated; the tunica vaginalis is then attached to the skin by a few points of suture, and the parts dressed antiseptically. This treatment is said to be more certain and less painful than that by the seton. It would be especially useful in old cases with thickened walls, in which the injection had failed.

Acupuncture.—Small hydroceles in elderly men may sometimes be dispersed by simple acupuncture, in an almost painless manner. The scrotum having been put upon the stretch, the hydrocele is punctured at two or three points with a large darning-needle, introduced slowly by being rotated between the finger and thumb. From the punctures thus made the serum slowly escapes into the cellular tissue of the scrotum, whence in two or three days it is absorbed.

This mode of treatment will be found also the safest and most effectual in the hydroceles of young children, in whom it would be extremely dangerous to attempt a cure by injection of iodine. It may always be safely employed if the application of the lotion before mentioned fails to cure the disease.

It is not always prudent to have recourse to the radical cure in the treatment of hydrocele. In persons advanced in years, or of feeble and unhealthy constitution, the inflammation excited in the tunica vaginalis by any of the means just detailed may run on to such an extent as to give rise to inflammatory oedema, and even sloughing of the scrotum, with great danger to life. In these subjects it is much safer and usually sufficient to temporize with the hydrocele, and only to tap as occasion arises from the increasing size of the swelling.

ENCYSTED HYDROCELE.—In this variety of the disease the fluid does not lie in the tunica vaginalis, but is contained in a cyst which projects from the surface of the epididymis or testis, and pushes the serous investment of the gland before it.

These cysts are much more frequently found connected with the epididymis than with the body of the testicle. Indeed, Curling has pointed out the fact, that small pedunculated cysts about the size of currants, and composed of a fine serous membrane, lined with tessellated epithelium, are very frequently found beneath the visceral tunica vaginalis covering the epididymis. They are delicate in structure, contain a clear limpid fluid, and are very liable to rupture. They are met with at all ages after that of puberty. According to Gosselin, after the age of forty, they occurred in at least two-thirds of the testes examined to ascertain their presence. Such cysts as these may remain stationary, of small size, undiscernible during life; they may rupture into the tunica vaginalis; or they may enlarge and become developed into tumors of considerable magnitude.

The fluid of these cysts possesses the remarkable characteristic, discovered by Liston, of containing spermatozoa (Fig. 965).

Fig. 965.—Spermatozoa from Encysted Hydrocele.

Though spermatozoa do not always exist in this fluid, yet they are usually met with, sometimes in small quantities, at others so abundantly as to give it a turbid or opalescent appearance. This admixture of spermatozoa with the clear fluid of the cyst is probably due, as pointed out by Curling, to the accidental rupture of a seminal duct into an already existing cyst. Spermatozoa have also, but very rarely, been found in the fluid of an ordinary hydrocele of the tunica vaginalis; and then probably their presence was due to the rupture of one of these cysts into the tunica vaginalis. Hence their presence in the fluid of hydrocele may in most cases be considered as characteristic of the encysted variety of the disease.

The *Signa* of encysted hydrocele differ in some respects from those presented by hydrocele of the tunica vaginalis.

The tumor is smaller, more irregular in shape, and does not envelop the testis completely, but is situated behind and above it, rather in connection with the epididymis.

The *Diagnosis* from ordinary hydrocele of the tunica vaginalis may be made by observing: 1. That the testis is below and in front, and not covered in by the encysted form of the disease; 2. That the tumor is more globular or irregular, and less pyriform; 3. When tapped, the fluid will usually be found to be opalescent.

The *Treatment* consists in injecting the sac with tincture of iodine, or in incising the tumor and allowing it to granulate from the bottom. The injection by iodine is not so frequently successful in this as in the last variety of the disease, but deserves a trial; if it fail, incision of the tumor will always effect a cure.

In encysted hydrocele, the iodine injection should not be so strong as that which is used for injecting the tunica vaginalis. It should be diluted with two or three parts of water, as it comes more directly into relation with the structure of the testis.

HYDROCELE OF THE CORD.—This disease is characterized by the presence of a round or oval tumor, situated on the cord, below or within the inguinal canal. It is smooth, elastic, and, if of sufficient size, may show semi-transparency on examination by transmitted light. It can be pushed up into the abdomen, unless the testicle be drawn firmly down so as to put the cord on the stretch, when the cyst becomes fixed. It receives no impulse on coughing, and does not alter in size on being steadily compressed. Occasionally more than one cyst may be met with. It appears to be due, in some cases, to imperfect closure at one or more points of the funicular portion of the tunica vaginalis, and to distention by fluid of the unclosed portions; though it is possible that in other instances it may arise as a distinct cystic growth. These tumors may occur at all ages, but are met with chiefly in the young, and are not unfrequent amongst children.

The fluid of a hydrocele of the cord is lighter in color than that of one of the tunica vaginalis.

Treatment.—The obliteration of the cyst is best conducted by passing a seton through it, or by making an incision into it, treating it antiseptically, and letting it granulate from the bottom.

DIFFUSED HYDROCELE OF THE SPERMATIC CORD consists in the infiltration of the cord with serous fluid, contained in rather distinct spaces, and giving rise to an oval or oblong irregular circumscribed tumor, extending below and into the inguinal canal.

The *Treatment* consists in the application of blisters, or of counter-irritant plasters. Should the disease prove very troublesome, an incision might be made down to and into the swelling, so as to let out the fluid and allow the cyst to become consolidated.

HÆMATOCELE.—By *Hæmatocele* is meant an accumulation of blood in the tunica vaginalis, distending that sac, and compressing the testis. It is of two kinds, *Traumatic* and *Spontaneous*. The *Traumatic* is the most common form of the disease, usually arising from a blow on or a squeeze of the testis, by which one of the veins ramifying on the surface of the gland is ruptured, and blood is poured into the tunica vaginalis. It may arise also in tapping a hydrocele, from the point of the trocar being pushed too directly backwards and puncturing the testis, or wounding a vessel in the cord. *Spontaneous Hæmatocele* is a disease of rare occurrence, arising apparently from the rupture of an enlarged spermatic vein into the tunica vaginalis. It attains a larger size, and is altogether a more formidable affection, than the traumatic hæmatocele.

Characters.—In whatever way occurring, a hæmatocele slowly but gradually increases in size until it attains about the magnitude of a duck's egg, or even that of a cocoanut. It is seldom that it becomes larger than this; but cases are recorded in which the tumor has attained an enormous magnitude. I once operated in a case in which a spontaneous hæmatocele had existed for six years; it was as large as a good sized melon, and contained, besides about a quart of dark thin blood, a handful of partially decolorized and tough fibrin, the greater portion of which was firmly adherent to the inside of the greatly thickened tunica vaginalis in filamentary and laminated masses, with here and there nodules interspersed. The whole of the interior of the tunica vaginalis closely resembled an aneurismal sac.

The fluid contained in the hæmatocele, when the disease is recent, consists of pure blood. The blood so effused will continue fluid for years; but at last it may decompose and set up fatal inflammatory mischief; in some rare instances the tumor becomes partly solidified by the deposit of masses of fibrous coagulum lining the interior of the tunica vaginalis, which are sometimes decolorized and arranged, as in the case just referred to and in one

recorded by Bowman, in a laminated manner, like the contents of an aneurismal sac. When the hæmatocele is of old standing, changes take place both in the effused blood and in the sac. The blood in old hæmatocele becomes at first dark and treacly. As chemical changes advance further it becomes converted into a dirty-brownish fluid, full of shreds of partially decolorized fibrin and crystals of cholesterine. The tunica vaginalis becomes thickened and indurated, and in exceptional cases may undergo calcification. This change I found in a patient whose disorganized testis I removed for a hæmatocele of nearly forty years' standing.

Symptoms.—These are generally sufficiently obvious. The occurrence of the tumor subsequently to a blow, strain, or injury when traumatic, its gradual increase in size, its somewhat heavy but semi-elastic or obscurely fluctuating feel, and the absence of translucency, form the most important signs. Its shape is somewhat uncertain. When recent it may have the pyriform shape of a hydrocele, but an old hæmatocele is always more or less oval or rounded in form and smooth on the surface, and thus comes closely to resemble a solid tumor. Except in very old cases, in which atrophy of the testicle from pressure has occurred, the peculiar "testicular sensation" will be perceived by the patient if the site of the gland is pressed upon.

Diagnosis.—Hæmatocele may be mistaken for hydrocele, hernia, and other scrotal swellings. The mode of distinguishing it will be described at the end of this chapter, with the diagnosis of scrotal tumors in general. It is most frequently confounded with solid tumors of the testicle; and upon this fact is founded the excellent rule of practice never to remove a doubtful tumor of the testis without first ascertaining, by an incision into its substance, that it is not a hæmatocele.

Treatment.—This must vary with the size and duration of the tumor. When it is small and recent, and has fluid contents, the Surgeon may try the effect of tapping it; it is possible that, after the evacuation of the blood, closure and obliteration of the tunica vaginalis will take place. This happened in a case under my care, in which, though the disease had existed for three years, a complete cure followed the operation of tapping. Such simple

treatment as this, however, cannot be depended upon; and it usually becomes necessary to lay the sac open, treat the wound antiseptically, and to cause it to contract and to granulate from the bottom, when the obliteration of the cavity of the tunica vaginalis necessarily results. If the tumor were of very large size, and the tunica vaginalis much thickened, hardened, and parchment-like, with adherent and laminated fibrin, castration might possibly be required. In the instance to which I have already referred, and which is represented in Fig. 966, this was rendered necessary in consequence of these conditions, and was successfully done.

Fig. 966. — Hæmatocele with Thickened Tunica Vaginalis and adherent Fibrin.

denly arising after a strain or some violent exertion, giving rise to rupture of a varicose spermatic vein. It commences in the inguinal canal, and thence extends downwards along the course of the cord, through the abdominal ring into the scrotum; but it does not surround or implicate the testis, which can be felt free and movable at its lowest part. On incising such a tumor as this, a quantity of blood, partly fluid and partly conglobated, has been found, some-

Hæmatocele of the Spermatic Cord has been observed by Pott, Curling, Bowman, and others; it is a rare disease, and usually occurs in the form of a tumor of considerable magnitude, sud-

times contained in a cavity, occasioned by the laceration and separation of the tissues of the cord and scrotum. The most remarkable case of this kind on record is one related by Bowman, in which the tumor, after existing for ten years, had attained so enormous a size, that it reached to the patella, and was so heavy as to require both hands and a considerable effort to raise it from its bed. In this case, death appears to have resulted from decomposition of the contents of the tumor.

Diagnosis.—In its early stages, hæmatocele of the cord would run considerable risk of being confounded with an *inguinal hernia*. The more diffused character of the swelling, however, its regular feel, its semi-fluctuating sensation, and the impossibility of reduction, might enable the diagnosis to be made (p. 787, vol. ii.). Hæmatocele of the cord may always be distinguished from an accumulation of blood in the *tunica vaginalis*, by the testicle not being implicated in the former case, but surrounded by the fluid in the latter instance.

The *Treatment* of this disease must in the earlier stages be of a palliative kind; consisting in rest, support of the tumor, and the application of evaporating lotions. Care should be taken not to incise it at this period, lest the loss of blood from the ruptured vein, after the evacuation of the contents of the tumor, become uncontrollable. In one instance I have known fatal consequences from this cause to ensue in half an hour after making an incision into the tumor and turning out the coagula. When, however, the disease has reached a chronic stage, and is no longer increasing, it may be incised; and, its contents being turned out, the cavity may be allowed to suppurate and granulate.

VARICOCELE.

Varix, or *Enlargement of the Spermatic Veins*, is a disease that is commonly met with from the age of puberty to about the thirtieth year, seldom commencing later than this. It usually occurs in feeble individuals having the scrotum lax and pendulous; and in some cases appears to have been brought on by venereal excesses. The spermatic veins, extending as they do from opposite the lumbar vertebræ to the plexus pampiniformis, which constitutes the base of the pyramidal tumor formed by a fully developed varicocele, are necessarily subject to considerable tension from the weight of so long a column of blood as that contained within them, to which they eventually yield, becoming much dilated and tortuous. The left spermatic veins are far more frequently affected than the right; owing partly to their compression by feculent accumulations in the sigmoid flexure of the colon, and possibly in part to the obstacle at the mouth, occasioned by their pouring their contents into the left renal vein, at right angles to the current of blood flowing through that vessel into the vena cava. The right spermatic veins are rarely affected; and never, I believe, without those on the left side participating in the disease. In these cases of double varicocele, the left is almost invariably the more seriously affected; but I have seen exceptions to this in one or two instances, in which the veins on the right side formed the larger tumor.

SYMPTOMS.—The symptoms of varicocele consist of a tumor of pyramidal shape, having a soft knotted or knobbed feel, owing to the irregularly swollen and convoluted condition of the veins, with its base upon the testis and the apex stretching up to the external ring. The swelling increases when the patient stands up, if he take a deep inspiration, cough, or make any violent exertion. Its size varies from slight fulness of the veins to a large mass, several inches in circumference at the base. When the patient lies down, it goes up to a certain extent, but immediately returns to its former magnitude

when he stands up. It is attended by a sensation of weight and sometimes of pain, which is occasionally very acute, of a severe and neuralgic character, even in the scrotum, the groins, and the loins, more particularly when the tumor is unsupported. This pain is greatly increased on the patient walking or riding; so much so, that in some cases he is almost debarred from taking necessary exercise, and is prevented from following any active occupation. Debility of the generative organs, with a tendency to seminal emissions and much mental depression, frequently accompanies varicocele. Atrophy of the testicle is sometimes found associated with varicocele, and is believed to be dependent upon it. The rupture of a varicocele may occur from external injury, giving rise to an enormous extravasation of blood into the areolar tissue of the scrotum. Of this Pott relates a case. I have known the accident to be attended with fatal consequences. A man who, to use his own expression, "had been romping with his wife," received a blow on a varicocele, when an enormous extravasation of blood rapidly formed in the scrotum and the cord, for which he was admitted into the Hospital. The tumor was incised, and, large masses of coagula were turned out. The patient shortly after, in the absence of assistance, suddenly became faint and died of venous hemorrhage. The bleeding was found to have proceeded from a ruptured spermatic vein.

DIAGNOSIS.—The diagnosis of varicocele is always sufficiently easy: its peculiar convoluted feel, its broad base and narrow apex, the manner in which it goes up when the patient lies down, and returns again when he stands up, are sufficient to distinguish it from all other scrotal tumors. From *inguinal hernia* the disease may be distinguished by attention to the test described at p. 787, vol. ii.

TREATMENT.—The treatment of varicocele must be conducted with reference to the severity of the symptoms occasioned by it, and to the extent of the disease. When, as is usually the case, it gives rise to but slight inconvenience, palliative treatment is fully sufficient; but if, as occasionally happens, the disease be a source of very intense suffering, or tend to the induction of atrophy of the testis, or to generative debility, with much mental disquietude or hypochondriasis, then the Surgeon may feel disposed to endeavor to cure the varicocele radically.

The *Palliative Treatment* of varicocele resolves itself into means of various kinds, having for their object the support of the testis and the diminution of the length, and of the consequent pressure, of the column of blood. This is usually most conveniently done by supporting the scrotum in a well-made suspensory bandage; or pressure may be made upon the part, as well as support given, by enclosing the testis in an elastic bag. In other cases, support may be afforded by drawing the lower portion of the scrotum on the affected side through a ring made of soft metal, covered with leather, or, better still, through a small vulcanized India-rubber ring, so as to shorten the cord. And, with the same object, excision of the lower portion of the scrotum has been recommended; so that, by the contraction of the cicatrix, the testis may be pressed up against the ring, and the cord thus shortened. This plan, however, is somewhat severe; and though it might be attended by temporary benefit, the advantage accruing is not likely to be very continuous. The pressure of the pad of a truss on the spermatic cord, as it issues from the external ring, will break the length of the column of blood in its veins, and might thus be of service. But many patients cannot bear the irksome pressure of the instrument; moreover, it must also be remembered that it will at the same time obstruct the return of blood, and consequently in all probability do as much harm as good.

In addition to these mechanical means, the part may be braced by cold

douching, sea-bathing, and the general strength improved by the administration of iron.

The Radical Cure of Varicocele consists in the obliteration of the enlarged veins, on the same principle that guides us in the management of varix in other situations.

The circumstances for which operation may be and has been practised in this disease can be arranged in the following categories.

1. When the existence of a varicocele disqualifies the sufferer from admission into the public services, there is, in my opinion, a perfectly legitimate reason for operating. One of the cases in which I have effected a radical cure was that of a man in the prime of life, who, wishing to enlist in the Marines, was refused solely on the ground of having a small varicocele. This I cured by operation, and the man afterwards entered the service.

2. In some cases, the presence of a varicocele of inordinate size causes a distressing sense of weight and pain in the loins and groins, and often inability to stand or walk for any length of time. Here, when the patient is in continual discomfort, or more or less prevented from pursuing his ordinary avocations—in fact, quite crippled—it is perfectly justifiable to resort to operation.

3. When atrophy of the testicle is a consequence of the pressure of the blood in the veins, an operation may be performed.

4. Cases not uncommonly occur where the pressure of the enlarged veins on the spermatic nerves produces repeated attacks of spermatorrhœa. These cases are, however, more frequently met with out of hospitals, than in individuals of the class who apply to such institutions for relief. In fact, young men of the more highly educated classes are very subject to varicocele, especially those who habitually lead a sedentary and studious life, as, for instance, young clergymen and lawyers. In these persons a peculiarly hypochondriacal state is brought on by the tendency of the mind to dwell on the condition of the genital organs, and the patient is constantly fidgeting about the local and tangible disease he observes in them.

The radical cure of this condition may be produced by exciting inflammatory thrombosis of the spermatic veins, through an application of the same principle which sets up that process in the veins of the lower extremity. There are several different ways of doing this; some are very objectionable. The twisted suture, as applied to the veins of the leg, induces too great irritation in the scrotum, and there its introduction is often followed by violent inflammation or sloughing, or by an opening up of the areolar tissue of the scrotum with œdema, and even purulent infiltration. It is better, I think, not to use this method here; indeed, I have twice, in the practice of others, seen it followed by death. The plan I have adopted for some years is that suggested and practised by Vidal de Cussis, and is as follows: The vas deferens, readily distinguished by its round cord-like feel, is first separated

Fig. 967.—Iron Pin for Treatment of Varicocele.

from the veins, and intrusted to an assistant; next, an iron pin bored with a hole at each end (Fig. 967), is passed between the vas and the veins, and brought out at the point of perforation, the scrotum being first notched with a scalpel; then a silver wire, threaded on a needle so constructed that the wire shall follow it without catching (Fig. 968), is passed in at the aperture of entry of the pin, and carried between the integument of the scrotum and the veins, the wire being brought out at the second puncture (Fig. 969). Each

end of the wire is now passed through the corresponding hole of the pin, which is twisted round and round repeatedly, each turn causing the wire to be rolled around the pin, and so tightened, till the veins are firmly compressed between the pin behind and the loop of wire in front (Fig. 970). By this

Fig. 968.—Split Needle threaded with Silver Wire.

means the scrotum is quite free and uncompressed, and there is no danger of exciting inflammation or oedema. The wire should be tightened from day to day, as it causes ulceration in the veins until it has completely cut through, which results, usually, in about a week or ten days. Meanwhile, there is

Fig. 969.—Vidal's Operation for Varicocele. Needles and Wire applied.

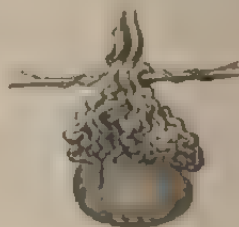

Fig. 970.—Wire twisted and Veins rolled up.

much inflammation around the veins; this finally contracts and obliterates their channels. This method produces an effectual and permanent cure (Fig. 971).

Of late, I have been in the habit of employing a simpler method. I separate the vas deferens in the usual way, and then make a small incision, about

Fig. 971.—Vidal's Operation. Appearance of Needle and Wire when removed.

half an inch long, in the front and back of the scrotum; afterwards I pass a needle armed with silver wire, as before described, between the vas and the veins, bringing it out behind; I then return the needle, but this time carrying it in front, between the veins and the skin; and thus the veins are included in a loop of wire, without implicating the scrotum. The loop is then tightly twisted together, so as to constrict the enclosed vessels. This plan has a similar effect to that of the wire and pin combined; by repeated tightnings the wire gradually effects a passage by ulceration through the veins, which are obliterated by the same process.

It has been objected to this and similar operations, that atrophy of the testis may take place, from the spermatic artery being included together with the veins. Experience shows that there is no risk of this. Even if the spermatic artery were obliterated, the artery of the vas deferens, the cremasteric, and other branches, would enlarge and take its place. In most cases,

however, it probably escapes, being held out of the way with the vas deferens, but observations on the dead body show that this is not always the case.

Since the introduction of the antiseptic treatment of wounds the risk of pyæmia following ligature of a vein is so completely abolished that the operation of exposing the enlarged veins and tying them may be safely undertaken. It is thus performed. A small incision, one inch in length, is made over the spermatic cord, commencing about one inch below the external abdominal ring. The skin and superficial fascia are then dissected carefully through, until the cord is exposed. An assistant then grasps the cord immediately above and below the incision, and squeezes it forwards till it projects from the wound. The veins are then isolated, and a double ligature of carbolized catgut or silk is passed under each by means of an aneurism-needle. The veins are then divided between the ligatures, which are cut short, and dropped into the wound. If the incision is made high enough up, two or three veins at most will require ligature. The wound is then closed, a small drain being laid in its lower angle, and an antiseptic dressing is applied. It is dressed at the end of twenty-four to forty-eight hours, and the drain removed. At the second dressing, which should be at the end of a week, the small wound will usually be found to have united by the first intention. The operation has the great advantage of causing no pain during the after-treatment, and it is certainly as safe as any other. It has been repeatedly performed in University College Hospital with the best results. Pearce Gould has also operated successfully on a considerable number of cases, by dividing the veins with a galvanic cautery, the wire being passed round them from a small puncture in the skin.

SOLID ENLARGEMENTS OF THE TESTIS.

All tumors of the testicle were formerly classed together under the generic term of *Sarcocoele*; and when they were conjoined with fluid accumulations in the tunica vaginalis, they were termed *Hydro-sarcocoele*. The term is of little use; but so long as it is understood that it means no more than a solid enlargement of the testicle, there is no harm in using it. Solid enlargements of the testicle may be divided into the *Simple*, the *Syphilitic*, the *Tubercular*, and the true *Tumors of the Testicle*.

CHRONIC ORCHITIS.—SIMPLE SARCOCELE is a chronic enlargement of the testis resulting from inflammatory mischief in the organ, not arising from syphilis or deposit of tubercle. It is, in fact, chronic orchitis. Both the epididymis and the body of the gland are usually affected. The testicle feels hard, smooth, solid, though perhaps slightly elastic at points: it is ovoid in shape, and usually about as large as a duck's egg. It is heavy and but slightly painful, and, except in very old cases, the peculiar sensation felt on squeezing a testicle is present. The cord is usually somewhat thickened, and, as well as the groin, is the seat of pain of a dragging character. The tunica vaginalis occasionally contains serous fluid lying in front of and obscuring the testis. The scrotum is always healthy, and usually one testicle only is affected. Occasionally simple chronic inflammation may slowly give rise to suppuration, and one or more abscesses may form, especially in strumous subjects. In these circumstances, a part of the indurated testicle softens and becomes prominent, the skin becomes red, shining and thinned, and adhesions form between it and the gland beneath. At last the abscess bursts and a fistulous opening is left. Through this aperture a fungus (hernia testis, or benign fungus of the testicle) speedily protrudes, which grows sometimes slowly, sometimes rapidly, perhaps attaining a very considerable size (Fig. 972). As the fungus increases, the organ

appears to atrophy, but in reality is pressed out of the scrotum and into the fungus. This fungus is not a new growth, but is composed of tubuli testis and inflammatory products. It is in the form of a pale red yellow granular mass.

Fig 972. — Hernia Testis.
Benign Fungus of the
Testicle

If small and firm, it may become a very discomfiant; but if large, rapidly growing, and textured, it speedily destroys the secreting structure of the testis, leaving nothing but a thick epididymis and a contracted and shrunken albuginea. It is, however, surprising how the functions of this organ will continue, though the tissue is in a great measure destroyed and its structure traversed by suppurating fistulae. In cases no fungus appears but a fistulous track is left, leading to an imperfectly drained abscess surrounded by indurated tissue, and this may remain unhealed for months or even years. Occasionally, instead of bursting and giving rise to a fungus, the abscess may become surrounded by dense fibroid tissue and remain stationary, as a dense wall has been known to entirely enclose it.

Simple chronic orchitis can usually be due to a blow, squeeze, or other injury, in which inflammation has been excited in the

Structure.—On making a section of a testicle affected with simple inflammation, the tunica vaginalis will be found to be more or less inflamed and perhaps separated from the tunica albuginea in parts by small accumulations of fluid. The tunica albuginea is thickened, often presenting on its external surface a series of firm, glistening layers. The septa of the testis are seen to be thickened, rendering the whole organ hard and giving it a bluish-gray appearance. In the midst of this, soft opaque spots may be seen. These have been mistaken for tubercles, but are in fact masses of chronic inflammatory products that have undergone fatty degeneration. The microscope shows that the chronic inflammation chiefly affects the intertubular fibrous tissue, but in many cases this is accompanied by a **catharrhal overgrowth of the epithelium.**

Prognosis.—Simple chronic orchitis usually terminates in recovery, though the organ may be left somewhat enlarged and indurated, or in other cases it may undergo atrophy as the inflammatory products become absorbed.

Treatment.—Strapping and the administration of an alterative such as perchloride of mercury may be tried. If the organ does not diminish in size by these means, or if it be a source of much inconvenience to the patient, it must be removed. If accompanied by hydrocele, the tunica vaginalis may be tapped, but on no account should injection of iodine be resorted to, as abscesses form, they must be opened. When a fungus has protruded through one of the fistulous apertures, means must be taken to repress or remove it, lest it go on to complete destruction of the testis. If it be of small size, the best plan will be to sprinkle it with red oxide of mercury, and to press it tightly down with a piece of lint and strapping. If it be larger, it may be shaved off, and the cut surface then dressed with the ointment of red oxide of mercury; care being taken during cicatrization to repress the scrotal folds below the level of the surrounding integument by steady pressure. Syme has recommended that the pressure should be exerted on the integument of the part; an elliptical incision being made round the fungus and the edges of the opening in the skin through which it protruded pared away, the scrotal integuments are freely separated by dissection

their subjacent connections, and brought together over the protruding mass and secured by sutures. This operation I have practised with success. Should the fungus be of very large size, so as to include within itself the whole or greater part of the structure of the testis, it may not be possible to save any of that organ; and in these circumstances it is better to remove the whole gland; if left, it could never be of any service, and would continue slowly to suppurate.

TUBERCULAR TESTICLE, SCROFULOUS TESTICLE, OR TUBERCULAR SARCOCELE.—This disease, although occasionally met with in individuals apparently strong and healthy, usually occurs in those of a febrile or cachectic constitution, most frequently in early manhood; and, although commonly associated with phthisis, may occur without any evidence of tubercle in other organs. It is very common to find both glands affected, but the disease is usually more advanced in one than in the other. In some cases it arises apparently as a sequence of gonorrhoeal epididymitis, or there may be a history of some injury to the testicle. The disease almost invariably commences in the epididymis, either at the globus major or minor, which becomes swollen, indurated, and slightly tender. As it progresses, it spreads upwards along the vas deferens until it may reach the prostate and vesiculæ seminales, and forwards through the corpus Highmorianum into the body of the testis. In some rare cases, it is said to commence in the body of the gland. The progress of the disease is usually slow, but it may go on rapidly to almost complete destruction of the testis. In a well-marked case the following conditions will be found: The testicle is moderately enlarged, but on examination this enlargement will be found to be chiefly in the epididymis, which can be felt as an irregular, craggy, nodulated mass, half surrounding the body of the gland in the form of a crescent situated at its posterior aspect (Fig. 973). In the hard mass, which often considerably exceeds the body of the gland in bulk, spots of softening may be felt. The gland itself may seem soft and natural, or a nodule or two may be felt in its substance. The affection is scarcely ever complicated by hydrocele, and in the earlier stages the scrotum is unaffected. The spermatic cord will usually present no general thickening, but the vas deferens is enlarged. Instead of feeling like a piece of whipcord between the fingers, it may be as large as a quill. If the disease have extended to the vesiculæ seminales, these can be felt enlarged and hardened by introducing the finger into the rectum. There is little or no pain, and on squeezing the gland the ordinary sensations will be perceived by the patient except in a very advanced stage of the disease. As the disease advances, one of the craggy nodules softens, and the skin becomes adherent over it. This process is accompanied by more acute inflammation, usually causing marked increase of pain and tenderness. The adherent skin becomes red and shining, and finally gives way, and the tuberculous abscess discharges, leaving an unhealthy cavity yielding thin pus mixed with soft, shreddy, whitish-yellow sloughs. In some favorable cases the cavity may granulate and close completely, or leave merely a fistulous opening discharging small quantities of serous fluid. In most cases, however, the process of softening extends, other nodules break down, and a great part of the testicle may be destroyed. If an abscess should form in the body of the gland, a hernia or

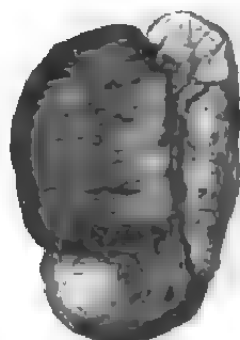

Fig. 973.—Tubercular Testicle, showing the diseased Epididymis forming a crescentic mass partially surrounding the healthy body.

fungus testis may follow, as in simple chronic orchitis. Occasionally exuberant granulations may sprout out from the region of the epididymis, closely resembling the true fungus testis. The general health suffers greatly, and at a comparatively early stage of the case tubercular disease of the lungs is almost certain to make its appearance. In the great majority of cases, the opposite testicle also becomes affected. Death usually results from the disease of the lungs, but may occur from acute general tuberculosis with tubercular meningitis. Occasionally the disease may extend to the urinary tract, and terminate fatally from tubercular disease of the kidneys.

In some cases of phthisis, in which the testicles enlarge, and yet give but little trouble, the whole organ, both body and epididymis, may be found converted into a uniform, soft, cheesy mass. A specimen of two such testicles, from a patient who died from disease of the lungs, is in the Museum of University College. In cases of acute general tuberculosis, gray granulations have been found in the testicles.

Structure.—On making a section from before backwards through a typical specimen of tubercular disease of the testicle, the following conditions will be found. The tunica vaginalis may be perfectly healthy, or may be here and there adherent to the tunica albuginea. The tunica albuginea will be normal in appearance, except in the immediate neighborhood of a tubercular growth, where it will be thickened. That part of the body of the gland nearest the surface may be perfectly healthy in appearance, there is no thickening of the septa, and the tubules can be teased out under water as in a healthy testicle. As we approach the corpus Highmorianum, the gland becomes studded with small, hard nodules, not growing in the septa, but in the glandular substance of the testis. In their earliest stage these are merely hard, semi-transparent granulations; but they soon show signs of undergoing fatty degeneration in the centre, so that the majority have the appearance of small bodies about the size of a millet-seed, having a yellow, opaque centre, and a delicate, grayish, semi-transparent, growing margin. Still nearer the corpus Highmorianum these yellow spots coalesce, and form a solid, cheesy substance, continuous with a still larger mass of the same kind, which represents the epididymis, and half surrounds the body of the gland in the shape of a crescent. In this larger mass, patches of softening are found forming the tubercular abscesses above described, and these may extend into the body of the gland. On making transverse sections of the vas deferens, its walls will be seen to be thickened, and its centre filled up with a yellow, cheesy material. If the disease be further advanced, the whole gland may be converted into a single cheesy mass, in which softening may be taking place at various parts.

The exact nature of the change that takes place in the production of the condition above described, has given rise to much difference of opinion; some authors maintaining that the primary change consists in an overgrowth of the epithelium of the tubuli seminiferi and epididymis, which afterwards undergoes fatty degeneration; and others asserting that the primary growth takes place between the tubuli, and that the changes in the epithelium are secondary.

The accompanying drawing (Fig. 974) represents a section of one of the small outlying nodules in the body of the gland, as described above. It will be seen that the change consists chiefly in an accumulation of small round cells in a more or less perfect reticulate stroma between the tubules, separating them from each other. At the same time the walls of the tubules have undergone a change, being infiltrated with cells in the same way as the surrounding parts. The tubules also are choked with epithelium, which in some parts of the same testicle was found to be undergoing fatty degeneration.

Towards the centre of the nodule the intertubular growth also becomes caseous. Scattered through the new growth are many large masses of protoplasm containing many nuclei, the so-called giant-cells. It is most probable, therefore, that the change commences in the lymphatic tissue in the walls of the duct of the epididymis and between the tubuli seminiferi, and gives rise to secondary proliferation of the epithelium; both the intertubular growth and the proliferated epithelium afterwards undergoing fatty degeneration, and forming cheesy masses.

Prognosis.—The prognosis of tubercular disease of the testis is extremely bad. Treatment is of little if any avail, and the patient almost invariably

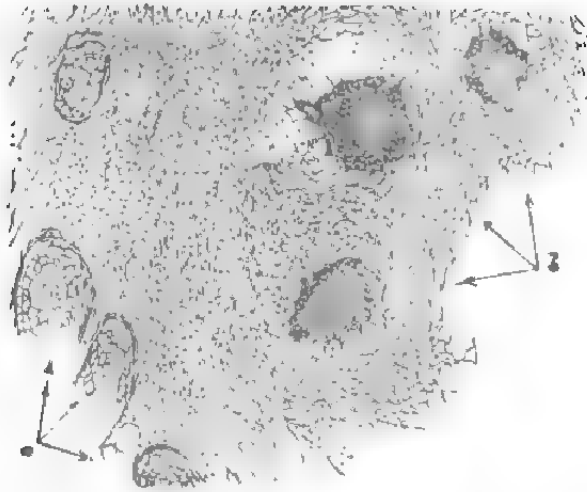

Fig. 974.—Tubercular Testis. a. Tubuli seminiferi; b. Giant-cells (40 diam.).

dies sooner or later of disease of the lungs, from general acute tuberculosis, or from extension of the disease to the bladder, prostate, and even, in rare cases, the kidneys. In some cases, however, after the abscesses have burst, the cavities may heal, and the testicle remain withered, but free from active disease.

Treatment.—The more I see of this disease the more convinced I am that the sooner the diseased organ is removed the better will be the patient's chance of prolongation of life. The danger of infection of the system by acute tuberculosis from a tubercular testis is so great that when once the diagnosis has been made, castration should not be delayed. In most cases, however, the operation is at best calculated to give the patient only temporary relief, as the disease usually extends along the vas deferens beyond the reach of the knife, and will continue to progress in the vesiculæ seminales and prostate, unless the patient succumb early from tubercular disease of the lungs or brain. Before undertaking it, the urine must be examined for pus, and the state of the prostate and vesiculæ seminales ascertained from the rectum, as the operation would, of course, be useless if the affection of the testicle were merely a part of tuberculosis of the whole genito-urinary tract. Should the patient decline to submit to the operation, or his health be so bad that its performance is not advisable, the treatment must be conducted on general principles; alteratives, tonics, especially the iodide of iron, with cod-liver oil, and general hygienic means calculated to improve the health, must be steadily persevered with. Local applications are of little avail.

The abscesses must be opened when they form. The cavity should be thoroughly scraped out with a sharp spoon and dressed with iodoform. Under this treatment it sometimes heals rapidly, but the cure is rarely permanent. If fungus form, it is of little use to try to treat it by the methods before described. If the body of the testis be deeply infiltrated with tubercle, no good could result.

SYPHILITIC ORCHITIS, SYPHILITIC SARCOCELE.—Syphilitic disease of the testicle appears under two forms, a simple inflammatory and a gummata. The latter was formerly confounded with tubercle, under the name of tuberculo-syphilitic sarcocele. The error arose before the exact nature of the syphilitic gumma was understood. Syphilitic orchitis of both forms may occur either as the result of inherited syphilis in infants or of acquired syphilis in adults. It is usually one of the later manifestations of the disease.

The Simple Inflammatory Form, which has been accurately described by Virchow, consists essentially of a chronic inflammatory overgrowth of the connective tissue between the tubuli seminiferi. The disease may uniformly affect the whole gland or be limited to localized patches. If the whole gland be affected, the organ slowly enlarges to perhaps more than double its natural size. The enlargement will be found to affect the body of the gland, the epididymis undergoing but little if any change. In fact, it may be so far concealed by the thickening round it as to be scarcely recognizable. The cord and vas deferens are unaffected. The body of the gland feels hard, almost cartilaginous, and the surface is smooth or perhaps slightly irregular. There is no pain, except a dragging sensation in the groin due to the increased weight of the testicle. There is little or no tenderness, and in the more advanced stages the peculiar sensation caused by squeezing a healthy testicle is absent. There is no tendency to softening or to the formation of abscess. The disease is almost always accompanied by hydrocele, but at the same time adhesions may exist at various parts between the parietal and visceral layers of the tunica vaginalis, dividing the fluid into two or more portions, or limiting it to a small part of the surface of the testicle. Most commonly only one testicle is affected, but both may be attacked. In the localized form the induration is limited to one or more portions of the gland, the remainder being soft and healthy.

Structure.—On making a section from before backwards, the following appearances are found. If hydrocele exist, the tunica vaginalis will be opaque and thickened, and probably adherent at various points to the surface of the testicle. If no hydrocele be present, the tunica vaginalis may be uniformly adherent. The tunica albuginea will always be found greatly and irregularly thickened, and from it proceed opaque white dense fibroid processes into the substance of the gland. These may in extreme cases be so abundant that no healthy gland-substance can be seen between them; in less severe cases, patches of healthy tubular substance are found at various parts of the organ. A process of cicatricial contraction taking place in these fibroid processes may lead to a dimpling of the surface of the organ. The microscope shows that the change is due to an inflammatory small rounded growth, which afterwards undergoes a development into a dense fibroid tissue, situated in the connective tissue between the tubuli seminiferi (Fig. 976). The new growth separates and presses on the tubules, and may cause their destruction in large areas.

The Gummata Form is an aggravation of that just described, and presents the same symptoms, with the addition of those caused by the presence of the gummata. These form hard craggy nodules on the surface of the gland, the irregularities so produced being much greater than those arising

from simple fibroid induration. The gummata have little tendency to soften, and discharge externally; yet in rare cases they may do so.

Structure.—On making a section of a gland in this condition, more or less of the fibroid induration, above described, will always be found combined with thickening of the tunics of the testicle. The gummata vary in size, from a pea to a hazel-nut. They are of an opaque yellow color, irregular

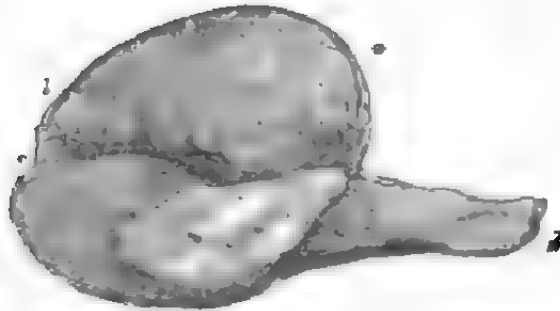

Fig. 975.—Syphilitic Gummata of the Testis. *a, b.* Gummata cut across; *c.* Section of Globus minor; and *d.* Cord.

shape, and dense leathery hardness. They may be tolerably sharply circumscribed to the naked eye, but are usually surrounded by a zone of fibrous induration of an opaque white color. The microscope shows around them the same small-celled growth above described, situated between the tubules. Nearer the centre the tubules are found to be pressed upon and destroyed, and the cells of the new growth commence to undergo degeneration; until in the

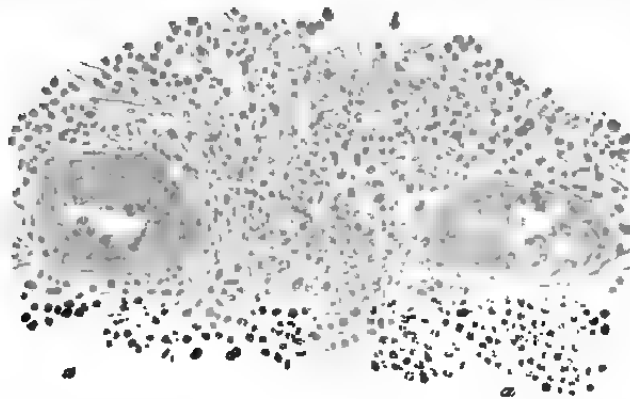

Fig. 976.—Syphilitic Testis. *a.* Tubuli Seminiferi; *b.* A part of the round-celled growth beginning to undergo fatty degeneration (1-8 diam.).

yellow part of the gumma, nothing but granular debris is to be recognized. The gummata may be distinguished from tubercle by their greater toughness and more opaque yellow color. Tubercle is rarely limited to the body of the testes; gummata, on the other hand, rarely affect the epididymis.

Prognosis.—If the disease be recognized and treated early, complete recovery may be confidently hoped for; although relapses are of frequent occurrence. In the more advanced stages, the prognosis is not so hopeful,

for, although under proper treatment the new growth may be absorbed, the gland will remain shrunken, puckered, and indurated. This is but what would be expected; as the tubuli seminiferi, as above stated, become more or less extensively destroyed by the pressure of the new growth in the later stages of the disease.

The *Treatment* is that laid down in Chapter XXXVI. for constitutional syphilis. Locally, the hydrocele may be tapped (but on no account injected), and pressure may be applied, by strapping over some mercurial ointment.

Diagnosis of the Simple, Tubercular, and Syphilitic Sarcocoeles. The diagnosis of these affections is in some cases easy, in others very difficult. Whatever the form of disease may be, if it be complicated by hydrocele, this must first be tapped in order that the gland may be accurately examined. The hydrocele in these cases may not be translucent, as the tunica vaginalis is often thickened. It must be remembered that hydrocele is a very rare complication of cancer, or of cystic sarcoma; it is rare with tubercular sarcocoele; less rare with simple chronic orchitis, and very common with syphilitic disease. From hæmatocoele and tumors, the diagnosis may be made by attention to the rules laid down on p. 1132. It having been determined that the swelling is due to one of the three above-mentioned causes, it remains to ascertain which it is. This may be done by attention to the following points. The cord is often thickened and tender in simple chronic orchitis; in tubercular sarcocoele, the vas deferens alone is affected, being frequently considerably enlarged; in syphilis the cord is perfectly healthy. In simple chronic orchitis, the epididymis may be swollen, but the chief enlargement is in the body; in tubercular disease, the epididymis is almost always the starting point of the disease, and is enlarged more than the body; in syphilitic sarcocoele, the body is first and almost exclusively affected. In chronic orchitis, the enlargement is usually uniform and smooth, and fluctuation is rarely present; in tubercular sarcocoele, the enlarged epididymis is craggy and nodular, and spots of softening may be felt; in syphilitic sarcocoele, the body of the gland is greatly indurated, often noduleated, and softening is very rare. The testicle is usually painful and tender in chronic orchitis; in tubercular sarcocoele it is sometimes tender, seldom painful; in syphilitic disease, it is almost invariably perfectly painless, and free from tenderness. The constitutional condition of the patient should also be carefully inquired into. Chronic orchitis usually arises as a sequence of injury, or perhaps gonorrhœa, in patients possibly strumous, gouty, or rheumatic; tubercular disease occurs almost always in cachectic subjects, with a tubercular history and a tendency to phthisis. The lungs should therefore be carefully examined. In syphilitic sarcocoele, the ordinary symptoms of constitutional syphilis may be present, or a syphilitic history may be obtained. In tubercular sarcocoele, the vesiculæ seminales may often be felt to be enlarged through the rectum.

CYSTIC DISEASE OF THE TESTIS, OR CYSTIC SARCOMA OF THE TESTIS, OR CYSTIC SARCOCELE.—In this disease the testis becomes enlarged, indurated, of a yellowish-white opaque appearance, and studded with a multitude of cysts, that vary in size from a pin's head to a cherry, containing clear amber-colored or brownish fluid (Fig. 977). The disease may run a simple or a malignant course. The enlarged testicle may reach a very great size, without showing any signs of general malignancy. In the simpler forms, the disease somewhat resembles the adenocarcinoma of the mamma. The new growth is found to be composed of a stroma, consisting of various modifications of connective tissue in all stages of growth, in the midst of which are spaces lined with epithelium. The stroma shows great irregularity of structure. In the same specimen may be found fibriloid tissue, cartilage, myxoma-

tissue, spindle-celled and round-celled sarcoma-tissue. Paget has found the cartilage to be arranged in beaded branching lines, resembling the course and shape of the lymphatic vessels, and has shown that it actually lies within them. The epithelial spaces are irregular in shape and size. It is difficult to say whether they represent the remains of tubuli seminiferi or not. The cysts are formed by dilatation of these spaces, and are lined by an irregular cubical epithelium. Intracystic growths may be found, as in the mamma, projecting into the cysts. The disease may assume a malignant form, becoming generalized in the internal organs like a sarcoma; or, according to Rindfleisch, actual cancerous transformation may take place, the stroma assuming the form of a cancer-stroma, and the epithelium of the spaces taking on the active growth of the cells of a true carcinoma. According to Curling, cystic disease of the testicle is the result of morbid changes in the ducts of the rete testis.

Diagnosis.—This affection has been carefully studied by Sir A. Cooper; who, with great justice, adverts to the difficulty of distinguishing it from other diseases of this organ, more especially from *hydrocele*. The points to be especially attended to in distinguishing the cystic sarcocele, are its want of translucency, the more globular shape of the organ, its weight, and the enlarged and varicose state of the veins of the cord. If there be any doubt, an exploratory puncture will resolve this, and should always be practised.

Treatment.—Cystic sarcocele requires early removal of the diseased organ.

Sarcoma of the Testicle.—Pure sarcoma of the testicle without the presence of the cysts just described is of rare occurrence. It is indistinguishable from cancer before removal, presenting the same rapid growth, and softness of structure, giving rise to a smooth elastic globular or oval enlargement of the testicle. It is usually met with in younger subjects than cancer, sometimes even in young children.

Its microscopic structure varies in different cases. Small round-celled sarcoma, and myxo-sarcoma with large spindle-cells intermixed with it, have been described.

The *Treatment* consists in early removal of the gland by castration.

Enchondroma of the Testicle.—Cartilage, as before stated, is almost always present in the cystic sarcoma of the testis. It may, however, appear alone, in larger or smaller nodules, or infiltrating the gland. It usually commences in the body, but may invade the epididymis. According to Cornil and Ranvier, whenever it reaches any considerable size it is no longer purely cartilaginous, but is mixed with sarcoma-tissue and complicated with cysts, so that both clinically and pathologically it merges into the disease just described as cystic sarcoma.

Cysts Containing Colored Matters.—Occasionally, cystic tumors of the testicle are met with, in which the substance of the organ is atrophied or absorbed, and its place occupied by one or more large thin-walled sacculi containing fluids of different colors and consistence, dark and fatty. One of the most remarkable of these anomalous tumors of the testis that I have seen was under the care of my colleague, Marshall, at the hospital. The diseased organ, which was about the size of an ostrich's egg, and felt partly solid and partly fluid, was found after removal to be composed of a large cyst filled with an oily fluid, like melted butter, which solidified on cooling.

Fig 977.—Cystic Sarcoma of the Testicle.

After removal Marshall found that the sac contained some fetal debris, was doubtless of an embryonic character. The patient, who was thirty years of age, had been affected with the tumor from early childhood.

CANCER OF THE TESTICLE, OR MALIGNANT SARCOMA.—Does not occur, and almost invariably assumes the encephaloid character. Indeed a question whether any other form of cancer ever occurs in the

Characters.—Cancer of the testicle most commonly occurs in the substance in the body of that organ, rarely, if ever, affecting the epididymus primarily. The ordinary characters of encephaloid are always well marked in this affection; and the tumor eventually fungates, becomes bleeding and pulpy. The mass on section is soft, pink in color, with large patches of fatty degeneration scattered through it. Its substance is broken down in parts by hemorrhage. It is impossible to distinguish from a soft sarcoma without microscopic examination. The micro-structure is that of encephaloid cancer. The stroma is small in amount and encloses spaces of great size filled with large cells of irregular form.

A malignant testicle may rapidly attain a very considerable magnitude, becoming as large as a coconut in a few weeks or months. When of this size it is, of course, abundantly supplied by bloodvessels; consequently the spermatic artery and accompanying veins will be found a good deal enlarged. The lymphatic glands in the neighborhood speedily become enlarged, especially in the iliac fossa, as may be ascertained by deep pressure on the flank. The inguinal glands do not in general become affected, until the tumor has become implicated by the progress of the disease. It is then also the cancerous cachexy rapidly develops itself.

The *Symptoms* of encephaloid of the testicle are usually somewhat obscure in the early stages, although they become clearly and distinctly developed as the disease progresses. It is most commonly met with after middle life. The patient first complains of some degree of dragging pain and weight in the testes, which on examination will be found to be indurated and enlarged, though preserving its normal shape. The enlargement continues until the testicle attains about the size and shape of a duck's egg, being somewhat tense and elastic, but smooth and heavy. As it increases in size, which usually does with rapidity, it becomes rounded and somewhat deep red or pulpy in parts, where, indeed, it may almost be semi-fluctuating, in others it continues hard and knobbed. This alteration in feel is partly due to softening of the substance of the tumor, and partly to its making its way through the tunica albuginea. The scrotum is much distended, red and purplish, and becomes covered by a network of tortuous veins; it may become somewhat enlarged, hard, and knotty. As the disease advances the scrotum becomes adherent at some of the softened parts, obscuring its place, and a fungus projects, which presents all the characteristics of fungus hsematodes; it does not commonly happen, however, that the tumor is allowed to go so far as this before removal. The pain is not very severe at first, but after a time assumes a lancinating character, extending up the thigh and into the loins. Secondary infection of the system takes place through the medium of the lumbar and iliac glands in which the absorbents of the testis terminate. In cancer of the scrotum, just as in the same disease of the penis, the inguinal glands become secondarily affected.

Treatment.—The only treatment of any avail to our mind of the tumor is the removal of the diseased organ. This operation is not performed much with the view of curing the patient of his disease, which will probably return in the lymphatic glands or in some internal organ, as of affording temporary relief from the suffering and inconvenience of the enlarged testicle. It is therefore an operation of expediency, and should be done

in those cases in which the disease is limited to the testicle, the cord being free and the glands not evidently involved; so that, if recurrence takes place, it may not be a very speedy one.

An Undescended Testis may become the seat of a tumor, just as it may be affected by inflammation. The combination of malposition of the organ and a tumor is necessarily rare. But its possible occurrence must be borne in mind by the Surgeon, as it may lead to the necessity of an operation for the removal of the diseased mass from the inguinal canal. Cases of this kind are recorded by Storks and J. M. Arnott. The tumor in the first case was as large as a cocoanut; in the second as a man's fist. Both were medullary. The operation consists in exposing the tumor by a free incision—if necessary, carried through the tendon of the external oblique—opening the tunica vaginalis, enucleating the mass, and tying with care the shortened spermatic cord, which would probably be the most difficult part of the operation. The possible coexistence of a congenital hernia must be remembered. But it is remarkable that peritonitis does not appear to be the chief danger of this operation. In neither of the cases above referred to did it occur, the patient dying of erysipelas in Arnott's case; of recurrent cancer, a year after the operation, in that of Storks.¹

OPERATION OF CASTRATION.

This operation may be required for the various non-malignant affections of the testicle that have resisted ordinary constitutional and local treatment, and have become sources of great annoyance and discomfort to the patient; in the early forms of malignant disease, also, it may be advantageously practised. The operation is performed in the following way. The patient, having had the pubes shaved, should lie upon his back with the legs and thighs hanging over the end of the table. If the tumor be of large size and vascular, an India-rubber tourniquet may be applied (Fig. 10, vol. i. p. 73). The Surgeon should then take his stand in front of the patient between his legs, and, grasping the tumor at its posterior part with his left hand, make the scrotum in front of it tense. If the mass to be removed be of small size, he makes a longitudinal incision over its anterior surface; if of large size, or if the skin be implicated, two curved incisions, enclosing a portion of the scrotum. The incision should commence opposite to the external abdominal ring, and be carried rapidly down to the lower part of the scrotum. By a few touches with a broad-bladed scalpel or bistoury, whilst the skin is kept upon the stretch, the tumor is separated from its scrotal attachments, and left connected merely by the cord, which must then be divided. In some cases, it will be found advantageous to expose and divide the cord in the first instance, before dissecting out the tumor from the scrotum, as in this way a better command over it is obtained.

The **Division of the Cord** constitutes the most important part of the operation, whether this be done first or last; as, unless care be taken, the cord may be retracted through the abdominal ring into the inguinal canal, where it is extremely difficult to follow it, and where the stump may bleed very freely, pouring out blood into its own areolar tissue so as to swell up rapidly and form a large extravasation of blood, and, if not properly secured, giving rise to extensive and even fatal infiltration into and between the muscles of the part and into the flank. This accident may be prevented by separating the cord cleanly from the sheath—more especially from the cremasteric

¹ I would refer those who wish for further information on this subject to Curling's excellent work on the Testis.

fibres which are the chief causes of the retraction. It may then be seized with a pair of clamp forceps, or tied tightly with a tape (Fig. 978). It is very slippery, and apt to slip through the assistant's fingers, hence the use of the clamp or tape. It may then be cut across below this, and the arteries tied separately. The veins must be tied as well as the arteries. The arteries requiring ligature are usually the spermatic, the cremasteric, and the artery of the vas deferens. The spermatic artery will be found at its anterior part—the artery of the vas deferens behind. When all the vessels are secured the tape or clamp must be removed.

If the Surgeon has not a very reliable assistant, it is safer to tie the cord as a whole. This is done by passing a piece of strong carbolized silk under

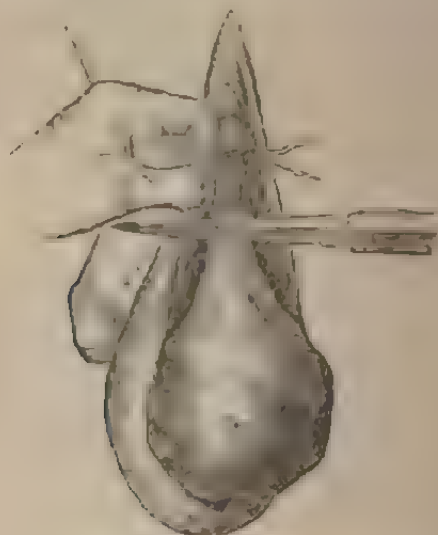

Fig. 978—Division of the Cord in Castration.

the cord, and tying the whole of this structure very tightly before dividing it. In this way hemorrhage is most effectually restrained; and the ligature separates about the eighth day, or may heal into the wound if cut short, provided efficient antiseptic treatment is carried out.

In castration for tubercular testicle it is better to separate the vas deferens from the other constituents of the cord and to divide it separately. If it be found diseased, it may be drawn down and a further piece removed in the hope of getting above the disease.

A large number of vessels usually require ligature in the scrotum. All bleeding from this source must be very thoroughly arrested, otherwise the loose tissues of the scrotum may become distended with extravasated blood and very troublesome suppuration result. After the operation the wound must be accurately closed with sutures and a good sized drainage-tube inserted at its lower end.

In cancer of the testicle, it is of great consequence to divide the cord as high up as possible, for obvious reasons. It will not, however, be safe to do this opposite the abdominal ring in the way that has just been described, as there would not be sufficient space for the assistant to hold the cord above the part to be divided. In cases of this kind, I have found it a good prac-

tice to expose the cord by dissection up to the abdominal ring; then to draw it well down, and to include the whole in a strong ligature, tied round it as tightly as possible. The section is then made a quarter of an inch below this, and the operation is completed as usual; the stump of the cord may retract into the inguinal canal, but cannot bleed if properly tied, and will always be under command by drawing upon the ligature. This plan of tying the cord *en masse* was at one time generally adopted in all cases of castration, but is not now commonly employed. The objection to it is, that by compressing the nerves of the cord with the ligature the after-pain is increased; but this certainly does not always happen, for, in the instances in which I have done it, but little pain was complained of; and the practice in malignant disease of the testicle has the advantage of enabling the Surgeon to divide the cord at a higher point than he otherwise could; which advantage is still further increased by the parts within and below the ligature sloughing away, and thus eventually carrying the section to a level with the point tied.

There is one danger that may occur in castration in young children. It is that in young subjects the processus vaginalis testis may not be obliterated, and that thus the peritoneum may be opened up into the wound on dividing the cord. In one case I have known this condition to lead to fatal peritonitis.

GENERAL DIAGNOSIS OF SCROTAL TUMORS.

The diagnosis of scrotal tumors is not only of considerable importance, but is often attended with very great difficulty: the more so, as they are frequently associated with one another, so that much tact and care are required to discriminate their true nature. Thus it is not uncommon to find a hydrocele and a hernia; a hydrocele and a varicocele; or these affections coexisting with a solid tumor of the testicle. In other cases, again, as in the annexed figure (979), an encephaloid tumor may coexist with a hydrocele of the tunica vaginalis, and with an encysted hydrocele of the cord; and the different forms of hydrocele may occur together.

Tumors of the scrotum may, from a diagnostic point of view, be divided into two distinct classes: 1, the Reducible; and, 2, the Irreducible.

1. REDUCIBLE TUMORS.—These are Hernia, Congenital Hydrocele, Diffuse Hydrocele of the Cord, and Varicocele; in all of which the swelling can be made to disappear more or less completely by pressure and by the patient lying down; reappearing on the removal of the pressure, or on his assuming the erect posture. The mode in which the tumor disappears, tends greatly to establish its diagnosis; though the general character of the swelling, and the history of the case, afford important collateral evidence on this point.

a. In **Hernia** there are the ordinary signs of this affection, such as impulse on coughing, &c. On reducing the tumor, it will be found that its return into the abdomen is accompanied by a gurgling noise, and by the sudden slip upwards of an evidently solid body. In the other reducible tumors, the diminution and eventual disappearance under pressure are more gradual, and there is no reduction of the mass as a whole.

b. The gradual squeezing out of the contents of a **Congenital Hydrocele**,

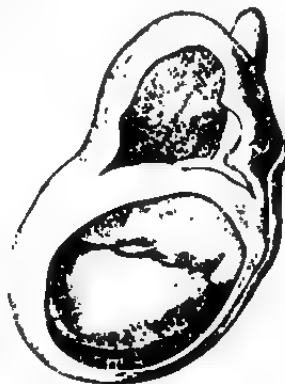

Fig. 979.—Encephaloid Testicle with Hydroceles of the Tunica Vaginalis and of the Cord.

together with its translucency, and the early age at which it occurs, will establish its true character. It must be remembered, however, that hernia in very young infants may be translucent if the gut contains little or no fecal matter.

c. In the **Diffuse Hydrocele of the Cord**, there is a uniform semi-fluctuating swelling on and near the ring; in which, however, there is no gurgling, etc., nor complete reduction nor sudden disappearance as in hernia. It is also less defined, and has a less distinct impulse on coughing.

d. **Varicocele** may always be distinguished by its pyramidal shape, and its knotted, soft, and irregular feel. After being reduced when the patient lies down, it will, when he stands up, fill again, even though the Surgeon compress the external ring with his fingers. This sign, which distinguishes it from a hernia, occurs also in congenital hydrocele; from which, however, the varicocele may be distinguished by the absence of translucency, the want of fluctuation, and the general feel of the tumor.

2. **IRREDUCIBLE SCROTAL TUMORS** are of various kinds; such as Omental Hernia, Hydrocele, Hematocele, the various forms of Sarcocoele, and Cancer of the Testicle. These tumors, though presenting certain characters in common, yet differ somewhat in the predominance of particular signs. Thus, the shape of the tumor is usually pyriform in hydrocele, globular in hematocele, and oval in sarcocoele; though this is subject to much variation. The weight is least in hydrocele and greatest in sarcocoele, proportionately to the size of the tumor. The characters of the surface present considerable differences, being smooth and tense in hydrocele and hematocele; often irregular, hard or knotted in the other varieties. The rapidity of the formation of the tumor is greatest in hematocele.

a. **Irreducible Scrotal Hernia** may be recognized by its irregular feel, by its impulse on coughing, by its occupying the canal, and concealing the cord, and by the testicle being distinctly perceptible below it.

b. **Hydrocele of the Tunica Vaginalis** is recognizable by its translucency; and the amount of opacity combined with this will enable the Surgeon to distinguish the degree of enlargement of the testis, and how far there is a sarcocoele combined with it.

c. In **Hematocele** the tumor is of sudden or rapid formation, somewhat globular, opaque, but not very heavy or hard, and smooth upon the surface.

d. In **Sarcocoele** generally the tumor is heavy for its size, frequently globular or irregular in shape, sometimes knotted, and usually attended by a good deal of dragging pain in the groin, and frequently by some enlargement of the cord.

In these three forms of scrotal tumor, viz. hydrocele, hematocele, and sarcocoele, the diagnosis can always be made at once from hernia, by the Surgeon feeling the cord free above the tumor.

The point of most importance in the diagnosis of solid enlargements of the testicle is to distinguish the malignant tumors, sarcoma, and cancer, from the more benign forms of disease. In malignant tumors, rapidity of growth, softness and elasticity of the mass, the implication of one testis only, and the early enlargement of the cord, with its indurated and knotted condition, are the most signs; especially if the disease occur in young men. In a more advanced condition, the softening of the swelling at parts with a tuberculation of the rest, and the occurrence of fungus with speedy constitutional decay, will point to the malignant nature of the tumor. In cases of much doubt and difficulty, an exploratory puncture may be made, when the contents of the groove in the needle or of the fine canula will probably determine the character of the growth. In more than one instance, in which there was much obscurity, I have seen the true nature of the disease cleared up

SPERMATORRHOEA AND IMPOTENCE.

Various forms of debility, of loss of power, or of irregularity of action in the generative organs of the male, are confounded together under the terms **Spermatorrhœa** and **Impotence**. These conditions require a more careful consideration on the part of the educated Surgeon than they have hitherto received, as their existence is a source of the deepest mental depression and distress to the sufferer. They are certainly one cause of conjugal unhappiness, leading, perhaps, to infidelity on the part of the wife, and occasionally even to suicide of the husband. These affections, which are of extreme frequency amongst all classes of the community, having scarcely as yet received that attention on the part of the profession generally that their importance deserves, the unfortunate sufferers from them are too often driven into the hands of those pestilent quacks who flourish in the metropolis, and infest almost every town in the country, by whom they are not unfrequently ruined in health as well as in purse.

The **Sexual Melancholia** that accompanies these conditions, is one of their most striking characteristics. The patient is languid in manner, depressed in spirits, his countenance is pale and haggard, eye dull, expression listless, and devoid of all energy. He takes no interest in the ordinary affairs of life, his whole thoughts are concentrated on his own condition, and he feels himself degraded as being unfit for that duty which is alike the first and the lowest of man. This state of mind is commonly the result of some local irritation or disease, reacting on a morbidly sensitive nervous system; and, on examination, the Surgeon will commonly find some local condition that has been the starting-point of the mental malady. **Balanitis**, **phimosis**, or **varicocele** in the male, are the common occasioning causes. But the most frequent direct exciting cause is undoubtedly that pernicious and disgusting habit alike destructive of bodily vigor and of mental power, which, heedlessly contracted in youth, lays the foundation for an effete and impotent manhood, and for premature senility in the one sex, and entails hysteria, in its most aggravated and intractable forms, in the other.

We may recognize at least three distinct varieties of generative debility in the male, of whom I alone speak, which may in some cases amount to actual impotence: 1, **True Spermatorrhœa**, or **Seminal Flux**; 2, **Spasmodic Spermatorrhœa**, or **Spermaspasmus**; and, 3, that arising from **Want of Seminal Secretion**, or **Aspernia**.

1. **TRUE SPERMATORRHOEA, OR SEMINAL FLUX**, is a rare disease and is met with chiefly in young men, usually from the ages of eighteen to thirty. It is commonly the consequence of that hideous sin, engendered by vice, and practised in solitude, which alike emasculates the body, enfeebles the mind, and degrades the moral nature of its perpetrator, or of debility of the generative organs induced by gonorrhœa, or of the continued struggle to repress the natural sexual desires by a life of forced or unavoidable continence. In this form of the disease there is a mixture of irritability and of debility. The generative organs are excited by slight emotional causes, or by trivial and ordinary physical stimuli—a thought, a look, a word, the movements of a carriage, the effort of straining at stool, will excite the secretion of the testes, which the debilitated state of the parts allows to escape with a feeble ejaculatory effort, or in a kind of leakage of a few drops from the urethra. In the slighter cases, and in the earlier stages of the malady, these emissions take place but occasionally—three or four times a week, chiefly in the morning, in the mid state between waking and sleeping, and are preceded by an erection. In the more advanced stages, the emissions occur once or oftener in the

twenty-four hours without an erection; the semen at last, when discharged, flowing back into the neck of the bladder, escaping with each discharge of the urine, or being squeezed out after defecation. The patient's physical and mental state becomes seriously implicated in these more advanced cases of true spermatorrhoea. His countenance is pallid, anæmic, and sallow; his features are drawn, their expression is listless; his eyes lifeless; his spirits depressed, often to the lowest depths of despondency and despair. Coitus is impracticable, as the discharge of semen takes place either before erection occurs, or without its occurrence.

Diagnosis.—The first point in making a diagnosis is to ascertain that there is some real disease, and that the patient is not merely the subject of hypochondriasis or sexual melancholia. Various conditions are mistaken for spermatorrhoea by a nervous patient. The white discharge of phosphates occurring at the end of micturition (p. 903), when the urine is alkaline or some form of dyspepsia, is often believed by the patient to be seminal fluid, and as this condition is frequently accompanied by the languor of dyspepsia, and is common in those who sit up too late at night and overwork themselves, this harmless condition may give rise to the deepest mental depression.

Prostatorrhoea (p. 1016, vol. ii.) is very apt to be confounded with spermatorrhoea; but the diagnosis may always be effected by a microscopical examination of the discharge.

An occasional involuntary emission is not spermatorrhoea. It is common to young men of an ardent and excitable temperament, and is often the occasion of much groundless alarm. It occurs at that period of life when the generative power and sexual feeling are at their highest point of development. It is simply the result of a hypersecretion of the testes and overflow of the semen. For its repression, moral advice and medicinal agents are equally unnecessary and unavailing. For it, early and congenial marriage is the only remedy. Unless this be adopted, Nature will assert herself—she is indifferent to social considerations—she will enforce her rights in spite of all restraint. "*Naturam expellas furca; tamen usque recurret*."

The escape of a small quantity of seminal fluid from the vesiculae seminales while straining at stool is of common occurrence in young men leading a continent life, and need cause no anxiety, and requires no treatment beyond a purge and a cold hip-bath.

Frequent nocturnal emissions in many cases are merely a symptom of dyspepsia, the languid feelings of which the patient complains being very often due to this much rather than to the loss of semen. The loss of semen by an involuntary emission causes no more depression than a corresponding loss during coitus, and if occurring not more than twice a week has no evil effect. It is the constipation and dyspepsia accompanying it, that are the real source of the symptoms complained of.

Treatment.—The curative treatment of true spermatorrhoea should consist in giving tone to, and in lessening the irritability of, the genito-urinary organs. In these cases it becomes necessary to maintain and improve the tone of the system by remedies calculated to remove the anæmia and to stimulate the nervous energies. With this view, the preparations of iron, phosphorus, nux vomica, and cantharides will be found the most effective. The syrup of the phosphate of iron and strychnine, or the tincture of the perchloride of iron, in combination with those of nux vomica and cantharides, will be found of the greatest service. But under any form of treatment the cure will be slow, and long continued perseverance in the use of remedies, local and constitutional, is imperatively necessary. In addition to these means the cold hip-bath should be assiduously employed. This the patient should use every night and morning; remaining in it, at first, for about three

minutes, but gradually increasing the time of immersion to ten or fifteen. The patient must sleep on a hard mattress, be lightly covered, and eat no supper. Some satisfactory mental occupation should also be provided, or travelling if possible. In some cases the cold shower-bath appears to give more tone, and then should be preferred. These means, useful as adjuncts, will not, however, cure the patient. For this purpose, the local irritability must be removed by the application of the nitrate of silver to the prostatic and bulbous portions of the urethra. It will usually be found that there is a good deal of tenderness in these situations, felt on pressing upon the perineum, or on passing an instrument into the urethra, when, as the point enters the bulb, the patient will suffer much pain. The continuance of this irritation certainly keeps up the seminal emissions, and thus maintains the debility of the genital organs, and the nervous irritability, that are so characteristic of these cases. It may most effectually be remedied by the application of the nitrate of silver, as originally recommended by Lallemand; and, if this be done in a proper manner, a cure will usually be accomplished. For many years past I have employed, with much advantage in such cases, the instrument here figured (Fig. 980). It consists of a silver catheter, having about

Fig. 980.—Syringe-catheter for applying Caustic to the Urethra.

a dozen minute apertures near the end. In the interior is contained a slender piece of sponge, about two inches long, fixed to the expanded end of a firm stylet that moves within the catheter. The instrument is charged by filling the sponge with some solution of nitrate of silver by withdrawing the stylet. It may then be well oiled, and, being passed down to the spot to be cauterized, the solution is forced out of the aperture by pushing down the rod, which compresses the sponge. I have found this syringe-catheter far safer and more manageable than Lallemand's or any other *porte-caustiques* that act by protruding a spoon or sponge, which is apt to be grasped by the spasmodic action of the muscles of the part, often being returned with difficulty into the shaft, and not without risk of lacerating the mucous membrane. I generally use a solution of the strength of \mathfrak{ss} of the nitrate to an ounce of water; though sometimes only a half or a third of this strength can be borne. The application usually occasions a good deal of irritation for a time, sometimes even a muco-purulent discharge, and can be repeated only at intervals of from ten days to a fortnight. Any undue amount of irritation, particularly after the application, must be subdued by ordinary anti-phlogistic treatment. After the nitrate of silver has been used two or three times, the treatment may be advantageously continued by passing twice a week a similar instrument charged with glycerine of tannin. This acts as an admirable astringent, and suits many people better than the nitrate.

2. SPASMODIC SPERMATORRHEA, or SPERMASPMOS, more frequently occurs between the ages of twenty-five and forty. It is frequently predisposed to by residence in a warm climate, or by the existence of some disease about the generative organs; such as stricture, varicocele, neuralgia testis, etc. In these cases there is not, properly speaking, a seminal flux; but complete connection cannot be effected, as erection and ejaculation are either simultaneous acts, or the erection partially subsides before the emission takes

place. This form of generative debility is often as much dependent on mental or moral as on purely physical causes.

Treatment.—This is a condition of irritability rather than of debility. It often occurs in strong and otherwise healthy men, accustomed to field-sports and out-of-door exercises. There is no evidence of anemia or of debility of any kind. Hence tonics are not necessary; nor, indeed, would they be in any way useful.

The remedy most to be relied upon is the bromide of potassium in doses of 20 to 30 grains, with local cold bathing, and, perhaps, when there is urethral irritation, blisters to the perineum and along the penis, with belladonna to the interior of the urethra. In addition to these means, it is of the first importance to enjoin moderation in food and drink, and above all, avoidance of alcoholic stimuli; for, in many of these cases, it will be found that abdominal plethora coexists, and exercises an injurious influence.

3 IMPOTENCE arising from absence of all sexual desire or power, or from premature decay of that power, is not unfrequently met with, and often in individuals who are otherwise strong and healthy; sometimes, indeed, in those characterized by great muscular power, and much given to athletic exercises. This want of sexual desire may be looked upon in many instances as a natural deficiency in the organization of the individual, for which medical or surgical treatment can do little. In other cases it arises from exhaustion of the nervous system by habitual physical or mental exertion, by excessive sexual indulgence, over-training, or study carried to too great and injurious a degree. Complete absence of seminal secretion—*Asperma*—except in cases of atrophy or absence of the testes, must be especially rare. In a patient of mine who died at 54 years of age, and who, according to his own and his wife's account, had been completely impotent for the twenty-four preceding years, spermatozoa in considerable quantities were after death found in the testes, which were carefully examined with the view of ascertaining whether they ever secreted semen. Retention of both testicles, or atrophy of both glands from mumps, will of course cause impotence. Temporary impotence from nervousness is not uncommonly met with in young men immediately after marriage. In these cases the treatment recommended by Sir A. Cooper, of ordering some harmless medicine, and forbidding the patient to attempt connection, will usually be effectual.

STERILITY in the male is a condition that has attracted some amount of attention of late years. It is, of course, not unfrequently connected with, and probably dependent on, the same conditions that give rise to the various forms of sexual debility that have just been described. But it may occur independently of any of these states, in individuals, indeed, who are possessed of a very considerable amount of sexual desire and vigor. It would appear to be due to some morbid condition of the seminal fluid, in consequence of which the spermatozoa are either absent, or are possessed of insufficient vitality to effect impregnation. The causes of this condition are very obscure; but over-indulgence in sexual intercourse appears to be amongst the most frequent. It would seem as if each individual were endowed with a certain amount of procreative power, which, if early exhausted, or habitually wasted in indiscriminate intercourse, cannot be restored. Hence, polygamists in the East, or their Western congeners, do not propagate as a rule, more than the average number of children. Amongst organic causes of this state, chronic epididymitis appears to be the most frequent (p. 1104). The only *Treatment* that can be adopted with any prospect of success, is in the one case prolonged avoidance of sexual excitement, and in the other the removal of local disease existing in the urethra or testis, such as stricture,

or thickening or condensation of structure, by the long-continued use of absorbent remedies on general principles. Tonics are valueless in such cases.

Sterility arises also from malformation of the penis, such as complete hypospadias, and more rarely from the size of the male organ rendering complete coition impossible.

In conclusion, I need scarcely say that, in the treatment of that general melancholia or hypochondriasis that accompanies these various affections, much good may be effected by means that directly influence the spirits and the mental condition of the patient. He should be encouraged to travel, to occupy himself with healthy out-door pursuits and amusements, to take regular exercise, to avoid all enervating habits; and, above all, his mind should be cheered by the hope of eventual cure. Should there be any local disease, such as balanitis, phimosis, or varicocele, that should be subjected to treatment or operation.

CHAPTER LXXV.

DISEASES OF THE FEMALE GENITAL ORGANS.

SOME of the more important surgical affections of these organs, such as vesico-vaginal and recto-vaginal fistulæ, lacerated perineum, etc., have already been discussed. The remaining affections, implicating the Vagina, the Uterus, and the Ovaries, are of considerable practical interest; but, as their full consideration would lead me far beyond the limits that can be assigned to them in this work, and, indeed, belongs to another department of Medicine, I must content myself with a brief indication of the principal surgical points deserving attention.

INTRODUCTION OF INSTRUMENTS.

SPECULUM VAGINÆ.—Vaginal specula of various shapes and materials are commonly used by Surgeons. When the os and cervix of the uterus require exploration, the most convenient instrument is certainly the cylindrical reflecting glass speculum (Fig. 981); which, being coated with a layer of tinfoil, covered by India-rubber, always presents internally a mirror-like surface, by which a strong body of light is thrown into the bottom of the tube. It has the additional advantage of being very cleanly, and not stained by any caustics that may be used in it. These specula should be of different sizes, and may be sometimes advantageously bevelled off at the inner end. When the wall of the vagina requires examination, as in some operations for fistula, a bivalve speculum (Fig. 983), one with expanding blades (Fig. 982), a cylindrical one, provided with a sliding side, or the "duck-billed" speculum (Fig. 942) may advantageously be used.

Introduction of the Speculum may readily be effected, without any exposure of the person, under the dress or bed-clothes. There are two positions in which the patient may conveniently be placed for this purpose. In the first, she lies upon her back, with the nates well raised or brought to the edge of the bed or couch, her legs separated, and her feet resting on two chairs; the Surgeon, standing or sitting in front of the patient, introduces

the fore and middle fingers of his left hand into the vagina, dilates its walls, passes the speculum, well greased, gently and steadily between and under them, exerting any pressure that may be required backwards on the perineum. This position is the most convenient when caustics require to be applied, but is often objectionable to the patient, as it appears to entail much exposure, though in reality it need not do so. Another mode of introducing the speculum, which should always be adopted when practicable, consists in placing the patient on her left side across the bed, with the knees drawn up, and the nates near the edge; the instrument is then introduced in the same way as before, the Surgeon sitting by the patient's side. In whichever

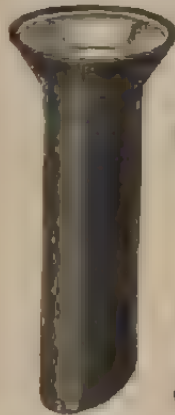

Fig. 281.—Cylindrical Speculum.

Fig. 282.—Branched Speculum.

Fig. 283.—Bivalve Speculum.

way the speculum is used, no force should be employed; the patient should be placed opposite a good light, and care should be taken that the instrument be introduced fairly to the uterus, the position of which may have been previously ascertained by tactile examination.

FEMALE CATHETER. The use of the female catheter is often required in various diseases and operative procedures about the genito-urinary organs of women. It should be introduced without exposure, by the aid of the touch alone. This may readily be done, as the patient lies in bed, under the clothes. The Surgeon, standing on her left side, passes his left index-finger downwards between the nymphæ until he feels the projection of the *meatus urinarius*, immediately above the entrance into the vagina; keeping his finger just below this, he uses it as a guide to direct the point of the catheter into the canal. Or the reverse way may be adopted; the Surgeon, passing his finger just into the orifice of the vagina, feels the urethra like a cord under the arch of the pubes. He carries it along this until the urethral orifice is reached, when the catheter is slipped in. This method has the advantage that the clitoris is not touched, a matter of importance in hysterical females.

DISEASES OF THE EXTERNAL ORGANS AND VAGINA.

The vulva is the seat of numerous morbid conditions, consisting principally of hypertrophy or of warty growths, or the formation of cysts.

HYPERTROPHY OF THE LABIA to a limited extent is not unfrequently met with, one labium hanging down considerably below the other. In these cases,

it will often be found that the enlargement is due to a kind of solid œdema, originally dependent, perhaps, upon a fissure or ulcer of the part. In other cases, large fibro-cellular tumors form as outgrowths from the natural structures in this region; these may require removal by excision.

LARGE CONDYLOMATA or VERRUCÆ are often met with here as the result of gonorrhœal or syphilitic disease, forming at last irregular pendulous masses which require extirpation, either by knife or scissors. I have had occasion also to remove a large *Nævus* by ligature from this situation; and, in fact, any growth that occurs in the skin or cellular tissue may be met with here.

CYSTIC TUMORS are not unfrequently met with in the labia, and may sometimes resemble rather closely the ordinary forms of inguinal hernia; with which, however, their incompressibility, irreducibility, and the absence of impulse on coughing, will prevent their being confounded. These cysts, which require removal by a little simple dissection, usually contain a dark, turbid, or sanguineous fluid, and sometimes atheromatous matter. Tolerably free hemorrhage may follow their removal, the vascular tissues of the labia being cut into. This may, however, always be arrested by Paquelin's or some other form of cautery, or by firm pressure by means of a T-bandage. Occasionally they project from the inside of the vagina, and then require removal by dissection or ligature, as can be best practised.

IMPERFORATE VAGINA is occasionally met with in young children, and occasions a good deal of anxiety to the parents. This condition, however, may always be very readily and speedily removed by tearing open the canal, as it were, by dragging open its walls in opposite directions, and breaking through the adhesions, which are little more than epithelial, with the thumbnail, a blunt probe, or the handle of a scalpel, and then introducing a small pledget of greased lint.

IMPERFORATE HYMEN is occasionally met with, causing great inconvenience, and even danger, by the retention of the menstrual secretion, which may accumulate to an immense extent, and become converted into a kind of chocolate-colored grumous fluid. This malformation does not usually attract attention until the age of seventeen or eighteen. When the menstrual flux has, however, not appeared, notwithstanding periodical constitutional disturbance, an examination is instituted, and the cause of the obstruction is revealed. In these cases the hymen, which forms a dense elastic membrane, is pushed down between the labia, and the uterus distended by accumulated secretion may generally be felt as an elastic fluctuating tumor above the pubes, reaching sometimes nearly to the umbilicus.

The *Treatment* consists in puncturing the hymen with a trocar, enlarging the opening with a probe-pointed bistoury, and thus discharging the retained fluid, which may be in very large quantity. This operation, unless performed with antiseptic precautions, is by no means free from risk. Before any incision be made, the parts should be thoroughly cleansed with a 5 per cent. solution of carbolic acid. The cavity left after complete evacuation of the fluid must be well washed out with carbolic lotion or a strong solution of iodine, after which a pad of iodoform gauze, or other efficient antiseptic dressing should be applied and retained in place by a T-bandage. Daily syringing, with renewal of the dressing, is to be practised at first until all danger of septic mischief be over, the urine meanwhile being drawn off as required by means of the catheter. In opening the membrane, it need scarcely be said that wound of the urethra should be carefully guarded against; and, with care, that canal may always be avoided. I have, however, seen one case in which it had been slit up by the Surgeon who punctured the membrane.

Occasionally the Surgeon's advice may be sought by married women, for a rigid and only *partially perforate hymen*; when incision with a probe-pointed bistoury or forcible dilatation may be required. Impregnation, however, is possible, even though the hymen be not ruptured; and it may be necessary during parturition actually to complete the division of that membrane, if thickened and unruptured, though in most cases it gives way under the pressure of the fetal head.

It may happen that surgical aid is needed to supplement conjugal efforts in the consummation of the marriage rite. In these so-called "delicate" cases, anaesthesia having been induced, the Surgeon introduces a small bivalve speculum shut (Fig. 983), or an ordinary "glove-stretcher," and, expanding the blades, ruptures the hymen, and dilates the vagina to the necessary extent as he withdraws the instrument. When severe spasmodic pain, of the character known as *vaginismus*, is habitually caused by coition, its origin may occasionally be traced to a hyperaesthetic condition of the remains of the hymen. In such cases, excision by means of curved scissors of a complete ring of the sensitive tissue seated immediately within the entrance of the vagina, usually serves to cure the affection; and this all the more surely if followed by forcible dilatation of the part and the introduction of a firm plug of iodoform gauze, which should be allowed to remain *in situ* for several days.

ABSENCE OF THE UTERUS AND OVARIES, with imperforate vagina, is occasionally met with in women, otherwise perfectly well formed: the external organs of generation, labia, and nymphæ being present, and the breasts developed. In such cases, it is remarkable that sexual desire usually exists. The true condition may, however, be detected by an examination *per rectum*, and especially by the introduction of a catheter into the bladder whilst the finger is in the rectum, when the two cavities will be found to be in close apposition without the intervention of uterus or ovaries, the point of the instrument being felt, thinly covered, through the gut. In two of the cases of this kind in which I have been consulted, there had been monthly epistaxis. No surgical interference can be of any avail in such cases; and an attempt to restore the vagina would necessarily lead to fatal results by opening the peritoneal cavity. Occasionally, if the woman has been married, the fruitless attempt at coition on the part of the husband has caused dilatation and expansion of the urethral orifice to such an extent, that the index finger may be introduced into the cavity of the bladder. I have known this expanded urethra mistaken for the vaginal aperture, coitus effected into it, and the existence of the malformation for a long time completely overlooked. *Simultaneous vesical and rectal exploration* will always clear up the true nature of the case.

HYPERTROPHY OF THE CLITORIS is occasionally met with; this organ becoming enlarged, elongated, and pendulous, and in some cases attaining an enormous size. Hargrave mentions an instance where it was found after removal to constitute a tumor weighing five pounds and a half. When the clitoris is enlarged, it may give rise to a good deal of irritation, and require excision, an operation that is often followed by rather troublesome hemorrhage, requiring the use of the actual cautery for its arrest. The clitoris may also occasionally be the seat of epithelioma; which, however, is more commonly met with affecting the labia minora and the orifice of the vagina. In either situation excision by means of Paquelin's cautery knife is the most effectual mode of treatment.

Removal of the Clitoris, even though not enlarged, was some years ago recommended and extensively practised as a means of cure in some forms of epilepsy and of erotomania. This is an operation as unscientific as it would

be to remove the glans penis for the cure of similar affections in the male, and one that the experience of the profession has proved to be as useless in its results as it is unscientific in its principle.

TUMORS of various kinds are met with in the interior of the vagina, springing from its walls. These may be of a Cystic character; but occasionally true Mucous Polypi are found dependent and projecting from the side of this canal. These may most readily be removed by trausfixing their base by a double whipcord ligature, and then strangling them. In performing this operation, however, when the tumor grows from the posterior wall, care must be taken to ascertain, by proper digital examination, that a portion of the rectum has not been dragged down into its base.

VAGINAL HEMORRHOIDS are occasionally, though rarely, met with. They occur chiefly towards the anterior part of the vagina, or about the lower wall of the urethra, as rounded, smooth, purple masses of enlarged and congested veins. In one case I have seen a mass of this kind in an old lady give rise to permanent incontinence of urine or dysuria, by keeping the urethral aperture patent. Destruction by Paquelin's or the galvanic cautery is the best method of treatment, care being taken not to touch the healthy mucous membrane, which must be protected by a bone speculum.

PROLAPSE of the anterior or the posterior wall of the vagina may occur, giving rise, in the first instance, to protrusion of the bladder, or *Cystocele*; in the other to a *Rectocele*. In either case, but especially in the first, it occasions very serious and troublesome consequences, amongst which chronic irritation of the mucous membrane of the bladder, with perhaps phosphatic deposits in the urine, are the most marked. These protrusions may be supported by the use of properly constructed belts or pessaries combined with the use of astringent injections.

In some cases the Surgeon may feel disposed to undertake plastic operations, in order to narrow the vaginal orifice by freely paring opposite portions of its wall, bringing together the freshened surfaces by means of the silver suture, and thus procuring narrowing of the canal and permanent support to the protruded part. The success of such operative proceedings will greatly depend on attention to details. The mucous membrane at the orifice of the vagina should be dissected off from about half an inch below the meatus on one side, to a corresponding part on the other, in a strip about an inch and a half wide; the dissection being carried well up posteriorly in the fourchette. Two or three deep, and as many superficial, sutures should be passed; the deep being left in for about five, the superficial for seven days. Great attention should be paid to cleanliness, the patient lying on her side with a catheter in the bladder communicating with an India-rubber tube to carry off the urine; and the bowels should be confined by opium.

VARIOUS DISCHARGES connected with the female organs of generation fall under the observation of the Surgeon; these may occur from the external organs, from the mucous membrane covering the cervix uteri, or from the interior of the cavity of that organ. These discharges, when proceeding from the mucous membrane covering the external organ, or lining the vagina, are frequently, though not necessarily, of a gonorrhoeal character; and then require to be treated in the way that has been mentioned at p. 1042, vol. ii. When they are of a simple nature, proceeding from mere excessive secretion of these parts, astringent injections, and attention to the general health, will usually succeed in effecting a cure.

VAGINAL DISCHARGES of a purulent character not unfrequently occur in young female children, as the result of constitutional debility or strumous derangement. Occasionally such discharges lead to the suspicion of the child having been improperly tampered with; and, although they may, of

course, be occasioned by some violence inflicted on the genitals, or even from gonorrhoeal infection, it must be borne in mind that, in the great majority of instances, they certainly arise from constitutional conditions solely, and are in no way referable to external causes. The Treatment consists in attention to cleanliness, the use of warm lead-lotions, and improvement of the general health.

Discharges dependent upon unhealthy conditions of the cervix and lining membrane of the uterus usually require special treatment, for the details of which the reader may best refer to works devoted to the Diseases of Women, where a consideration of the nature and management of uterine discharges also will be found.

TUMORS OF THE UTERUS.

The so-called Fibroid, or, more correctly, Fibro-myomatous growth, constitute by far the most common form of uterine tumor. These occur either singly, or as multiple formations affecting chiefly the fundus and body of the uterus. As a rule, they develop slowly, and in the majority of instances give rise to no symptoms calling for surgical treatment, but occasionally active interference is necessitated in consequence of danger to life arising from one or more of the following conditions, viz., persistent and uncontrollable uterine hemorrhage; rapid increase in the size of the tumor (sometimes due to cystic degeneration); or constant and severe pain caused by pressure.

The ordinary classification adopted of subperitoneal, intramural and submucous growths, may conveniently be followed in considering the surgical treatment of these tumors.

1. The *subperitoneal* variety, when unaccompanied by much excessive enlargement of the uterine body, is not uncommonly met with as a smaller less distinctly pedunculated growth springing from the fundus. If of moderate size, this may readily be removed on abdominal section by securing the pedicle with a transfixing ligature of stout silk previous to division, and then suturing the cut edges of its peritoneal investment across the surface of the stump. In cases, however, in which a tumor, often of very large size, is composed of a multiple mass of subperitoneal outgrowths, involving also the uterine body, the operation of hysterectomy is to be had recourse to. This procedure, involving the ablation of the entire mass of the tumor including the body of the uterus together with the ovaries and tubes, has recently come to be regarded as the most satisfactory mode of dealing with such cases. The operation is performed as follows: The tumor, having been turned out of the abdominal cavity, is held up by an assistant, while the Surgeon encircles the uterus, usually at about the level of the junction of the body and cervix, with a soft iron wire connected with a small screw known as Kocher's *serre-nod*. Whenever possible, the ovaries and tubes should be included in the loop; while care is required that no part of the intestine be nipped by it, and that the bladder be kept out of harm's way in front. The wire, having been properly secured, is tightened by means of the spiral screw of the *serre-nod* sufficiently to prevent all risk of hemorrhage, and a stout steel pin is then passed through the pedicle immediately above the constricting loop, before cutting away the tumor. After this has been done, the abdominal incision is carefully closed around the stump, which is maintained in position externally by the transfixing pin. Then the wire is again tightened by a turn or two of the screw, the stump is then thoroughly tanned by means of the solid perchloride of iron, and a dry dressing is applied. If all go well, the wire usually comes away about the 16th to the 20th day, leaving a cavity which heals by granulation.

2. The intramural variety of fibro-myoma occurs in one of two forms. The first of these may be described as a more or less uniform hypertrophy of the uterine tissue, constituting the tumor commonly known as a *soft fibroid*. This enlargement is usually accompanied by profuse uterine hemorrhage, which may occasionally necessitate active surgical interference. In such cases either one of two operations may be performed for the relief of the patient, viz., removal of the uterine appendages (ovaries and tubes) with a view to arresting hemorrhage and promoting atrophy of the growth by premature induction of the menopause; or else the above-described operation of hysterectomy, which is, on the whole, the most satisfactory mode of dealing with these tumors. The second form of intramural fibro-myoma consists of localized hypertrophic growths, which, as a rule, are distinctly encapsuled. When multiple, these may occasionally give rise to a considerable tumor, requiring the same treatment as the above.

3. The submucous variety of fibro-myoma, when occurring as a more or less sessile growth, projecting into and dilating the uterine cavity, may occasionally demand surgical interference in consequence of alarming and persistent hemorrhage. If the cervix be expanded over the protruding mass, a free incision, made through the capsule of the presenting portion, will enable the operator to shell out the tumor by a gradual process of enucleation, while firm supra-pubic pressure is maintained by the hand of an assistant, in order to facilitate the extraction. This operation, often a very severe and difficult one if the growth be of any size, should be undertaken only for the relief of most urgent symptoms, since all submucous growths have a natural tendency to become polypoid in character, and thereby more easily removable.

The ordinary fibroid polypus is usually met with as an oval or pyriform mass, attached to the posterior aspect or fundus of the uterine cavity by means of a more or less distinct pedicle. Such growths not uncommonly give rise to repeated and dangerous hemorrhage, often altogether disproportionate to their size. The most efficient mode of treatment consists in removal by means of a wire *écraseur*, of which the loop is passed round the pedicle and gradually tightened until division is effected. Unless the growth be protruding through the cervix, preliminary dilatation of this structure will be required in order to permit of the necessary manipulations.

Two other varieties of uterine polypi are met with, viz., the glandular and the cellular polyp. These usually grow from the cervix or its immediate neighborhood, and their removal by means of the wire *écraseur*, or by simple torsion, if of small size, commonly presents no difficulty.

It is an important rule, after all operations involving the uterine cavity, freely to apply pure tincture of iodine to the interior of the womb, in order to avoid the risks of septic mischief otherwise liable to ensue.

Malignant disease of the uterus may occur in any one of the three following forms, viz., as glandular carcinoma (usually of the medullary type); as epithelioma; or very rarely as sarcoma.

1. **Glandular carcinoma**, which is much the most common form of malignant disease here met with, commences as a hard, somewhat nodular hypertrophy of the cervix, with a tendency speedily to affect the neighboring tissues of the broad ligaments, thereby leading to early impairment of the natural mobility of the uterus. As the disease progresses, infiltration rapidly extends, until the pelvic organs are found completely fixed, and surrounded by the new growth. Destructive changes next take place in the tissues implicated, usually accompanied by fetid discharge, and by occasional attacks of hemorrhage. The amount of pain complained of varies in different cases,

but it is often of a most severe character. General constitutional cachexy ensues, and the patient dies exhausted.

Treatment in advanced cases must necessarily be purely palliative, the chief indications being to control hemorrhage, relieve pain, and sustain the patient's strength by suitable nourishment. In the earlier stages of the affection, before there is any apparent implication of neighboring parts, attempts are occasionally made to arrest the disease either by excision, or the use of the cautery, or else by resorting to the solvent properties of a strong bromine solution injected into the diseased tissue. Such treatment, although, perhaps, justifiable, can be of little use in retarding the progress of the malady.

Complete extirpation of the uterus, practised per vaginam or by abdominal section, is a procedure which, unless resorted to in the very earliest stage of the disease, when the uncertainty of diagnosis must render its adoption barely justifiable, cannot possibly hold out hopes of prolonging life. The immediate results of the operation have so far proved most disastrous in this country; while, in the very few exceptional cases where the patient has survived, recurrence of the disease has invariably taken place within the course of a few months.

2. **Epithelioma** of the uterus, commonly known as cauliflower excrescence, commences as a papillomatous growth, affecting the mucous lining of the cervix, which rapidly spreads to a soft fungating mass, with a tendency to implicate neighboring parts.

While still confined to the tissues of the cervix, the disease may be eradicated by removal with the écraseur, or by free excision; but, if once the broad ligaments have been invaded, rapid infiltration takes place, and the affection inevitably proves fatal.

3. **Sarcoma** of the uterus is of very rare occurrence, being met with either as a localized submucous growth, or still more rarely as a diffuse infiltration of the uterine wall. The prognosis is always unfavorable, although not so speedily so than in the case of the cancer. When confined to the fundus the removal of the projecting growths may occasionally be effected after dilatation of the cervical canal, by means of the curette or sharp spoon, followed by the application of strong nitric acid. The only other treatment likely to prove effectual, is extirpation of the entire uterus, as referred to above.

TUMORS OF THE OVARY.

For clinical purposes, may be broadly classed in two main groups, cystic and solid. The first of these, including those in which cyst-development is the most marked feature of the growth, can be subdivided as follows: 1. Unilocular cysts; 2. Multilocular cysts; 3. Dermoid cysts; 4. Colloid cysts; 5. Cystosarcomata. The second group, consisting of the more or less solid formations, would include: 1. Sarcoma; 2. Fibroma; 3. Carcinoma.

Of these growths, those included in the first group constitute a large majority of the ovarian tumors met with; the multilocular variety being of the whole the most common, while dermoid cysts and cysts with colloid contents are comparatively rare. The solid tumors, referred to in the second group, occur very much less frequently than any of the above.

Tumors of the ovary may develop at almost any age, being occasionally met with in quite young children, and not very uncommonly in women who have long passed the menopause; but the largest proportion of cases occur between the ages of twenty and fifty. One or both ovaries may be affected.

If uninterrupted with, the disease invariably proves fatal after a shorter or longer interval, usually within two or three years from the first development.

of an abdominal tumor, death occurring from gradual exhaustion due to interference with the functions of neighboring viscera. But, in the great majority of instances, an earlier fatal termination is liable to result from some intercurrent complication or accident—such as rotation of the pedicle, inflammation of the cyst, rupture of its wall, etc., conditions which, unless promptly dealt with by operation, must inevitably hasten the patient's death.

DIAGNOSIS.—The differential diagnosis of ovarian tumors from the numerous abdominal enlargements which may simulate them is too extensive a subject to be treated of here. The following may, however, be enumerated as conditions possibly requiring elimination before a definite diagnosis of ovarian disease can be arrived at. 1. Obesity, œdema of the abdominal wall, tonic spasm of the recti muscles with hysterical tympanitis (phantom tumor). 2. Stercoraceous accumulation, distended urinary bladder, retained menstrual fluid, distended gall bladder. 3. Tumor of liver, spleen, or kidney, sarcoma of the abdominal glands. 4. Peritoneal hæmatocele, abdominal or pelvic abscess. 5. Normal pregnancy, hydramnios, extra-uterine pregnancy, uterine fibro-myoma, uterine fibro-cyst, hydro- or pyo-salpinx. 6. Hydro-nephrosis, hydatid cysts, subperitoneal cysts, parovarian cysts. 7. Simple ascites, encysted dropsy of peritoneum, peritoneal cancer with ascitic fluid. The conditions enumerated in the last three of these groups are perhaps the most likely to mislead in forming an opinion.

In all cases of abdominal tumor, the patient should be examined undressed and lying upon her back with the shoulders somewhat raised and the knees drawn up. After carefully noting the salient points in the history of the case, such as the duration and rate of growth of the enlargement, its apparent seat of origin, the past and present condition of the menstrual function, etc., the Surgeon should proceed to determine the nature of the tumor by the systematic employment of the following means: 1. *Inspection*: Condition of the abdominal wall; amount of distention; shape and contour of the swelling, whether symmetrical or not, prominent anteriorly, or bulging laterally; extent of downward movement visible on deep inspiration. 2. *Percussion*: Position and extent of resonance, whether strictly limited or diffused, altered or not by change of position on the part of the patient; presence and nature of fluctuation, whether limited (encysted), or general (free fluid). 3. *Palpation*: Size, outline, and consistence of the tumor; its relative mobility; solid or with fluid contents; presence of nodular outgrowths. 4. *Auscultation*: Presence of the fetal heart in case of suspected pregnancy; uterine souffle. 5. By *Vaginal* or *Rectal* examination may be determined whether the tumor have a pelvic connection or not; and if so, whether it be uterine, tubal, or ovarian.

Tapping or aspiration of a fluctuant abdominal tumor of doubtful origin is occasionally resorted to with a view to ascertain its nature by examination of the fluid withdrawn; and of late years an exploratory incision has been recommended in obscure cases as a more definite means of clearing up the diagnosis. This last procedure, although comparatively safe if performed with all due precautions, should by no means be rashly undertaken; but if practised, the operator must be prepared at once to proceed to the removal of the tumor, should such a step be found advisable.

Treatment of Ovarian Tumor.—1. *By Medical means.* These cannot possibly exercise any curative influence, or in any way materially retard the progress of the disease. Specific treatment by mercury or iodine only hastens the progress of the malady, by breaking down the constitutional powers of the patient; and attempts at promoting the absorption of the fluid by purgatives, diuretics, etc., are invariably unsuccessful. The utmost that can be done by medical treatment in ovarian disease is to attend to the general

health, and to support the patient's strength by tonics, pending the removal of the tumor.

2. *Tapping in ovarian dropsy* was formerly recommended as a palliative mode of treatment, occasionally resulting in a cure. That this may possibly follow in the case of a unilocular serous cyst of the broad ligament is doubt can be entertained; but experience has shown that after withdrawal of the fluid from a true ovarian cyst, reaccumulation invariably takes place, necessitating more and more frequent repetition of the tapping, if the treatment be persisted in, until the patient finally dies exhausted. The operation, therefore, not only holds out no prospect of cure; but, as a matter of fact, its adoption is usually the precursor of a more rapidly fatal termination to the case than would otherwise occur. For, in addition to the many immediate risks attendant upon the procedure, such as wound of a vessel in the abdominal wall, in the subjacent omentum, or in the cyst-wall itself, puncture of adherent intestine or urinary bladder; escape of irritating ovarian fluid into the peritoneal cavity, etc.; tapping entails also certain remote dangers which render its adoption of very questionable advantage to the patient, even when undertaken as a means of temporary relief. Foremost among these may be mentioned adhesive peritonitis, inflammation of the cyst-wall, suppuration of its contents—conditions which, if not rapidly fatal, must very seriously complicate any future attempt to extirpate the tumor. Even though some of these untoward events should result, yet the operation, unless performed with the strictest antiseptic precautions, is always liable to induce septic contamination of the cyst-fluids, a state of things which, although not necessarily leading to any obvious trouble at the time, will surely tend to diminish the patient's chance of recovery from a subsequent ovariectomy by exposing her to the risk of septicæmia. Finally, the puncture in the cyst-wall may find some cause or other remain unsealed, thus allowing free escape of ovarian fluid into the peritoneal cavity with all its attendant dangers, among which not the least is that of malignant infection of the peritoneum from a protruding papillomatous growth.

The above enumeration of the dangers incurred through tapping ovarian cysts is in accordance with the experience of those surgeons who have had the fullest opportunities of judging of the results of this operation, and it is not too much to say that the procedure is one to which recourse should but very rarely be had, only when rendered justifiable by exceptional circumstances.

As a means of relieving urgent dyspnoea, tapping is clearly applicable only to unilocular cysts, or to those multilocular tumors in which one cavity largely predominates in size over its neighbors. When imperatively called for with this view, the operation should invariably be performed with the strictest antiseptic precautions, including the use of the carbolic spray in order to obviate the risks of septic infection of the cyst contents. The puncture may be made through the linea alba, as in the case of ordinary ascites; but not unfrequently the tumor presents more distinctly at some other part of the abdominal wall, and the point selected may be varied accordingly, care being taken always to choose a spot free from intestinal resonance, and sufficiently remote from the pubes to avoid any possibility of puncturing the bladder which may be drawn up in front of the tumor.

Incision and Drainage is a method of treatment occasionally applicable with advantage in exceptional cases of universally adherent suppurated cysts, when attempted extirpation of the tumor would entail extreme risk to life, owing to the probability of rupture of the cyst-wall during its removal—an accident most likely to prove fatal, as involving the escape of irritant septic matter into the peritoneal cavity. The operation in such instances

involves a short incision in the usual situation, of sufficient extent to enable the Surgeon to judge of the closeness of the parietal adhesions, and by puncture of the cyst to determine the putrid nature of its contents. After thorough evacuation and sponging out of the cyst-cavity with a strong solution of iodine, a glass drainage-tube should be inserted, and the incision closed by means of sutures connecting the cyst with the margins of the opening in the abdominal wall. The subsequent management of the case involves frequent withdrawal of fluid from the tube by means of a suitable syringe, and the use of some efficient antiseptic to prevent putrefaction of the discharges. Under this treatment, the cyst-cavity rapidly contracts, and finally closes entirely.

Other means of dealing with unilocular ovarian cysts have from time to time been suggested, all aiming at the same principle, viz., that of inducing gradual contraction of the cyst and cohesion of its walls. But of the procedures advocated, that above described is the only one to be at all recommended, and that only in the exceptional instances alluded to. No operation, however, short of complete extirpation, can be looked upon as surely curative, since, even after incision and drainage, followed apparently by complete contraction, it not uncommonly happens that secondary cysts develop in the wall or base of the original tumor, and eventually a multilocular growth may be substituted for what was apparently in the first instance a unilocular cyst. These measures have consequently, wherever possible, given way to the safer and far more certain procedure of ovariectomy.

Ovariectomy is probably the greatest triumph of modern Surgery in its operative department. In its original conception, as in its ultimate perfection, it reflects the greatest lustre on the British School of Surgery.

Its history is curious. Its progress was slow, and was marked by those oscillations in the judgment and the favor of the Profession which frequently precede the final establishment of a great advance in practice. The operation was originally proposed, and its practicability discussed in 1762, by William Hunter. It was strongly advocated and its practicability taught by John Bell, at a later period. It is said to have been performed in France, by L'Aumonier, in 1782, in a case of "scirrhus disease with abscess" of the ovary, the patient recovering. A pupil of John Bell—McDowell, of Kentucky, who is the father of ovariectomy—first performed the operation in America in 1809; and in all operated thirteen times. In 1823, Lizars operated for the first time in this country. But the operation, though several times repeated, fell into discredit, in a great measure, owing to the imperfection of the diagnosis of the cases in which it was done, and was not revived until 1836, when Jeaffreson, of Framlingham, practised it successfully through a small incision an inch and a half long only. From this operation we must date the revival of ovariectomy in Great Britain. This operation was followed by others performed by King, of Saxmundham, Crisp, of Harleston, and West, of Tonbridge. The example of these provincial Surgeons was followed by their brethren in London, and the operation was practised by many, especially by Walne, F. Bird, and Baker Brown, but with very discouraging results; for of 162 cases collected by Robert Lee, in 60 the disease could not be removed, and of these 19 died; whilst of the remaining 102, 42 terminated fatally. Not only did these unfavorable results discourage the Profession, but a growing belief sprang up that this mortality, great as it was, did not by any means represent the whole extent of the fatal cases, and notwithstanding that C. Clay, of Manchester, continued to operate, ovariectomy was in great danger of falling into such disrepute as to be excluded from ordinary surgical practice. In 1857 appears for the first time in connection with ovariectomy the name of a Surgeon, who was not only destined to revive

ovariotomy, but to reëstablish it firmly and definitely amongst the great operations in surgery; for in December of that year Sir Spencer Wells performed his first operation of this kind. This case, the first of a series of 1000 cases that he had performed up to the year 1881, led to a revival of the operation. In Sir Spencer Wells's hands, ovariotomy assumed a new state; its performance was guided by definite rules, the operative details were carefully worked out and systematized, and the after-treatment much improved. The results obtained showed a gradually increasing success, thus, of the first series of 100 cases published, 34 cases died and 66 recovered; of the second series, 28 died and 72 recovered; of the third 100 cases, 23 died and 77 recovered; while of the last 100, completing his 1000 cases, only 11 died and 89 recovered; this representing in 1880 a mortality less than a third of that recorded in 1860. These results, admirable as they are, have been still further improved upon during late years by other well-known workers in the field of Surgery, and the procedure, formerly so fatal as to be pronounced unjustifiable, is now the most successful of all great surgical operations.

In comparing the decreased mortality after ovariotomy at the present day, with that which obtained even so recently as ten years ago, there are four important factors connected with the operation as now practised which must be taken into account: (1) the diminution in the number of cases which have been tapped previous to operation; (2) the system of drainage of the peritoneal cavity; (3) the general adoption of the intraperitoneal treatment of the pedicle; (4) the systematic employment of antiseptics in abdominal surgery.

With regard to the *first* of these, there can be no doubt that the practice of tapping ovarian cysts, formerly so commonly in vogue, had much to answer for in retarding the progress of ovariotomy. The disastrous consequences of the procedure failed from some cause or other sufficient to oppress the mind of the profession at large; and, until within the last ten years, tapping was looked upon as the proper preliminary treatment before recommending abdominal section. That such a course should have appeared justifiable in the early times of ovariotomy, when the diagnosis of ovarian disease was comparatively in its infancy, is not unnatural; but, at the present day, when the study of abdominal tumors has been so greatly perfected, the fact that tapping is an operation to be looked upon with the greatest distrust, is daily becoming more generally recognized; and this belief has undoubtedly contributed to the success of ovariotomy.

The *second* factor alluded to, viz., drainage of the abdominal cavity practised by the insertion at the lower extremity of the abdominal incision of a glass tube reaching to the bottom of Douglas's pouch, has certainly taken a share in reducing the mortality after the operation. The value of this method, as a means of preventing the accumulation in the peritoneal cavity of fluids liable to undergo septic changes is undoubtedly great; but its employment nevertheless involves certain disadvantages which must not be lost sight of. Foremost among these are the risk of entry of the causes of peritonæal infection along the track of the tube; the possible irritation caused by its presence, involving the danger of intestinal obstruction from the formation of lymph around its extremity; the tendency to subsequent weakening of the cicatrix at the seat of its insertion; and, finally, the inconvenience to the patient caused by the frequent dressings necessitated by its presence, which in some degree prevent that absolute quiet so beneficial to a rapid convalescence after ovariotomy. In view of these objections, it is fortunate that the antiseptic system, by the protection which it affords against sepsis, now enables the Surgeon to dispense with drainage in the great majority of instances where its use would formerly have been justly deemed essential.

The *third*, and perhaps the most important, factor in the increased success of ovariectomy, has been the general adoption of the intraperitoneal method in the treatment of the pedicle, as opposed to the extraperitoneal method, by means of the clamp, which was formerly used to a very large extent. The disadvantages of the clamp are now so self-evident, that it is difficult to understand how it should so long have held its ground against the ligature. Certainly the practice of tying the pedicle with a silk thread, cutting the ends short off, and returning the stump, is the simplest and, if properly managed, the safest plan of treatment; and it is now universally adopted in dealing with ovarian tumors. The use of the actual cautery, either alone or more commonly combined with that of the ligature, is still continued by some few operators, but appears to possess little, if any, advantage over the more usual method, even in cases where the condition of the pedicle is most favorable for its employment.

The *last*, but by no means the least important, of the factors mentioned as having of late years influenced the mortality after ovariectomy, is the application of the antiseptic system to abdominal surgery. Although the utmost importance had for long been attached by all operators to the employment of the strictest hygienic measures both during and after the performance of ovariectomy, it is only within the last five or six years that the antiseptic treatment has been systematically applied to the operations of this nature.

The extent to which it is necessary to carry out so-called strict Listerism, may still, possibly, be a matter for discussion, but of the now well-established value of antiseptics in these operations, as shown by published results, no doubt can be entertained.

The advocates for the use of the strictest antiseptic precautions in ovariectomy, recommend their employment on the following grounds, viz.: that, since their introduction, the rate of mortality has diminished; the after-treatment is simplified; recovery is more rapid and complete; and drainage can be dispensed with, thus obviating the liability to ventral hernia as a result of the operation.

Those who object to the use of antiseptics, base their practice on the following statements: that they are unnecessary—the diminution in the rate of mortality being due to circumstances other than the employment of antiseptics, such as increased personal experience, the diminution in the number of cases which have been tapped before operation, the general adoption of improved methods of hygiene and cleanliness, and the employment during the operation of special means for cleansing the peritoneal cavity.

The true estimate of the relative value of these conflicting statements may be safely left to time; but meanwhile the fact remains, that the employment of antiseptics in abdominal surgery is rapidly gaining ground, as the beneficial effects of the method are becoming more widely recognized.

In the days when the results of ovariectomy were much less good than they now are, the opinion generally held was in favor of postponing any surgical interference so long as the patient was tolerably free from pain and able to move about. Of late years, however, the increasing success of the operation, together with the fuller recognition of the serious risks entailed by delay in such cases, has led to the belief that an ovarian tumor should be removed so soon as its nature and connections can be clearly ascertained, and its presence is beginning in any way to affect the patient's well-being.

Preparation of the Patient.—No special medical treatment is as a rule necessary, beyond attending to the state of the bowels. In the case, however, of a very large tumor of long standing, when the urine is scanty and highly concentrated, depositing quantities of mixed urates, benefit will be derived from the administration of full doses of citrate of potash or lithia

during the forty-eight hours preceding operation, combined with the employment of a hot bath, should the skin be habitually dry and discolored. Finally, a full dose of castor oil or some equivalent aperient should be given the evening before, to be followed by an enema administered in the morning of the operation, to insure thorough evacuation of the lower bowels.

The room selected for the operation and for subsequent occupation of the patient, must be thoroughly clean, airy, and well ventilated, it must have an open fire-place. A trustworthy and competent nurse, accustomed to the use of the female catheter, and to the giving of nutrient injections, should be chosen to take sole charge of the case; she, as well as all concerned in the operation, ought to be completely free from any taint of recent septicaemia.

All sponges and instruments, previously well cleansed, must be immersed in a warm 2 per cent. solution of carbolic acid, and placed within reach of the operator's hand. The silk employed for ligatures, sutures, &c. should be thoroughly purified by soaking in a 5 per cent. solution of acid for an hour or two before being used. It is an important rule, for various reasons, carefully to count the sponges and artery-forceps in use immediately before commencing the operation, so as to prevent the possibility of any subsequent doubt as to their number.

After the bladder has been emptied by means of the catheter, the patient is put in her night-dress and wearing a flannel bed-jacket and warm stockings.

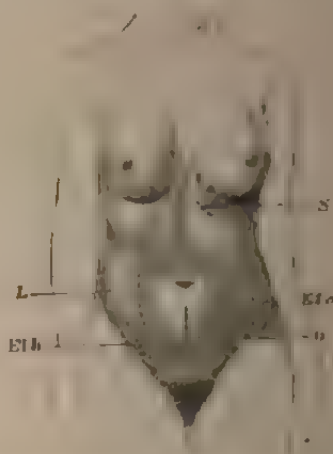

Fig. 934. — Diagram showing the incisions in the following operations: *EJa.* and *EJo.* *L.* of External Ilia according to Abernethy and according to Cooper. *L.* Abdominal S. rectomy. *O.* Ovariectomy. *S.* Gastrostomy.

placed upon the operating table with her head and shoulders carefully supported by pillows. Anæsthesia having been induced, the lower limbs wrapped in a blanket are secured by a broad strap buckled across just above the knees, while her hands are fastened on either side of the table. A thin muslin sheet, large enough entirely to cover the patient from the shoulders downwards, and having an opening in the centre four inches by six, coated over with adhesive material, is next applied to the abdomen, of which the skin, previously well cleansed with soap and water, should be sponged over with carbolic lotion before turning on the spray. The Surgeon, standing on

right side of the patient, is faced by his assistant on the opposite side of the table.

Operation.—No definite rule can be laid down as to the length of the incision, beyond stating that while necessarily proportionate to the size and nature of the tumor, it should in all cases be as limited as possible. A small cut, two to three inches long, extending in the mid-line to within an inch of the pubes, will suffice for the removal of any simple cyst; and, if necessary, may readily be prolonged upwards. All hemorrhage from bleeding points in the abdominal wall having been arrested by the application of Wells's pressure-forceps, the peritoneum must be divided, care being taken to open it fairly; for, if adherent, it may readily be mistaken for the cyst-wall, and so stripped off the under surface of the abdominal muscles.

On exposing the tumor, any soft parietal adhesions in the immediate neighborhood of the incision may be separated by the Surgeon's finger. The growth if cystic, should then be tapped with Wells's trocar, care being taken to avoid the escape of any fluid into the abdominal cavity by fixing the edges of the puncture with the trocar-clamps, which enable the operator to extract the gradually collapsing cyst. Should this prove impracticable owing to the multilocular nature of the growth, the trocar must be carefully withdrawn after applying Nélaton's forceps, and the puncture in the cyst-wall sufficiently enlarged to permit of the Surgeon's introducing his hand for the purpose of breaking down the contents of the tumor. If still unable to extract it, he must prolong his incision upwards, and carefully separate any parietal, omental, or intestinal adhesions which may be present, applying pressure-forceps as required to all bleeding points. Immediately after the extraction of the tumor, a flat sponge squeezed thoroughly dry, should be introduced for the purpose of protecting the intestines and preventing their protrusion.

The pedicle is now examined and its connection with the uterus clearly defined. As a rule, it is most convenient to tie it before cutting away the tumor; but, if desirable, it may be temporarily secured with strong pressure-forceps during division, and then dealt with subsequently. The following is an efficient method of procedure: a single thread is first passed at a point just internal to the large plexus of veins in the outer edge of the pedicle, and securely tied so as to include the plexus, together with the ovarian artery which runs along this border. The pedicle is next transfixed centrally with a double ligature, and tied in equal halves, care being taken that the loops interlace at the seat of puncture. Pressure-forceps are then applied to either border on the distal side of the ligatures, and the tumor is cut away. Finally a single loop of stout silk is tied firmly round the stump, either exactly in or immediately behind the groove formed by the previous ligatures. All the threads should be cut short, and the pedicle be returned, without, however, removing the pressure-forceps, which are left on in order to facilitate a final examination of the stump before closing.

The condition of the remaining ovary should next be ascertained; and if diseased, it should be removed.

Parietal adhesions, unless of long standing, do not as a rule require ligature, temporary compression by forceps usually sufficing for the arrest of hemorrhage. Should there, however, be general oozing from a somewhat extensive surface, the application of a sponge moistened with strong Liq. Ferri Perchloridi will serve readily to control it. Bands of pelvic adhesions must always be tied as near as possible to their seat or origin, and cut short. Omental and intestinal adhesions need careful management; the former should be dealt with either by transection and tying off in sections, or else by separate ligature of bleeding vessels; the latter, if extensive, may

require to be laced by a fine continuous suture involving only the peritoneal coat of the intestine.

The peritoneal cavity should now be thoroughly and systematically spunged out, care being especially directed to the uterine pouches, and to the lumbar regions. The pedicle is again examined to make certain that it is left secure: the forceps holding it are removed, and it is dropped in. A small flat sponge is then introduced for the purpose of protecting the intestines during the insertion of the sutures, for which no better material is employed than fine silk, passed at intervals of about half an inch. To form a satisfactory cicatrix, each stitch should include the edges of the sheath, the rectus muscles, in addition, of course, to the peritoneum, which is the most important layer of any in the wall. Before closing, all sponges and forceps are carefully counted to make sure that none are missing.

Should drainage be deemed advisable, a glass tube of the required length is introduced to the bottom of Douglas's pouch from the lower end of the abdominal incision, a suture thread being left untied at the point of insertion so as to permit of subsequent closure of the opening. The use of a rubber sheet, perforated in the centre so as to fit closely round the end of the tube, will greatly facilitate the after-management.

Finally a dry dressing, preferably of carbolic gauze, is applied and fastened in place by broad straps of adhesive plaster, over which a flannel band is fastened securely round the patient's abdomen before placing her in bed.

After-treatment.—On recovery from the anæsthetic, an opiate should once be administered, either in the form of a hypodermic injection of morphia or perhaps more conveniently as the ordinary *Liq. Opi.*, of which two drops may be given by the bowel, and repeated as required, usually once every six hours, for the first three or four days. Should sickness be troublesome, nothing need be given by the mouth for the first twenty-four or thirty-six hours beyond a little ice, plain soda-water, or brandy and water; and which milk and water may be tried, to be succeeded, if retained, by plain bread and milk.

In the mean time nutrient injections of beef-tea with or without the addition of a tablespoonful of port wine, administered every three or four hours will probably be of service: the nurse being directed to introduce a rubber tube before each injection in order to facilitate the escape of flatus. Urine should be drawn off by the catheter four times daily for the first three days, or until the patient be able to pass it naturally. If all be going well, ordinary light diet, such as milk-pudding, fish, or chicken, may be allowed on the third or fourth day. Should there be much fever at any time, application of an ice bladder to the head will soothe and tranquilise the patient, and promote reduction of the temperature. As a rule, the bowels may be left undisturbed until they show some inclination to act, when they may be assisted by an enema. Finally the stitches should be removed on the seventh or eighth day, and the patient may be allowed to leave bed at the end of the second week, wearing a suitable abdominal belt.

After recovery from ovariectomy, the cure is usually complete.

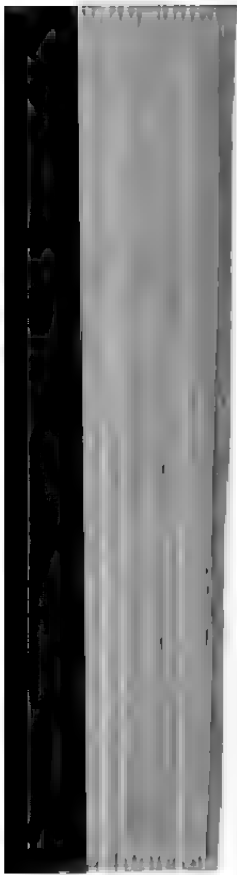

HERNIA OF THE OVARY.—It may happen that the ovary, on one or both sides, becomes displaced, and escapes from the pelvis through one of the openings which give passage to intestinal hernia. In three-fourths of the recorded cases (twenty-seven out of thirty-eight, according to Eschsché, Vienna) the displacement has been inguinal. In nearly one-half of the cases it was congenital; all these were instances of inguinal displacement, and the instances of double ovarian hernia were inguinal and congenital.

The *causes* of the displacement in the adult are not easily ascertained.

the congenital cases it would seem as if an abnormal descent of the ovary took place, analogous to the descent of the testis in the male.

Symptoms.—Congenital ovarian hernia is nearly always irreducible; while in most cases of acquired displacement of the ovary, it has been possible to return the tumor into the abdomen. The swelling is generally pyriform in the inguinal region, rounder in the femoral. There is no constant diagnostic symptom; but in several instances it has been noticed that the hernia became more tender on pressure, and larger, during menstruation. At this time, also, inflammation of the ovary may take place; and, being attended with vomiting, may lead the Surgeon to imagine that the case is one of strangulated hernia. The diagnosis here is not easy; indeed, according to Englisch, of twenty cases, in which symptoms of strangulated hernia were present, a correct diagnosis was made in seven only. The difficulty of diagnosis would be much increased if an intestinal or omental hernia were present with the ovarian. Abscess or sloughing of the displaced ovary occasionally occurs.

Treatment.—So long as the hernia presents no special symptoms there is little or no occasion for interference, beyond the wearing of a properly fitted truss. If inflammation occur, the case must be treated on ordinary principles; and if the ovary suppurate, the abscess should be opened. When the ovary is very painful, or has become cystic, extirpation may be practised.

APPENDIX.

CORROSIVE SUBLIMATE AS AN ANTISEPTIC.

[PAGES 211-216.—VOL. I.]

SINCE the early part of the present edition was revised, Corrosive Sublimate has come extensively into use as an antiseptic in surgical practice. Attention was first directed to it by Koch, who showed experimentally that even in the extreme dilution of one part in 20,000 of water it is capable of killing the spores of the bacillus anthracis, the most resisting of all known organisms. The results of these experiments cannot, however, be applied without modification to the prevention of decomposition in albuminous fluids, for corrosive sublimate forms with albumen a compound known as "mercuric albuminate" which, although not inert, possesses far less active properties than the watery solution. Thus Mikulicz found that the addition of one part of corrosive sublimate to 2000 parts of a mixture of equal parts of blood and water entirely failed to retard putrefaction and the development of bacteria; when added in the proportion of 1 in 1000 these processes were retarded, but not prevented, and it was not until the proportion of 1 in 400 was reached that the decomposition and the development of bacteria were completely excluded. Sir Joseph Lister has further demonstrated by a series of most interesting experiments that the mercuric albuminate is precipitated from blood-serum by the addition of corrosive sublimate, is soluble in excess of serum, and the solution thus formed is powerfully antiseptic, while at the same time its irritating properties are greatly diminished.

From these observations it is evident that although a weak watery solution is thoroughly efficient for cleaning sponges; disinfecting the Surgeon's hands or the skin round an operation wound, and for irrigation during the performance of an operation, a much stronger preparation is required to prevent putrefaction in the albuminous discharges which soak the dressing.

The strength generally agreed upon as the best for the watery solution is 1 in 1000, or 8½ grains to the pint. The solution may be conveniently

prepared as follows: take 2 parts (by weight) of corrosive sublimate in powder and add it to 3 parts (by weight) of glycerine; place it in a warm place and shake it occasionally till solution is complete. One fluid-drachm of this added to four pints of water gives a solution of 1 in 1000. Corrosive sublimate in this strength cannot be used to disinfect metal instruments, as it acts powerfully upon them. This must therefore be done, as already described, in a solution of carbolic acid.

Silk for sutures or ligatures may be prepared by soaking it in 1 per cent. solution of the sublimate for two hours, after which it may be kept in the 1 in 1000 solution. Catgut may be prepared by soaking it for twelve hours in a 1 in 1000 watery solution, after which it may be kept in a 1 in 400 alcoholic solution to which one-tenth part of glycerine is added.

The sublimate dressings have been very various, but all are composed of some absorbent material impregnated with mercuric chloride in varying proportions. Spun-glass, gauze, jute, absorbent cotton-wool, peat, sawdust, moss, ashes, sand, and a variety of other substances have been thus prepared. The following may be given as a typical specimen of a sublimate dressing. One part of corrosive sublimate is dissolved in 224 of water and 25 of glycerine, forming a solution of the strength of 1 in 250. Jute, gauze, or absorbent wool is then soaked in the solution, squeezed forcibly in a press to get rid of the excess, and then allowed to dry as far as the glycerine will permit. Bruns has used as the basis a material known as "wood-wool" prepared by grinding pine wood, and sawdust may be equally well prepared in the same way. These and other similar preparations are applied in bags of the prepared gauze.

Sir Joseph Lister, as the result of the experiments above quoted, was led to suggest the use of corrosive sublimate dissolved in blood-serum obtained from slaughter-houses as the material for impregnating the gauze, the mercuric albuminate possessing comparatively slight irritating properties. He has found that gauze impregnated with a preparation containing 1 of sublimate to 100 of serum is perfectly unirritating and in fact most skins can bear 1 to 50 without inconvenience.

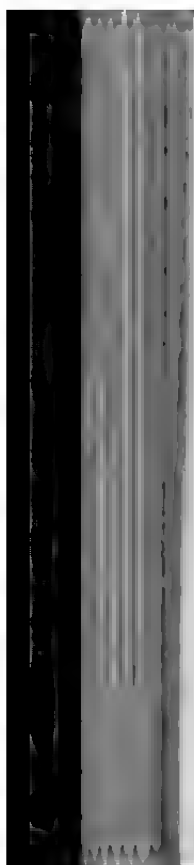

The results obtained by the use of corrosive sublimate have been so far very satisfactory as regards the prevention of septicæmia, pyæmia, and erysipelas. The wounds seem to unite well, primary union being obtained in the majority of cases, especially when the sublimate preparations have been used as "lasting dressings." These good results have not, however, been universal. The ordinary preparations are frequently very irritating and eczema has been a common consequence of their application. It was to avoid this that Sir Joseph Lister devised the non-irritating sero-sublimate dressing, but it remains to be seen whether it will fully attain the

desired object. Salivation and diarrhœa have been but rarely met with, but it must be remembered that in employing mercuric chloride we are dealing with a very dangerous drug. The maximum medicinal dose is contained in about $4\frac{1}{2}$ drachms of the 1 in 1000 solution and it is evident therefore that great caution must be used in syringing out wounds or cleaning the peritoneal cavity with sponges wrung out of the mercurial solution,—in fact, more than one fatal case of mercurial poisoning has already been recorded as resulting from the use of sublimate dressings.

Another important point suggested by Mikulicz also remains to be determined by time, and that is what effect the constant dabbling in strong mercurial solutions will have upon the health of the Surgeon.

Among the advantages of the sublimate dressings, especially in military practice, must be included the cheapness of the materials, the concentrated form in which it can be carried, and the ease with which almost any absorbent substance can be impregnated with it without the employment of any special apparatus.

So far as the evidence goes at present, it may be said that mercuric chloride has been proved to be a most powerful and efficient antiseptic and to be capable of being safely used in the treatment of wounds, but as with all other really potent antiseptics, it is locally irritating and generally poisonous and as it possesses these properties in a higher degree than most others, a corresponding degree of caution is necessary in the preparation of the solution and dressings and in their use.

 of forearm, 502
 of knee-joint, 511
 of lips, congenital, 552
 of muscles, 497
 spasmodic, of sphincter ani, 851
 of sterno-mastoid muscle, 499
 of toes, 529
- Cooper, Sir A.**, ligature of aorta, 252, 253
 duration of life in scirrhus of the breast, 715
 dysphagia from dislocated clavicle, 649
 lacteal tumor, 694
 ligature of external iliac artery, 246
 of subclavian artery, 226
 results of operation for hernia, 779
 serous cyst of breast, 703
- Cooper, Branaby**, lithotomy, 939
 obturator hernia, 804
 treatment of irreducible hernia, 752
- Cooper**, ligature of brachio-cephalic artery, 213, 214, 216
- Copaiba** in gonorrhoea, 1032
- Cord**, spermatic. *See* Spermatic cord
- Corley**, wound of obturator in hernia operation, 799
- Cornil and Ranvier** on acute endarteritis, 110
 on duct-cancer, 716
- Corns**, 46
 treatment of, 47
- Corpus spongiosum**, danger of wounding, in lithotomy, 937
- Corrosive sublimate** as an antiseptic, 1155
- Coulson**, dilated artery doubled upon itself simulating aneurism, 190
 lithotomy at various ages, 909, 940
 mortality from lithotomy, 940
 statistics of lithotomy, 977
- Coupland**, cases of chronic intestinal obstruction, 809
- Coxalgia** (*coxa*, the hip; *algos*, pain), 462.
See Hip disease
- Cracked nipple**, 695
- Cracks in tongue**, 623
- Cranial bones**, necrosis of, 310
- Credé**, cases of extirpation of spleen, 831
- Crippa**, excision of portion of the rectum, 843
- Crisp**, aneurism with regard to sex, 123
 femoral and popliteal aneurisms, 255
 mortality in ligature of larger arteries for aneurism, 147
 results of ligature of femoral, 261
- Croft**, results of excision of hip-joint, 468
- Croft and Greenfield**, microscopical appearances in chronic arthritis, 351
- Crosse**, influence of size of calculus on results of lithotomy, 943
- Croup**, spasmodic, 654
- Cubebs** in gonorrhoea, 1032
- Cuboid bone**, excision of, 413
- Cuneiform bones**, excision of, 413
- Curling**, hydrocele of hernial sac, 741
 spermatozoa in encysted hydrocele, 1112
- Curvature of spine**, angular, 419
 lateral, 489. *See* Spine
- Cusack**, puncture of subclavian aneurism, 227
- Cutaneous eruptions** in gonorrhoea, 1041
- Cuticle of ear**, thickening of, 533
- Cystic** (*κυστις*, a cyst or bladder) bronchocele, 668
 cancer of breast, 718
 hygromata, 559
 sarcocele, 1126
 diagnosis from hydrocele, 1127
 sarcoma, 705, 718
 of testis, 1126

 supra-pubic, 1010
- Cysts in bladder**, 1007. *See* Bladder
 dentigerous, 575
 hydatid, 560
 in neck, 560
 in omentum, 773
 in prostate, 1027
 in thyroid body, diagnosis from aneurism, 191
- Czermak**, the laryngoscope applied by, 655
- Czerny**, ligature of the aorta, 253
- DAVIE**, excision of sternal end of clavicle, 381
- Davies-Colley**, treatment of congenital talipes equino-varus, 525
- Davy**, excision of knee-joint, 399
 treatment of congenital talipes equino-varus, 524

- Ischemia**, 505
 from intra-cranial aneurism, 204
 in veins, 508
- DEFORMITIES**, 489
 of arm and hand, 501
 of face and neck, 499
 of leg and foot, 508
 of neck and limbs, 495
 of spine. See Spine.
- Degeneration of arterial tissue**, 116
 a cause of aneurism, 122
- Delahaye**, mesial fissure of upper lip, 606
- Delens**, intra-orbital aneurism, 208
- Delore**, treatment of gend. vagina, 506
- Dezome**, distal ligature of carotid, 199
- De-Mongin**, drainage in empyema, 686
- Dentigerous cysts**, 575
- Dental tumors**, 575
- Dentition in rickets**, 315
- Depressed nose**, operation for, 604
- Desormaux**, granular urethritis, 1030
- Detached portions of body**, restoration of, 594
- Diaphragmatic hernia**, 805
- DIATHESIS (diath)**, arrangement or disposition, aneurismal, 181
 hemorrhagic, 105
- Dickinson**, causes of acute suppurative nephritis, 884
 pathology of tetanus, 65
- Didot**, treatment of webbed fingers, 507
- Dieulafoy**, tapping the pericardium, 631
 aspirator. See Aspirator
- Diffused abscess of breast**, 700
 aneurism, 127, 136
 hydrocele of spermatic cord, 1113
 interstitial nephritis, 878
 pyo-cellulitis, 941
 phlebitis, 84
- Digital compression in aneurism**, 164
 in axillary aneurism, 223
 in carotid aneurism, 191
 in intra-orbital aneurism, 209
 in subclavian aneurism, 211
- Dilatation of prostate in lithotomy**, 925, 944
 of urethra for calculus in female, 987
 in stricture, 1051, 1057
- Diphtheria**, 669
 diagnosis from tonsillitis, 642
- Direct inguinal hernia**, 783
- Disarticulation at shoulder-joint for indurated axillary aneurism**, 234
 for subclavian aneurism, 220
- Discharge, fetid, from ear**, 537
 from nose, 541
- Discharges, utero-vaginal**, 1141
- Dislocation of clavicle, dysphagia from**, 649
 of femur in hip-disease, 447
 of tibia, backwards, in contraction of knee-joint, 515
- Dissecting aneurism**, 117, 127
- Distal ligature for aneurism**, 145
 for carotid aneurism, 198
 for innominate aneurism, 184
 for subclavian aneurism, 219
- Dolbeau**, perineal lithotomy, 978
- Double harelip**, 506
 operation for, 609
 hernia, 740
 inguinal, 785
- Drainage-tubes in empyema**, 686
- Drill for ankylosed joint**, 517
- Dropsy of antrum**, 574
 diagnosis from tumors of jaw, 577
 ovarian, treatment of, 1145
- Dublin surgeons**, compression of aneurism introduced by, 152
- Duchassay**, cases of intussusception, 818
- Duchenne**, low claw-foot, 528
 rheumatic paralysis, 78
- Duck-billed speculum**, 1082
- Duct-cancer of breast**, 716
- Dufour**, compression of artery in elephantiasis, 71
- Dullis**, statistics of suprapubic lithotomy, 951
- Duncan**, electro-puncture of aneurism, 169
- Dupuytren**, accident in ligature of subclavian, 227
 bilateral lithotomy, 950
 contraction of fingers, 503, 505
 enterotomy, 777
 ligature of axillary artery, 229
 of brachiocephalic artery, 212
 of carotid, 196
 of subclavian for innominate aneurism, 183
 lithotomy-catch, 551
- Dura mater**, fungus of, 539
- Durham**, ligature of subclavian and carotid, 185
- Dysphagia (dis, badly; dys, to eat from aortic aneurism**, 176
 from carotid aneurism, 648
 from dislocated clavicle, 649
 from foreign bodies in gullet, 647
 from innominate aneurism, 182
 from intrathoracic aneurism, 176
 from oedema of the larynx, 658
 causes of, 648
- Dyspnea (dis, badly; dys, I breathe**
 from aortic aneurism, 176
 from innominate aneurism, 182
 from intrathoracic aneurism, 176
- Dysuria (dis, badly; dys, urine)**, 1036
- EAR**, bloody tumors of, 533
 boils, 533
 concretions in, 533
 diseases of, external, 533
 middle, 531
 catarrh, 535
 eczema, 531
 exostoses, 534
 fetid discharge from, 537
 fibrous tumors of, 533
 gony concretions in, 533
 hypertrophy of, 533
 inflammation of, 533
 malformations, 532

- EAR** (*continued*).
 polypi in, 537
 thickening of cuticle of, 533
Ear-ache, 533
Écraseur (French, *écraseur*, to crush), removal of piles by, 808
 of tongue by, 631, 632
 galvanic, removal of penis by, 1096
 removal of tongue by, 632
Eczema of external ear, 533
 of nipple, 690, 717
ELBOW, ankylosis of, 382
 excision of, 381
Electricity in treatment of aneurism, 142, 168
 deformities, 497
Elephantiasis arabum, 70
 ligature of arteries for, 71
 of scrotum, 70, 1097

STANDARD TEXT-BOOKS.

STILLÉ AND MAISOCH'S NATIONAL DISPENSATORY. New Edition.
Just Ready.

The National Dispensatory: Containing the Natural History, Chemistry, Pharmacy, Actions and Uses of Medicines, including those recognized in the Pharmacopœias of the United States, Great Britain and Germany, with numerous references to the French Codex. By ALFRED STILLÉ, M.D., LL.D., Professor Emeritus of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania, and JOHN M. MAISOCH, Phar. D., Professor of Materia Medica and Botany in Philadelphia College of Pharmacy, Secretary to the American Pharmaceutical Association. Third edition, thoroughly revised and greatly enlarged. In one magnificent imperial octavo volume of 1767 pages, with 311 fine engravings. Cloth, \$7.25; leather, \$8.00; half Russia, open back, \$9.00. With Denison's "Ready Reference Index" \$1.00 in addition to price in any of above styles of binding.

CHARLES' PHYSIOLOGICAL AND PATHOLOGICAL CHEMISTRY.
Just Ready.

The Elements of Physiological and Pathological Chemistry. A Hand-book for Medical Students and Practitioners. Containing a general account of Nutrition, Foods and Digestion, and the Chemistry of the Tissues, Organs, Secretions and Excretions of the Body in Health and in Disease. Together with the methods for preparing or separating their chief constituents, as also for their examination in detail, and an outline syllabus of a practical course of instruction for students. By T. CRANSTOUN CHARLES, M.D., F.C.S., M.S., Formerly Assistant Professor and Demonstrator of Chemistry and Chemical Physics, Queen's College, Belfast. In one handsome octavo volume of 463 pages, with 38 woodcuts and 1 colored plate. Cloth, \$3.50.

FLINT'S PRACTICE. Fifth Edition, with Appendix.

A Treatise on the Principles and Practice of Medicine. Designed for the use of Students and Practitioners of Medicine. With an Appendix on the Researches of Koch, and their bearing on the Etiology, Pathology, Diagnosis and Treatment of Phthisis. By AUSTIN FLINT, M.D., Professor of the Principles and Practice of Medicine and of Clinical Medicine in Bellevue Hospital Medical College, New York. Fifth Edition, revised and largely rewritten. In one large and closely-printed octavo volume of 1160 pages. Cloth, \$5.50; leather, \$6.50; half Russia, \$7.00.

COATS' PATHOLOGY.

A Treatise on Pathology. By JOSEPH COATS, M.D., F.F.P.S., Pathologist to the Glasgow Western Infirmary. In one very handsome octavo volume of 829 pages, with 339 beautiful illustrations. Cloth, \$5.50; leather, \$6.50.

BARTHOLOW ON ELECTRICITY IN MEDICINE. Second Edition.

Medical Electricity. A Practical Treatise on the Applications of Electricity to Medicine and Surgery. By ROBERTS BARTHOLOW, A.M., M.D., LL.D., Professor of Materia Medica and General Therapeutics in the Jefferson Medical College of Philadelphia, etc. Second edition. In one very handsome octavo volume of 292 pages, with 109 illustrations. Cloth, \$2.50.

TAYLOR'S MEDICAL JURISPRUDENCE. Eighth Edition.

A Manual of Medical Jurisprudence. By ALFRED S. TAYLOR, M.D., Lecturer on Medical Jurisprudence and Chemistry in Guy's Hospital, London. Eighth American from the tenth London edition, thoroughly revised and rewritten. Edited by JOHN J. REESE, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania. In one large octavo volume of 937 pages, with 70 illustrations. Cloth, \$5.00; leather, \$6.00; half Russia, raised bands, \$6.50.

LEA BROTHERS & CO.'S
(Late HENRY C. LEA'S SON & CO.)
CLASSIFIED CATALOGUE
 OF
MEDICAL AND SURGICAL
PUBLICATIONS.

In asking the attention of the profession to the works advertised in the following pages, the publishers would state that no pains are spared to secure a continuance of the confidence earned for the publications of the house by their careful selection and accuracy and finish of execution.

The large number of inquiries received from the profession for a finer class of bindings than is usually placed on medical books has induced us to put certain of our standard publications in half Russia; and, that the growing taste may be encouraged, the prices have been fixed at so small an advance over the cost of sheep as to place it within the means of all to possess a library that shall have attractions as well for the eye as for the mind of the reading practitioner.

The printed prices are those at which books can generally be supplied by booksellers throughout the United States, who can readily procure for their customers any works not kept in stock. Where access to bookstores is not convenient, books will be sent by mail postpaid on receipt of the price, and as the limit of mailable weight has been removed, no difficulty will be experienced in obtaining through the post-office any work in this catalogue. No risks, however, are assumed either on the money or on the books, and no publications but our own are supplied, so that gentlemen will in most cases find it more convenient to deal with the nearest bookseller.

THE MEDICAL NEWS.

**A National Weekly Medical Periodical, containing 28 to 32 Quarto
 Pages of Reading Matter in Each Issue.**

THE MEDICAL NEWS endeavors to render efficient assistance in the daily work of the practising physician, surgeon and specialist. Every department of medical science finds adequate representation in its columns, and its plan and arrangement are well calculated to suit the convenience and secure the comfort of its readers. In the

THE MEDICAL NEWS—WEEKLY.

(Continued from first page.)

Original Department its columns are replete with articles of the highest practical value. Its Hospital Reports reflect the modes of treatment adopted in the most celebrated hospitals of the globe, and its Department of Progress contains judiciously chosen translations from all the leading medical periodicals of the world. The Editor's Articles are from the pens of a large and able Editorial Staff, and are everywhere conceded to be the most instructive and scholarly productions of their class in the country. Maintaining a large corps of qualified correspondents in all the medical centres of both hemispheres, THE NEWS is in early receipt, by cable, telegraph or mail, of intelligence from all quarters. It thus unites the energy of a newspaper with the elaboration of a scientific magazine. Its reputation for enterprise in the past is the best guarantee for the future that nothing will be left undone to render it a faithful counsellor and indispensable assistant to every professional man in active practice.

THE AMERICAN JOURNAL of the MEDICAL SCIENCES.

Edited by I. MINIS HAYS, A. M., M. D.,

Is published Quarterly, on the first days of January, April, July, and October, each Number containing over Three Hundred Octavo Pages, fully Illustrated.

In his contribution to "A Century of American Medicine," published in 1876, John S. Billings, U. S. A., Librarian of the National Medical Library, Washington, graphically outlines the character and services of THE AMERICAN JOURNAL. In ninety-seven volumes of this Journal need no eulogy. They contain many original papers of the highest value; nearly all the real criticisms and reviews which we possess; such carefully prepared summaries of the progress of medical science, and abstracts and notices of foreign works, that from this file alone, were all other productions of the past half-century destroyed, it would be possible to reproduce the great majority of the real contributions of the world to medical science during that period.

This opinion of a man pre-eminently qualified to judge is corroborated by the circle of readers of the Journal, which includes the thinkers of the profession in all parts of the world. During the coming year the features of the Journal which have secured unalloyed satisfaction to two generations of medical men, will be maintained in the vigorous maturity.

The Original Department will consist of elaborate and richly illustrated articles from the pens of the most eminent members of the profession in all parts of the world and England.

The Review Department will maintain its well-earned reputation for disinterestedness and impartiality, and will contain elaborate reviews of new works and topics, and numerous analytical and bibliographical notices by competent writers.

Following these comes the Quarterly Summary of Improvements and Discoveries in the Medical Sciences, which, being a classified and arranged compilation of important articles appearing in the chief medical journals of the world, furnishes a compact digest of medical progress abroad and at home.

The subscription price of THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES has never been raised during its long career. It is still sent free of postage for Five Dollars per annum in advance.

Taken together, the Journal and News combine the advantages of the elaborate publication that can be devoted to a quarterly with the prompt conveyance of intelligence by the weekly; while, by special management, duplication of matter is rendered impossible.

It will thus be seen that for the very moderate sum of NINE DOLLARS in advance the subscriber will receive free of postage a weekly and a quarterly journal, both containing the latest advances of the medical sciences, and constituting an equivalent of more than 60 octavo pages stored with the choicest material, original and selected, that can be furnished by the best medical minds of both hemispheres. It would be impossible to find elsewhere so large an amount of matter of the same value offered at so low a price.

LEA BROTHERS & Co.'s PUBLICATIONS—Period., Compendis, Manuals. 3

NOTE. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned; where these are not accessible, remittances for subscriptions may be made at the risk of the publishers by forwarding in registered letters. Address,

LEA BROTHERS & Co., Nos. 706 and 708 Sansom St., Philadelphia.

* * * Communications to both these periodicals are invited from gentlemen in all parts of the country. Original articles contributed exclusively to either periodical are liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author.

All letters pertaining to the *Editorial Department* of *THE MEDICAL NEWS* and *THE AMERICAN JOURNAL OF THE MEDICAL SCIENCES* should be addressed to the *EDITORIAL OFFICES*, 1004 Walnut Street, Philadelphia.

All letters pertaining to the *Business Department* of these journals should be addressed exclusively to LEA BROTHERS & Co., 706 and 708 Sansom Street, Philadelphia.

HARTSHORNE, HENRY, A. M., M. D.,

Lately Professor of Hygiene in the University of Pennsylvania.

A Conspectus of the Medical Sciences; Containing Handbooks on Anatomy, Physiology, Chemistry, Materia Medica, Practice of Medicine, Surgery and Obstetrics. Second edition, thoroughly revised and greatly improved. In one large royal 12mo. volume of 1026 pages, with 477 illustrations. Cloth, \$4.25; leather, \$5.00.

The object of this manual is to afford a convenient work of reference to students during the brief moments at their command while in attendance upon medical lectures. It is a favorable sign that it has been found necessary, in a short space of time, to issue a new and carefully revised edition. The illustrations are very numerous and unusually clear, and each part seems to have received its due share of attention. We can conceive such a work to be useful, not only to students, but to practitioners as well. It reflects credit upon the

industry and energy of its able editor.—*Boston Medical and Surgical Journal*, Sept. 3, 1874.

We can say, with the strictest truth, that it is the best work of the kind with which we are acquainted. It embodies in a condensed form all recent contributions to practical medicine, and is therefore useful to every busy practitioner throughout our country, besides being admirably adapted to the use of students of medicine. The book is faithfully and ably executed.—*Charleston Medical Journal*, April, 1875.

STUDENTS' SERIES OF MANUALS.

A Series of Fifteen Manuals, for the use of Students and Practitioners of Medicine and Surgery, written by eminent Teachers or Examiners, and issued in pocket-size 12mo. volumes of 300-540 pages, richly illustrated and at a low price. The following volumes are now ready: GOULD'S *Surgical Diagnosis*, ROBERTSON'S *Physiological Physics*, BRUCE'S *Materia Medica and Therapeutics*, POWER'S *Human Physiology*, CLARKE and LOCKWOOD'S *Dissectors' Manual*, RALFE'S *Clinical Chemistry*, TREVES' *Surgical Applied Anatomy*, PEPPER'S *Surgical Pathology*, and KLEIN'S *Elements of Histology*. The following are in press: BELLAMY'S *Operative Surgery*, BELL'S *Comparative Physiology and Anatomy*, PEPPER'S *Forensic Medicine*, and CURRIE'S *Medical Applied Anatomy*. For separate notices see index on last page.

SERIES OF CLINICAL MANUALS.

In arranging for this Series it has been the design of the publishers to provide the profession with a collection of authoritative monographs on important clinical subjects in a cheap and portable form. The volumes will contain about 550 pages and will be freely illustrated by chromo-lithographs and woodcuts. The following volumes are just ready: TREVES on *Intestinal Obstruction*; and SAVAGE on *Insanity and Allied Neuroses*; The following are in active preparation: HUTCHINSON on *Syphilis*; BRYANT on the *Breast*; MORRIS on *Surgical Diseases of the Kidney*; BROADBENT on the *Pulse*; BUTLIN on the *Tongue*; OWEN on *Surgical Diseases of Children*; LUCAS on *Diseases of the Urethra*; MARSH on *Diseases of the Joints*, PICK on *Fractures and Dislocations*, and BALL on the *Rectum and Anus*. For separate notices see index on last page.

NEILL, JOHN, M. D., and SMITH, F. G., M. D.,

Late Surgeon to the Penna. Hospital.

Prof. of the Institutes of Med. in the Univ. of Penna.

An Analytical Compendium of the Various Branches of Medical Science, for the use and examination of Students. A new edition, revised and improved. In one large royal 12mo. volume of 974 pages, with 374 woodcuts. Cloth, \$4; leather, \$4.75.

LUDLOW, J. L., M. D.

Consulting Physician to the Philadelphia Hospital, etc.

A Manual of Examinations upon Anatomy, Physiology, Surgery, Practice of Medicine, Obstetrics, Materia Medica, Chemistry, Pharmacy and Therapeutics. To which is added a Medical Formulary. Third edition, thoroughly revised, and greatly extended and enlarged. In one handsome royal 12mo. volume of 816 large pages, with 370 illustrations. Cloth, \$3.25; leather, \$3.75.

The arrangement of this volume in the form of question and answer renders it especially suitable for the office examination of students, and for those preparing for graduation.

DUNGLISON, ROBLEY, M. D.,*Late Professor of Institutes of Medicine in the Jefferson Medical College of Philadelphia.*

MEDICAL LEXICON; A Dictionary of Medical Science; Containing a concise Explanation of the various Subjects and Terms of Anatomy, Physiology, Pathology, Hygiene, Therapeutics, Pharmacology, Pharmacy, Surgery, Obstetrics, Medical Jurisprudence and Dentistry, Notices of Climate and of Mineral Waters, Formulae for the most Empirical and Dietetic Preparations, with the Accentuation and Etymology of the Terms, and the French and other Synonyms, so as to constitute a French as well as an English Medical Lexicon. Edited by RICHARD J. DUNGLISON, M.D. In one very large and handsome royal octavo volume of 1,330 pages. Cloth, \$6.50; leather, raised bands, \$7.50; very handsome half Russia, raised bands, \$8.

The object of the author, from the outset, has not been to make the work a mere lexicon or dictionary of terms, but to afford under each word a condensed view of its various medical relations, and thus to render the work an epitome of the existing condition of medical science. Starting with this view, the immense demand which has existed for the work has enabled him, in repeated revisions, to augment its completeness and usefulness, until at length it has attained the position of a recognized and standard authority wherever the language is spoken. Special pains have been taken in the preparation of the present edition to maintain this enviable reputation. The additions to the vocabulary are more numerous than in any previous revision, and particular attention has been bestowed on the accentuation, which will be found marked on every word. The typographical arrangement has been greatly improved, rendering reference much more easy, and every care has been taken with the mechanical execution. The volume now contains the matter of at least four ordinary octaves.

A book of which every American ought to be proud. When the learned author of the work passed away, probably not of us feared that the book should not maintain its place in the advancing science of medicine. Fortunate is Dr. Richard J. Dunglison, having assisted his father in the revision of several editions of the work, and having been, therefore, trained in the methods and imbued with the spirit of the book, has been able to edit it as a work of the kind should be edited—to carry it on steadily, without jar or interruption, along the grooves of thought it has travelled during its lifetime. To show the magnitude of the task which Dr. Dunglison has assumed and carried through, it is only necessary to state that more than six thousand new subjects have been added in the present edition.—*Philadelphia Medical Times*, Jan. 3, 1874.

About the first book purchased by the medical student is the Medical Dictionary. The lexicon explanatory of technical terms is simply a *consequens*. In a science so extensive and with such collateral as medicine, it is as much a necessity also to the practicing physician. To meet the wants of students and most physicians the dictionary must be condensed while comprehensive, and practical while perspicuous. It was because Dunglison met these conditions that it became at once the dictionary of general use wherever medicine was studied in the English language. In no former revision have the alterations and additions been so great. The added terms have been set in black letter, while the derivatives follow in small caps, an arrangement which greatly facilitates reference.—*Continents Lancet and Times*, Jan. 13, 1874.

As a standard work of reference Dunglison's

work has been well known for about forty years, and needs no words of praise on our part to recommend it to the members of the medical, and likewise of the pharmaceutical, profession. The other aspects are in need of a work which gives ready and reliable information on thousands of subjects and terms which they are liable to encounter in pursuing their daily vocation, but with which they cannot be expected to be familiar. The work before us fulfills this want.—*American Journal of Pharmacy*, Feb. 1874.

Particular care has been devoted to derivation and accentuation of terms. With regard to the latter, indeed the present edition may be considered a complete "Pronouncing Dictionary of Medical Science." It is perhaps the most valuable work published for the busy practitioner as containing information on every medical subject in a form for ready access, and with a brevity as admirable as it is practical.—*Southern Medical Record*, Feb. 1874.

A valuable dictionary of the terms employed in medicine and the allied sciences, and of the relations of the subjects treated under each head. It well deserves the authority and popularity it has obtained.—*British Med. Jour.*, Oct. 31, 1874.

For works of this class exhibit a grander monument of patient research and of scientific lore.—*London Lancet*, May 13, 1875.

Dunglison's Dictionary is incalculably valuable, and indispensable to every practitioner of medicine, pharmacologist and dentist.—*Western Lancet*, March, 1871.

It has the rare merit that it certainly has no rival in the English language for accuracy and extent of references.—*London Medical Gazette*.

HOBLYN, RICHARD D., M. D.

A Dictionary of the Terms Used in Medicine and the Collateral Sciences. Revised, with numerous additions, by ISAAC HAYS, M.D., late editor of *The American Journal of the Medical Sciences*. In one large royal 12mo. volume of 520 double-columned pages. Cloth, \$1.50; leather, \$2.00.

It is the best book of definitions we have, and ought always to be upon the student's table.—*Southern Medical and Surgical Journal*.

RODWELL, G. F., F. R. A. S., F. C. S.,*Lecturer on Natural Science at City College, England.*

A Dictionary of Science: Comprising Astronomy, Chemistry, Dynamics, Electricity, Heat, Hydrodynamics, Hydrostatics, Light, Magnetism, Mechanics, Meteorology, Pneumatics, Sound and Statics. Contributed by J. T. Butcher, M.A., F.C.S., William Crookes, F.R.S., F.C.S., Frederick Guthrie, B.A., Ph.D., R. A. Proctor, B.A., F.R.A.S., G. F. Rodwell, Editor, Charles Tomlinson, F.R.S., F.C.S., and Richard Wernell, M.A., B.Sc. Preceded by an Essay on the History of the Physical Sciences. In one handsome octavo volume of 502 pages, with 143 illustrations. Cloth, \$5.00.

GRAY, HENRY, F. R. S.,*Lecturer on Anatomy at St. George's Hospital, London.*

Anatomy, Descriptive and Surgical. The Drawings by H. V. CARTER, M. D., and Dr. WESTMACOTT. The dissections jointly by the AUTHOR and Dr. CARTER. With an Introduction on General Anatomy and Development by T. HOLMES, M. A., Surgeon to St. George's Hospital. Edited by T. Pickering Pick, F. R. C. S., Surgeon to and Lecturer on Anatomy at St. George's Hospital, London, Examiner in Anatomy, Royal College of Surgeons of England. A new American from the tenth enlarged and improved London edition. To which is added the second American from the latest English edition of **LANDMARKS, MEDICAL AND SURGICAL**, by LUTHER HOLDEN, F. R. C. S., author of "Human Osteology," "A Manual of Dissections," etc. In one imperial octavo volume of 1023 pages, with 564 large and elaborate engravings on wood. Cloth, \$6.00; leather, \$7.00; very handsome half Russia, raised bands, \$7.50.

This work covers a more extended range of subjects than is customary in the ordinary text-books, giving not only the details necessary for the student, but also the application to those details to the practice of medicine and surgery. It thus forms both a guide for the learner and an admirable work of reference for the active practitioner. The engravings form a special feature in the work, many of them being the size of nature, nearly all original, and having the names of the various parts printed on the body of the cut, in place of figures of reference with descriptions at the foot. They thus form a complete and splendid series, which will greatly assist the student in forming a clear idea of Anatomy, and will also serve to refresh the memory of those who may find in the exigencies of practice the necessity of recalling the details of the dissecting-room. Combining, as it does, a complete Atlas of Anatomy with a thorough treatise on systematic, descriptive and applied Anatomy, the work will be found of great service to all physicians who receive students in their offices, relieving both preceptor and pupil of much labor in laying the groundwork of a thorough medical education.

Landmarks, Medical and Surgical, by the distinguished Anatomist, Mr. Luther Holden, has been appended to the present edition as it was to the previous one. This work gives in a clear, condensed and systematic way all the information by which the practitioner can determine from the external surface of the body the position of internal parts. Thus complete, the work, it is believed, will furnish all the assistance that can be rendered by type and illustration in anatomical study.

This well-known work comes to us as the latest American from the tenth English edition. As its title indicates, it has passed through many hands and has received many additions and revisions. The work is not susceptible of more improvement. Taking it all in all, its size, manner of make-up, its character and illustrations, its general accuracy of description, its practical aim, and its perspicuity of style, it is the Anatomy best adapted to the wants of the student and practitioner.—*Medical Record*, Sept. 15, 1883.

There is probably no work used so universally by physicians and medical students as this one. It is deserving of the confidence that they repose in it. If the present edition is compared with that issued two years ago, one will readily see how much it has been improved in that time. Many pages have been added to the text, especially in those parts that treat of histology, and many new cuts have been introduced and old ones modified.—*Journal of the American Medical Association*, Sept. 1, 1883.

ALSO FOR SALE SEPARATE—

HOLDEN, LUTHER, F. R. C. S.,*Surgeon to St. Bartholomew's and the Finsbury Hospitals, London.*

Landmarks, Medical and Surgical. Second American from the latest revised English edition, with additions by W. W. KEEN, M. D., Professor of Artistic Anatomy in the Pennsylvania Academy of the Fine Arts, formerly Lecturer on Anatomy in the Philadelphia School of Anatomy. In one handsome 12mo. volume of 148 pages. Cloth, \$1.00.

This little book is all that can be desired within its scope, and its contents will be found simply invaluable to the young surgeon or physician, since they bring before him such data as he requires at every examination of a patient. It is written in language so clear and concise that one ought

almost to learn it by heart. It teaches diagnosis by external examination, ocular and palpable, of the body, with such anatomical and physiological facts as directly bear on the subject. It is eminently the student's and young practitioner's book.—*Physician and Surgeon*, Nov. 1881.

WILSON, ERASMUS, F. R. S.

A System of Human Anatomy, General and Special. Edited by W. H. GORRENT, M. D., Professor of General and Surgical Anatomy in the Medical College of Ohio. In one large and handsome octavo volume of 616 pages, with 397 illustrations. Cloth, \$4.00; leather, \$5.00.

SMITH, H. H., M. D., and HORNER, WM. E., M. D.,*Emeritus Prof. of Surgery in the Univ. of Penna., etc. Late Prof. of Anat. in the Univ. of Penna.*

An Anatomical Atlas, Illustrative of the Structure of the Human Body. In one large imperial octavo volume of 200 pages, with 634 beautiful figures. Cloth, \$4.50.

CLELAND, JOHN, M. D., F. R. S.,*Professor of Anatomy and Physiology in Queen's College, Galway.*

A Directory for the Dissection of the Human Body. In one 12mo. volume of 178 pages. Cloth, \$1.25.

ALLEN, HARRISON, M. D.,*Professor of Physiology in the University of Pennsylvania.*

A System of Human Anatomy, Including Its Medical and Surgical Relations. For the use of Practitioners and Students of Medicine. With an Introductory Section on Histology. By E. O. SHAKESPEARE, M. D., Ophthalmologist at the Philadelphia Hospital. Comprising 818 double-columned quarto pages, with 380 illustrations on 100 full page lithographic plates, many of which are in colors, and 241 engravings in the text. In six sections, each in a portfolio. Section I. HISTOLOGY. Section II. BONES AND JOINTS. Section III. MUSCLES AND FASCIAE. Section IV. ARTERIES, VEINS, AND LYMPHATICS. Section V. NERVOUS SYSTEM. Section VI. ORGANS OF SENSE, OF DIGESTION AND GENITO-URINARY ORGANS, EMBRYOLOGY, DEVELOPMENT, PATHOLOGY, SUPERFICIAL ANATOMY, POST-MORTEM EXAMINATIONS, AND GENERAL AND CLINICAL INDEXES. *Just ready.* Price per Section, each in a handsome portfolio, \$1.50; also bound in one volume, cloth \$25.00; very handsome half Russia, raised bands and open back, \$25.00. *For sale by subscription only. Apply to the Publishers.*

Extract from Introduction.

It is the design of this book to present the facts of human anatomy in the manner best suited to the requirements of the student and the practitioner of medicine. The author believes that such a book is needed, inasmuch as no treatise, as far as he knows, contains, in addition to the text descriptive of the subject, a systematic presentation of such anatomical facts as can be applied to practice.

A book which will be at once accurate in statement and concise in terms; which will be an acceptable expression of the present state of the science of anatomy, which will exclude nothing that can be made applicable to the medical art, and which will thus embrace all of surgical importance, while omitting nothing of value to clinical medicine, would appear to have an excuse for existence in a country where most surgeons are general practitioners, and where there are few general practitioners who have no interest in surgery.

It is to be considered a study of applied anatomy in its widest sense, a systematic presentation of such anatomical facts as will be applied to the practice of medicine as well as of surgery. Our authors are sensible, accurate and practical in his statements, and succeeds admirably in his attempt to present a study of anatomy generally, and indeed a very difficult. The department of Histology is treated in a masterly manner, and the general anatomy covered by a thoroughly familiar and clear text. The illustrations are made with great

care, and are simply superb. There is as much of practical application of anatomical points to the everyday wants of the medical student as to those of the operating surgeon. In fact, a general practitioner will read the work with a feeling of surprised gratification that so clear, precise, and complete a work should be so well presented for the consideration of the student. It is a work which should be the best of its kind in any language.—*Medical Record, Nov. 2, 1882.*

CLARKE, W. B., F.R.C.S. & LOCKWOOD, C. B., F.R.C.S.*Demonstrators of Anatomy at St. Bartholomew's Hospital Medical School, London.*

The Dissector's Manual. In one pocket-size 12mo. volume of 396 pages, with 49 illustrations. Limp cloth, red edges, \$1.50. *Just ready.* See *Students' Series of Manuals*, page 3.

This is a very excellent manual for the use of the student who desires to learn anatomy. The method of dissection is clearly and carefully explained. There are many woodcuts which, for the most

part, are good and instructive. The book is well made and easy to use. We are glad to recommend it.—*British Medical and Surgical Journal, Jan. 17, 1884.*

TREVES, FREDERICK, F. R. C. S.,*Senior Lecturer in Anatomy and Assistant Surgeon at the Lich Hospital.*

Surgical Applied Anatomy. In one pocket-size 12mo. volume of 340 pages, with 61 illustrations. Limp cloth, red edges, \$2.00. *Just ready.* See *Students' Series of Manuals*, page 3.

Here is published a work which is simple and a larger volume than the one for which it was written. The author of the manual, published in conjunction with these fundamental principles

is qualified by daily use as a teacher at a practical hospital, and with a view to prepare a work which should be a practical book for the student.—*The Anatomist, Practitioner, Feb. 1884.*

CURNOW, JOHN, M. D., F. R. C. P.,*Professor of Anatomy at King's College, Physicians' Hall, College Hospital.*

Medical Applied Anatomy. In one pocket-size 12mo. volume. *Prepared.* See *Students' Series of Manuals*, page 3.

BELLAMY, EDWARD, F. R. C. S.,*Senior Assistant Surgeon to the Charing Cross Hospital, London.*

The Student's Guide to Surgical Anatomy: Being a Description of the most important surgical Regions of the Human Body, and intended as an Introduction to operative Surgery. In one 12mo. volume of 390 pages, with 50 illustrations. Cloth, \$2.25.

HARTSHORNE'S HANDBOOK OF ANATOMY AND PHYSIOLOGY. Second edition, revised. In one royal 12mo. volume of 310 pages, with 220 woodcuts. Cloth, \$1.75.

HORNER'S SPECIAL ANATOMY AND PHYSIOLOGY. Eighth edition, extensively revised and enlarged. In two octavo volumes of 107 pages, with 150 woodcuts. Cloth, \$3.00.

DALTON, JOHN C., M. D.,

Professor Emeritus of Physiology in the College of Physicians and Surgeons, New York.

The Topographical Anatomy of the Brain. In three very handsome quarto volumes comprising 178 pages of descriptive text. Illustrated with forty-eight full page photographic plates of Brain Sections, with a like number of outline explanatory plates, as well as many carefully-executed woodcuts through the text. Price for the complete work, \$36. *Just ready. For sale by subscription.* As but few of the copies reserved for this country now remain unsold, gentlemen desiring the work will do well to apply to the publishers at an early date.

This is one of the most magnificent works on anatomy that has appeared during the present generation, and will not only supersede all its predecessors on the topographical anatomy of the brain, but make any further work on the same lines unnecessary. It contains forty-eight exquisite illustrations of the brain *en masse* and in sections. Not only has perfect accuracy been secured, but one of the finest and most artistic works of recent times has been presented to the medical public. Its value as a work of reference is considerably increased by the very careful outline sketches which accompany the plates and which enable them to be easily followed and understood. These sketches are very complete and accurate, and have been reproduced from tracings. The descriptions by the author are clear,

precise and accurate, and the methods by which the sections were made and the specimens reproduced are given very plainly in an introductory chapter, which cannot fail to be of the greatest value to any one desirous of making similar preparations. Criticism on such a work is superfluous. We can only congratulate Dr. Dalton, his assistants, and the publishers on the energy they have shown in undertaking such a work, and the success with which they have overcome a task presenting so many mechanical difficulties. We envy our American confrères the authorship and execution of so beautiful and useful an addition to medical literature. Much light is thrown on some obscure relations of parts of the brain which have never before been seen in correct juxtaposition.—*London Lancet*, April 18, 1885.

BY THE SAME AUTHOR.

Doctrines of the Circulation of the Blood. A History of Physiological Opinion and Discovery in regard to the Circulation of the Blood. In one handsome 12mo. volume of 293 pages. Cloth, \$2. *Just ready.*

In the progress of physiological study no fact was of greater moment, none more completely revolutionized the theories of teachers, than the discovery of the circulation of the blood. This explains the extraordinary interest it has to all medical historians. The volume before us is one of three or four which have been written within a

few years by American physicians. It is in several respects the most complete. The volume, though small in size, is one of the most creditable contributions from an American pen to medical history that has appeared.—*Medical and Surgical Reporter*, Dec. 6, 1884.

ELLIS, GEORGE VINER,

Emeritus Professor of Anatomy in University College, London.

Demonstrations of Anatomy. Being a Guide to the Knowledge of the Human Body by Dissection. From the eighth and revised London edition. In one very handsome octavo volume of 716 pages, with 249 illustrations. Cloth, \$4.25; leather, \$5.25.

ROBERTS, JOHN B., A. M., M. D.,

Prof. of Applied Anat. and Oper. Surg. in Phila. Polyclinic and Coll. for Graduates in Medicine.

The Compend of Anatomy. For use in the dissecting-room and in preparing for examinations. In one 16mo. volume of 196 pages. Limp cloth, 75 cents.

DRAPER, JOHN C., M. D., LL. D.,

Professor of Chemistry in the University of the City of New York.

Medical Physics. A Text-book for Students and Practitioners of Medicine. In one octavo volume of about 700 pages, with 376 woodcuts, mostly original. *In a few days:*

The object of the author has been to present in a clear and concise manner, without undue technicalities, the most modern views of physics in their special bearing on medical science. Familiarity with the laws and principles which govern the relations of force and matter is necessary, not only to a clear comprehension of physiology, but is an indispensable aid to the physician and surgeon in their daily practice; yet the subject is strangely neglected in professional education and is one for which the medical student has no special text-book. This want Professor Draper has endeavored to supply, and his distinguished reputation guarantees such a presentation of the subject that the work will be not only essential to the student, but of importance to the practitioner.

ROBERTSON, J. MCGREGOR, M. A., M. B.,

Medical Demonstrator of Physiology, University of Glasgow.

Physiological Physics. In one 12mo. volume of 537 pages, with 219 illustrations. Limp cloth, \$2.00. *Just ready.* See *Students' Series of Manuals*, page 3.

The title of this work sufficiently explains the nature of its contents. It is designed as a manual for the student of medicine, an auxiliary to his text-book in physiology, and it would be particularly useful as a guide to his laboratory experi-

ments. It will be found of great value to the practitioner. It is a carefully prepared book of reference, concise and accurate, and as such we heartily recommend it.—*Journal of the American Medical Association*, Dec. 6, 1884.

BELL, F. JEFFREY, M. A.,

Professor of Comparative Anatomy at King's College, London.

Comparative Physiology and Anatomy. *Shortly.* See *Students' Series of Manuals*, page 3.

DALTON, JOHN C., M. D.,*Professor of Physiology in the College of Physicians and Surgeons, New York, etc.*

A Treatise on Human Physiology. Designed for the use of Students and Practitioners of Medicine. Seventh edition, thoroughly revised and rewritten. In a very handsome octavo volume of 722 pages, with 252 beautiful engravings on wood. Cloth, \$5.00; leather, \$6.00; very handsome half Russia, raised bands, \$6.50.

The merits of Professor Dalton's text-book, his smooth and pleasing style, the remarkable clearness of his descriptions, which leave not a chapter obscure, his cautious judgment and the general correctness of his facts, are perfectly known. They have made his text-book the one most familiar to American students.—*Med. Record*, March 4, 1882.

Certainly no physiological work has ever issued from the press that presented its subject-matter in a clearer and more attractive light. A most every page bears evidence of the exhaustive revision that has taken place. The material is placed in a

more compact form, yet its delightful charm is retained, and no subject is thrown into obscurity. Altogether this edition is far in advance of any previous one, and we intend to keep the professor posted as to the most recent additions to our physiological knowledge.—*Michigan Medical News*, April, 1882.

One can scarcely open a college catalogue that does not have mention of Dalton's *Physiology*, as the recommended text or consultation book. For American students we would unreservedly recommend Dr. Dalton's work.—*The Med. Monthly*, July, 1882.

FOSTER, MICHAEL, M. D., F. R. S.,*Professor of Physiology in Cambridge University, England.*

Text-Book of Physiology. Third American from the fourth English edition, with notes and additions by E. T. REICHERT, M. D. In one handsome royal 12mo. volume of over 1000 pages, with about 300 illustrations. Cloth, \$3.25; leather, \$5.75. *In a few days* A notice of the previous edition is appended.

A more compact and scientific work on physiology has ever been published, and we believe ourselves not to be mistaken in asserting that it has now been introduced into every medical college in which the English language is spoken. This work conforms to the latest researches in zoology and comparative anatomy, and takes into consid-

eration the late discoveries in physiological chemistry and the experimental-physiology of Furrer and others. The arrangement followed is such as to render the whole subject in clear and well connected in its various parts. *Chicago Medical Journal and Examiner*, August, 1882.

POWER, HENRY, M. B., F. R. C. S.,*Examiner in Physiology, Royal College of Surgeons of England.*

Human Physiology. In one handsome pocket-size 12mo. volume of 396 pages, with 47 illustrations. Cloth, \$1.50. See *Students' Series of Manuals*, page 3.

The prominent character of this work is that of a modern scientific treatise, in which all the most successful attempts to have been made by its author, and to combine the most accurate facts in the latest periodical works. It is not a specimen of conventional intellectual pedantry, but a work of great merit, and it is to be carefully studied and followed by every practitioner who wishes to keep himself abreast of the most progressive of the time and science. The volume is one which we cordially recommend

to every one of our readers.—*The American Journal of the Medical Sciences*, October, 1881.

This little work is deserving of the highest praise, and we can hardly conceive how the mass facts of the science could have been more clearly or more fully stated. The price of the work is so low as to place it within the reach of all, while the excellence of the text will certainly secure for it a most favorable recommendation.—*Continental Lecture and Clinic*, Feb. 16, 1881.

CARPENTER, WM. B., M. D., F. R. S., F. G. S., F. L. S.,*Lecturer in the University of London, etc.*

Principles of Human Physiology. Edited by HENRY POWER, M. B., Lond., F. R. C. S., Examiner in Natural Sciences, University of Oxford. A new American from the eighth revised and enlarged edition, with notes and additions by FRANCIS G. SMITH, M. D., late Professor of the Institutes of Medicine in the University of Pennsylvania. In one very large and handsome octavo volume of 1284 pages, with two plates and 373 illustrations. Cloth, \$5.50; leather, \$6.50; half Russia, \$7.

FOWNES, GEORGE, Ph. D.

A Manual of Elementary Chemistry; Theoretical and Practical. Revised by HENRY WAITS, B.A., F. R. S. New American edition. In one large royal 12mo. volume of over 1000 pages, with 200 illustrations on wood and a colored plate. Cloth, \$2.75; leather, \$3.25. *In press.*

A notice of the previous edition is appended.

This book opens with a treatise on Chemical Physics, including Heat, Light, Magnetism and Electricity. These subjects are treated clearly and briefly, but not given to ensure the student to comprehend the facts and laws of Chemistry proper. The scientific basis of the volume is based on the latest facts from works on Chemistry, but the only one is not to be recommended. As was required by the great advance in the science of Chemistry

of late years, the chapter on the General Principles of Chemistry, which has been of late years considered the latest volume, is replaced by a new volume, etc., are added and five new facts. The last edition is a great improvement upon its predecessor, which was a little of a book, and has now been revised and enlarged.—*The American Journal of the Medical Sciences*, Oct. 1, 1878.

Wöhler's Outlines of Organic Chemistry. Edited by FRIEDE. Translated by IRA REMSEN, M. D., Ph. D. In one 12mo. volume of 550 pages. Cloth, \$3.

GALLOWAY'S QUALITATIVE ANALYSIS. New

edition. **LEHMANN'S MANUAL OF CHEMICAL PHYSICS.** 101 CRY. 12mo. 100 pages, with 41 illustrations. Cloth, \$1.25.

CARPENTER'S PRIZE ESSAY ON THE USE AND ABUSE OF ALCOHOLIC LIQUORS IN MEDICINE AND SURGERY. With explanation of scientific words. 5mo. 100 pages. Cloth, 60 cents.

ATTFIELD, JOHN, Ph. D.,*Professor of Practical Chemistry to the Pharmaceutical Society of Great Britain, etc.*

Chemistry, General, Medical and Pharmaceutical; Including the Chemistry of the U. S. Pharmacopoeia. A Manual of the General Principles of the Science, and their Application to Medicine and Pharmacy. A new American, from the tenth English edition, specially revised by the Author. In one handsome royal 12mo. volume of 723 pages, with 87 illustrations. Cloth, \$2.50; leather, \$3.00.

A text-book which passes through ten editions in sixteen years must have good qualities. This remark is certainly applicable to Attfield's Chemistry, a book which is so well known that it is hardly necessary to do more than note the appearance of this new and improved edition. It seems, however, desirable to point out that feature of the book which, in all probability, has made it so popular. There can be little doubt that it is its thoroughly practical character, the expression being used in its best sense. The author understands what the student ought to learn, and is able to put himself in the student's place and to appreciate his state of mind.—*American Chemical Journal*, April, 1884.

It is a book on which too much praise cannot be bestowed. As a text-book for medical schools it is unsurpassable in the present state of chemical science, and having been prepared with a special view towards medicine and pharmacy, it is alike indispensable to all persons engaged in those departments of science. It includes the whole chemistry of the last Pharmacopoeia.—*Pacific Medical and Surgical Journal*, Jan. 1884.

BLOXAM, CHARLES L.,*Professor of Chemistry in King's College, London.*

Chemistry, Inorganic and Organic. New American from the fifth London edition, thoroughly revised and much improved. In one very handsome octavo volume of 727 pages, with 292 illustrations. Cloth, \$3.75; leather, \$4.75.

Comment from us on this standard work is almost superfluous. It differs widely in scope and aim from that of Attfield, and in its way is equally beyond criticism. It adopts the most direct methods in stating the principles, hypotheses and facts of the science. Its language is so terse and lucid, and its arrangement of matter so logical in sequence that the student never has occasion to complain that chemistry is a hard study. Much attention is paid to experimental illustrations of chemical principles and phenomena, and the mode of conducting these experiments. The book maintains the position it has always held as one of

the best manuals of general chemistry in the English language.—*Detroit Lancet*, Feb. 1884.

The general plan of this work remains the same as in previous editions, the evident object being to give clear and concise descriptions of all known elements and of their most important compounds, with explanations of the chemical laws and principles involved. We gladly repeat now the opinion we expressed about a former edition, that we regard Bloxam's Chemistry as one of the best treatises on general and applied chemistry.—*American Jour. of Pharmacy*, Dec. 1883.

SIMON, W., Ph. D., M. D.,*Professor of Chemistry and Toxicology in the College of Physicians and Surgeons, Baltimore, and Professor of Chemistry in the Maryland College of Pharmacy.*

Manual of Chemistry. A Guide to Lectures and Laboratory work for Beginners in Chemistry. A Text-book, specially adapted for Students of Pharmacy and Medicine. In one 8vo. vol. of 410 pp., with 16 woodcuts and 7 plates, mostly of actual deposits, with colors illustrating 56 of the most important chemical reactions. Cloth, \$3.00; also without plates, cloth, \$2.50. *Just ready.*

This book supplies a want long felt by students of medicine and pharmacy and is a concise but thorough treatise on the subject. The long experience of the author as a teacher in schools of medicine and pharmacy is conspicuous in the perfect adaptation of the work to the special needs of the student of these branches. The colored

plates, beautifully executed, illustrating precipitates of various reactions, form a novel and valuable feature of the book, and cannot fail to be appreciated by both student and teacher as a help over the hard places of the science.—*Maryland Medical Journal*, Nov. 22, 1884.

FRANKLAND, E., D.C.L., F.R.S., & JAPP, Ph. D., F.I.C.,*Professor of Chemistry in the Normal School of Science, London.**Assist. Prof. of Chemistry in the Normal School of Science, London.*

Inorganic Chemistry. In one handsome octavo volume of 600 pages, with 51 woodcuts and 2 lithographic plates. Cloth, \$3.75; leather, \$4.75. *In press.*

This work on elementary chemistry is based upon principles of classification, nomenclature and notation which have been proved by nearly twenty years experience in teaching to impart most readily a sound and accurate knowledge of the science.

REMSEN, IRA, M. D., Ph. D.,*Professor of Chemistry in the Johns Hopkins University, Baltimore.*

Principles of Theoretical Chemistry, with special reference to the Constitution of Chemical Compounds. Second and revised edition. In one handsome royal 12mo. volume of 240 pages. Cloth, \$1.75. *Just ready.*

The book is a valuable contribution to the chemical literature of instruction. That in so few years a second edition has been called for indicates that many chemical teachers have been found ready to endorse its plan and to adopt its methods. In this edition a considerable proportion of the book has been rewritten, much new matter has been added and the whole has been brought up to date. We earnestly commend this book to every student

of chemistry. The high reputation of the author assures its accuracy in all matters of fact, and its judicious conservatism in matters of theory, combined with the fulness with which, in a small compass, the present attitude of chemical science towards the constitution of compounds is considered, gives it a value much beyond that accorded to the average text-books of the day.—*American Journal of Science*, March, 1884.

CHARLES, T. CRANSTOUN, M. D., F. C. S., M. S.*Formerly Asst. Prof. and Demonstrator of Chemistry and Chemical Physics, Queen's College, Belfast.*

The Elements of Physiological and Pathological Chemistry. A Handbook for Medical Students and Practitioners. Containing a general account of Nutrition, Food and Digestion, and the Chemistry of the Tissues, Organs, Secretions and Excretions of the Body in Health and in Disease. Together with the methods for preparing or separating their chief constituents, as also for their examination in detail and an outline syllabus of a practical course of instruction for students. In one handsome octavo volume of 468 pages, with 38 woodcuts and 1 colored plate. Cloth, \$3.50.

The work is thoroughly trustworthy, and informed throughout by a genuine scientific spirit. The author deals with the chemistry of the digestive secretions in a systematic manner, which leaves nothing to be desired, and in reality surpasses a vast English literature. The book appears to us to be at once full and systematic, and to show a just appreciation of the relative importance of the various subjects dealt with.—*British Medical Journal*, November 29, 1884.

Dr. Charles' manual admirably fulfils its intention of giving to readers of the medical and veterinary community a concise but thorough and reliable account of the mass of facts in the chemistry which have to do with the physiology and pathology of the human body, and a system of preparation, distillation, and minute analytical details of the most important substances may be pursued by any intelligent person.—*Archives of Medicine*, Dec. 1884.

HOFFMANN, F. A. M., Ph. D., & POWER F. B., Ph. D.*Public Analyst to the State of New York.**Prof. of Anal. Chem. in the Phil. Coll. of Pharmacy.*

A Manual of Chemical Analysis, as applied to the Examination of Medicinal Chemicals and their Preparations. Being a Guide for the Determination of their Identity and Quality, and for the Detection of Impurities and Adulterations. For the use of Pharmacists, Physicians, Druggists and Manufacturing Chemists, and Pharmaceutical and Medical Students. Third edition, entirely rewritten and much enlarged. In one very handsome octavo volume of 621 pages, with 179 illustrations. Cloth, \$4.25.

We congratulate the author on the appearance of the third edition of this work, which is the first time it has been revised. It is so useful and the information it undertakes to supply is both extensive and trustworthy. The selection of processes for determining the purity of the substances of which it treats is excellent and the descrip-

tion of them singularly exact. Moreover, it is exceptionally free from typographical errors. We have no hesitation in recommending it to those who are engaged either in the manufacture or the testing of medicinal chemicals.—*London Pharmaceutical Journal and Transactions*, 1885.

CLOWES, FRANK, D. Sc., London.*Senior Science Master at the High School, Newcastle-under-Lyme, etc.*

An Elementary Treatise on Practical Chemistry and Qualitative Inorganic Analysis. Specially adapted for use in the Laboratories of Schools and Colleges and by Beginners. Third American from the fourth and revised English edition. In one very handsome royal 12mo. volume of about 400 pages, with about 50 illustrations. Cloth, \$2.50. In a few days.

The clear and for more editions of this work proves the success of Professor Clowes' effort to provide a simple, concise and trustworthy guide to qualitative analysis. The use and preparation of apparatus, and the directions for working have been so fully and clearly detailed that the work is admirably adapted not only to relieve the teacher of unnecessary labor, but also to answer all the requirements of self-instruction.

RAFFE, CHARLES H., M. D., F. R. C. P.,*Assistant Physician at the London Hospital.*

Clinical Chemistry. In one pocket-size 12mo. volume of 314 pages, with 16 illustrations. Limp cloth, red edges, \$1.00. See *NEURASTHENIA*, page 3.

This is one of the most instructive little works that have been put with a working chemist. The author is a physician and a physiologist, as well as a chemist, and by the book is written for the physician and the chemist, and what he ought to know of the applications of chemistry in medicine.

See *NEURASTHENIA*, page 3. The author is thoroughly acquainted with the latest contributions to his science, and it is quite refreshing to find the old standards well maintained and simply yet so well explained, and with the modern scientific methods and apparatus. *Recess*, February 2, 1885.

CLASSEN, ALEXANDER.*Lecturer in the Royal Polytechnic School, Aachen-Compelle.*

Elementary Quantitative Analysis. Translated, with notes and additions, by F. SMITH, Ph. D., Assistant Professor of Chemistry in the Towne Scientific School, University of Penna. In one 12mo. volume of 324 pages, with 30 illust. Cloth, \$2.00.

This is probably the best manual of an elementary quantitative analysis as the methods are the most accurate, and the examples, commencing with simple and elementary, fill well by repetition,

and then advancing to the analysis of more and more complex products as are given with the application of the method. It is an indispensable book for the student of chemistry.—*Recess*, January 2, 1885.

SKIFFE, WILLIAM H., M. D.*Professor of Chemistry in the Medical Department of the University of Pennsylvania.*

A Manual of Medical Chemistry. For the use of Students. Based upon Bowditch's *Medical Chemistry*. In one 12mo. volume of 310 pages, with 74 illust. Cloth, \$1.75.

This is a very valuable manual of the most modern and accurate methods of the analysis of the various substances of the body, and the detection of the various pathological changes and the detection of the various pathological changes and the detection of the various pathological changes.

the method of the analysis of the various substances of the body, and the detection of the various pathological changes and the detection of the various pathological changes and the detection of the various pathological changes.

PARRISH, EDWARD,

Late Professor of the Theory and Practice of Pharmacy in the Philadelphia College of Pharmacy.

A Treatise on Pharmacy: designed as a Text-book for the Student, and as a Guide for the Physician and Pharmacist. With many Formulæ and Prescriptions. Fifth edition, thoroughly revised, by THOMAS S. WIGGAND, Ph. G. In one handsome octavo volume of 1093 pages, with 256 illustrations. Cloth, \$5; leather, \$8.

No thoroughgoing pharmacist will fail to possess himself of so useful a guide to practice, and no physician who properly estimates the value of an accurate knowledge of the remedial agents employed by him in daily practice, so far as their miscibility, compatibility and most effective methods of combination are concerned, can afford to leave this work out of the list of their works of reference. The country practitioner, who must always be in a measure his own pharmacist, will find it indispensable.—*Louisville Medical News*, March 29, 1884.

This well-known work presents itself now based upon the recently revised new Pharmacopœia. Each page bears evidence of the care bestowed upon it, and conveys valuable information from the rich store of the editor's experience. In fact, all that relates to practical pharmacy—apparatus, processes and dispensing—has been arranged and described with clearness in its various aspects, so as to afford aid and advice alike to the student and to the practical pharmacist. The work is judiciously illustrated with good woodcuts.—*American Journal of Pharmacy*, January, 1884.

BRUNTON, T. LAUDER, M. D.,

Lecturer on Materia Medica and Therapeutics at St. Bartholomew's Hospital, London, etc.

A Text-book of Pharmacology, Materia Medica and Therapeutics. In one handsome octavo volume of about 1000 pages, with over 200 illustrations. Cloth, \$5.50; leather, \$6.50. *In press.*

It is with peculiar pleasure that the early appearance of this long expected work is announced by the publishers. Written by the foremost authority on its subject in England, it forms a compendious treatise on materia medica, pharmacology, pharmacy, and the practical use of medicines in the treatment of disease. Space has been devoted to the fundamental sciences of chemistry, physiology and pathology, wherever it seemed necessary to elucidate the proper subject-matter of the book. A general index, an index of diseases and remedies, and an index of bibliography close a volume which will undoubtedly be of the highest value to the student, practitioner and pharmacist.

HERMANN, Dr. L.,

Professor of Physiology in the University of Zurich.

Experimental Pharmacology. A Handbook of Methods for Determining the Physiological Actions of Drugs. Translated, with the Author's permission, and with extensive additions, by ROBERT MEADE SMITH, M. D., Demonstrator of Physiology in the University of Pennsylvania. In one handsome 12mo. volume of 199 pages, with 32 illustrations. Cloth, \$1.50.

Prof. Hermann's handbook, which Dr. Smith has translated and enriched with many valuable additions, will be gladly welcomed by those engaged in this department of physiology. It is an excellent little book, full of concise information, and it should find a place in every laboratory. It ex-

plains the various methods and instruments used and points out what lines of investigation are to be pursued for studying different phenomena, and also how and what particularly to observe.—*American Journal of the Medical Sciences*, Jan. 1884.

MAISCH, JOHN M., Phar. D.,

Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy.

A Manual of Organic Materia Medica; Being a Guide to Materia Medica of the Vegetable and Animal Kingdoms. For the use of Students, Druggists, Pharmacists and Physicians. New (second) edition. In one handsome royal 12mo. volume of 550 pages, with 242 illustrations. Cloth, \$3.00. *Just ready.*

This work contains the substance,—the practical "kernel of the nut" picked out, so that the student has no superfluous labor. He can confidently accept what this work places before him, without any fear that the gist of the matter is not in it. Another merit is that the drugs are placed before him in such a manner as to simplify very much the study of them, enabling the mind to grasp them more readily. The illustrations are most

excellent, being very true to nature, and are alone worth the price of the book to the student. To the practical physician and pharmacist it is a valuable work for handy reference and for keeping fresh in the memory the knowledge of materia medica and botany already acquired. We can and do heartily recommend it.—*Medical and Surgical Reporter*, Feb. 14, 1883.

BRUCE, J. MITCHELL, M. D., F. R. C. P.,

Physician and Lecturer on Materia Medica and Therapeutics at Charing Cross Hospital, London.

Materia Medica and Therapeutics. An Introduction to Rational Treatment. In one pocket-size 12mo. volume of 555 pages. Limp cloth, \$1.50. *Just ready.* See *Students' Series of Manuals*, page 3.

One of the very latest works upon Materia Medica and Therapeutics, replete with information abreast of the times, we unhesitatingly

recommend it as one of the very best for either medical student or practitioner of medicine.—*Cincinnati Medical News*, August, 1884.

GRIFFITH, ROBERT EGLESFIELD, M. D.

A Universal Formulary, containing the Methods of Preparing and Administering Official and other Medicines. The whole adapted to Physicians and Pharmacists. Third edition, thoroughly revised, with numerous additions, by JOHN M. MAISCH, Phar. D., Professor of Materia Medica and Botany in the Philadelphia College of Pharmacy. In one octavo volume of 775 pages, with 38 illustrations. Cloth, \$4.50; leather, \$5.50.

STILLÉ, A., M. D., LL. D., & MAISCH, J. M., Phar. D.,

Professor of Materia Medica and Therapeutics at the University of Pennsylvania

Professor of Mat. Med. and Botany in the College of Pharmacy, and of the University of Pennsylvania

The National Dispensatory: Containing the Natural History, Chemistry, Pharmacology, Actions and Uses of Medicines, including those recognized in the Pharmacopœia of the United States, Great Britain and Germany, with numerous references to the French Codex. Third edition, thoroughly revised and greatly enlarged. In one magnificent imperial octavo volume of 1707 pages, with 311 fine engravings. Cloth, \$7.50; leather, \$8.50; half Russia, open back, \$9.00. With Denison's "Ready Reference Index" \$1.00 in addition to price in any of above styles of binding. *Just ready.*

In the present revision the authors have labored incessantly with the view of making the third edition of THE NATIONAL DISPENSATORY as even more completely representative of the pharmacological and therapeutic science of 1884 than its first edition was of that of 1859. For this, ample material has been obtained not only by the new United States Pharmacopœia, but by those of Germany and France, which have recently appeared and have been incorporated in the Dispensatory, together with a large number of recent official remedies. It is thus rendered the representative of the most advanced state of American, English, French and German pharmacology and therapeutics. The vast amount of new and important material thus introduced may be gathered from the fact that the additions to this edition amount in themselves to the matter of an ordinary full sized octavo volume, rendering the work larger by twenty five per cent than the last edition. The Therapeutic Index, a feature peculiar to this work, so suggestive and convenient to the practitioner, contains 1600 more references than the last edition—the General Index 3700 more, making the total number of references 22,200, while the list of illustrations has been increased by 80. Every effort has been made to prevent undue enlargement of the volume by having in it nothing that could be regarded as superfluous, yet care has been taken that nothing should be omitted which a pharmacist or physician could expect to find in it.

The appearance of the work has been delayed by nearly a year in consequence of the determination of the authors that it should attain as near an approach to absolute accuracy as is humanly possible. With this view an elaborate and laborious series of examinations and tests have been made to verify or correct the statements of the Pharmacopœia, and very numerous corrections have been found necessary. It has thus been rendered indispensable to all who consult the Pharmacopœia.

The work is therefore presented in the full expectation that it will maintain the position universally accorded to it as the standard authority in all matters pertaining to its subject, as registering the furthest advance of the science of the day, and as containing in a shape for convenient reference the recorded results of human experience in the laboratory, in the dispensing room, and at the bedside.

On the whole, in scope, vast in design and splendid in execution, THE NATIONAL DISPENSATORY may be justly regarded as the most important work of its kind extant.—*London Medical News*, Dec. 6, 1884

We have much pleasure in recording the appearance of a third edition of this excellent work of reference. It is an admirable abstract of all that relates to chemistry, pharmacy, materia medica, pharmacology and therapeutics. It may be regarded as embodying the Pharmacopœia of the civilized nations of the world, all being brought

up to date. The work has been very well done, a large number of extrapharmacopœial remedies having been added to those mentioned in previous editions.—*London Lancet*, N. 22, 1884

Its completeness as to details, the comprehensiveness of its descriptive language, the thoroughness of the treatment of its subjects, its beauty and simplicity of the desirable features of information for which such a work is needed make this volume a marvel of excellence.—*Pharmaceutical Journal*, Aug. 15, 1884

FARQUHARSON, ROBERT, M. D.,

Lecturer on Materia Medica at St. Mary's Hospital Medical School.

A Guide to Therapeutics and Materia Medica. Third American edition, especially revised by the Author. Enlarged and adapted to the U. S. Pharmacopœia by FRANK WOODBURY, M. D. In one handsome 12mo. volume of 524 pages. Cloth \$2.25

Dr. Farquharson's Therapeutics is constructed upon a plan which brings before the reader all the essential points with reference to the properties of drugs. It impresses these upon him in such a way as to enable him to take a clear view of the action of medicines and the disorders connected in which they must prove useful. The double-col-

ored pages—one side containing the recognized physiological actions of the medicine, and the other the manner in which disorders (who are nearly always mentioned) have obtained from it good results—make a very good arrangement. The chapters containing rules for prescribing is excellent.—*Canada Med. and Surg. Journal*, Dec. 1882

STILLÉ, ALFRED, M. D., LL. D.,

Professor of Therapeutics and Practice of Med. and of Clinical Med. in the Univ. of Penna.

Therapeutics and Materia Medica. A Systematic Treatise on the Action and Uses of Medicinal Agents, including their Description and History. Fourth edition, revised and enlarged. In two large and handsome octavo volumes, containing 1936 pages. Cloth, \$10.00; leather, \$12.00; very handsome half Russia, raised bands, \$15.00

We can hardly admit that it has a rival in the magnitude of its edition and the fulness of the revision. It is a standard work and a masterpiece of research in the pharmacopœia, and is a work of such a nature as to be a full representation of the present state of knowledge

in pharmacology, and as far as by the most complete treatise upon the chemical and practical side of the question.—*British Medical and Surgical Journal*, Nov. 5, 1884

COATS, JOSEPH, M. D., F. F. P. S.,*Pathologist to the Glasgow Western Infirmary.***A Treatise on Pathology.** In one very handsome octavo volume of 829 pages, with 339 beautiful illustrations. Cloth, \$5.50; leather, \$6.50.

The work before us treats the subject of Pathology more extensively than it is usually treated in similar works. Medical students as well as physicians, who desire a work for study or reference, that treats the subjects in the various departments in a very thorough manner, but without prolixity, will certainly give this one the preference to any with which we are acquainted. It sets forth the most recent discoveries, exhibits, in an interesting manner, the changes from a normal

condition effected in structures by disease, and points out the characteristics of various morbid agencies, so that they can be easily recognised. But, not limited to morbid anatomy, it explains fully how the functions of organs are disturbed by abnormal conditions. There is nothing belonging to its department of medicine that is not as fully elucidated as our present knowledge will admit.—*Cincinnati Medical News*, Oct. 1883.

GREEN, T. HENRY, M. D.,*Lecturer on Pathology and Morbid Anatomy at Charing-Cross Hospital Medical School, London.***Pathology and Morbid Anatomy.** Fifth American from the sixth revised and enlarged English edition. In one very handsome octavo volume of 482 pages, with 150 fine engravings. Cloth, \$2.50. Just ready.

The fact that this well-known treatise has so rapidly reached its sixth edition is a strong evidence of its popularity. The author is to be congratulated upon the thoroughness with which he has prepared this work. It is thoroughly abreast with all the most recent advances in pathology.

No work in the English language is so admirably adapted to the wants of the student and practitioner as this, and we would recommend it most earnestly to every one.—*Nashville Journal of Medicine and Surgery*, Nov. 1884.

WOODHEAD, G. SIMS, M. D., F. R. C. P. E.,*Demonstrator of Pathology in the University of Edinburgh.***Practical Pathology.** A Manual for Students and Practitioners. In one beautiful octavo volume of 497 pages, with 136 exquisitely colored illustrations. Cloth, \$6.00.

It forms a real guide for the student and practitioner who is thoroughly in earnest in his endeavor to see for himself and do for himself. To the laboratory student it will be a helpful companion, and all those who may wish to familiarize themselves with modern methods of examining morbid tissues are strongly urged to provide themselves with this manual. The numerous drawings are not fancied pictures, or merely schematic diagrams, but they represent faithfully the actual images seen under the microscope.

The author merits all praise for having produced a valuable work.—*Medical Record*, May 31, 1884.

It is manifestly the product of one who has himself travelled over the whole field and who is skilled not merely in the art of histology, but in the observation and interpretation of morbid changes. The work is sure to command a wide circulation. It should do much to encourage the pursuit of pathology, since such advantages in histological study have never before been offered.—*The Lancet*, Jan. 6, 1884.

CORNIL, V., and RANVIER, L.,*Prof. in the Faculty of Med. of Paris.**Prof. in the College of France.***A Manual of Pathological Histology.** Translated, with notes and additions, by E. O. SHAKESPEARE, M. D., Pathologist and Ophthalmic Surgeon to Philadelphia Hospital, and by J. HENRY C. SIMS, M. D., Demonstrator of Pathological Histology in the University of Pennsylvania. In one very handsome octavo volume of 800 pages, with 360 illustrations. Cloth, \$5.50; leather, \$6.50; half Russia, raised bands, \$7.

One of the most complete volumes on pathological histology we have ever seen. The plan of study embraced within its pages is essentially practical. Normal tissues are discussed, and after their thorough demonstration we are able to compare any pathological change which has occurred in them.

Thus side by side physiological and pathological anatomy go hand in hand, affording that best of all processes in demonstrations, comparison. The admirable arrangement of the work affords facility in the study of any part of the human economy.—*New Orleans Medical and Surgical Journal*, June, 1882.

KLEIN, E., M. D., F. R. S.,*Joint Lecturer on General Anat. and Phys. in the Med. School of St. Bartholomew's Hosp., London.***Elements of Histology.** In one pocket-size 12mo. volume of 360 pages, with 181 illus. Limp cloth, red edges, \$1.50. See *Students' Series of Manuals*, page 3.

Although an elementary work, it is by no means superficial or incomplete, for the author presents in concise language nearly all the fundamental facts regarding the microscopic structure of tissues.

The illustrations are numerous and excellent. We commend Dr. Klein's *Elements* most heartily to the student.—*Medical Record*, Dec. 1, 1883.

PEPPER, A. J., M. B., M. S., F. R. C. S.,*Surgeon and Lecturer at St. Mary's Hospital, London.***Surgical Pathology.** In one pocket-size 12mo. volume of 511 pages, with 81 illustrations. Limp cloth, red edges, \$2.00. See *Students' Series of Manuals*, page 3.

It is not pretentious, but it will serve exceedingly well as a book of reference. It embodies a great deal of matter, extending over the whole field of surgical pathology. Its form is practical, its language is clear, and the information set forth is well-arranged, well-indexed and well-

illustrated. The student will find in it nothing that is unnecessary. The list of subjects covers the whole range of surgery. The book supplies a very manifest want and should meet with success.—*New York Medical Journal*, May 21, 1884.

SCHÄFER'S PRACTICAL HISTOLOGY. In one handsome royal 12mo. volume of 306 pages, with 40 illustrations.

GLUGE'S ATLAS OF PATHOLOGICAL HISTOL.

OGY. Translated by JOSEPH LEISER, M. D. In one volume, very large imperial quarto, with 200 copper-plate figures, plain and colored and descriptive letter-press. Cloth, \$4.50.

FLINT, AUSTIN, M. D.,*Prof. of the Principles and Practice of Med., and of Clin. Med., in Bellevue Hospital Medical College, N. Y.*

A Treatise on the Principles and Practice of Medicine. Designed for the use of Students and Practitioners of Medicine. With an Appendix on the Researches of Koch, and their bearing on the Etiology, Pathology, Diagnosis and Treatment of Phthisis. Fifth edition, revised and largely rewritten. In one large and closely-printed octavo volume of 1160 pages. Cloth, \$5.50; leather, \$8.50; half Russia, \$7.

Koch's discovery of the bacillus of tubercle gives promise of being the greatest boon ever conferred by science on humanity, surpassing even vaccination in its benefits to mankind. In the appendix to his work, Professor Flint deals with the subject from a practical standpoint, discussing its bearings on the etiology, pathology, diagnosis, prognosis and treatment of pulmonary phthisis. Thus enlarged and completed, this standard work will be more than ever a necessity to the physician who duly appreciates the responsibility of his calling.

A well-known writer and lecturer on medicine recently expressed an opinion, in the highest degree complimentary of the admirable treatise of Dr. Flint, and in recognizing it, he described it accurately as "readable and reliable." No text-book is more calculated to combine the interest of the student, and to more better classify the multitudinous subjects included in it. It has already so far won its way in England, that no inconsiderable number of men use it alone in the study of pure medicine, and we can say of it that it is in every way adapted to serve, not only as a college text-book, but also as an ample instructor in the science and practice of medicine. The style of Dr. Flint is always powerful and engaging. The work abounds in perspicuous explanation, and is a most valuable text-book of medicine.—*London Medical News.*

This work is so widely known and accepted as the best American text-book of the practice of medicine that it would seem hardly worth while to give this, the fifth edition, any thing more than a passing notice. But even the most cursory examination shows that it is practically, much more than a revised edition. It is, in fact, rather a new work, bearing out the statement well understoodly continue to hold the first place in the estimation of American physicians and students. No one of our medical writers approaches Professor Flint in clearness of dissection, lucidity of view, and, above all, regard of transcendent importance, rational estimate of the value of remedial agents. It is thoroughly practical, therefore preeminently the need for American readers.—*St. Louis Clin. Rec.* Mar '91

HARTSHORNE, HENRY, M. D., LL. D.,*Lately Professor of Hygiene in the University of Pennsylvania.*

Essentials of the Principles and Practice of Medicine. A Handbook for Students and Practitioners. Fifth edition, thoroughly revised and rewritten. In one royal 12mo. volume of 669 pages, with 144 illustrations. Cloth, \$2.75; half bound, \$3.00.

Within the compass of 600 pages a treatise of the history of medicine, general pathology, general symptoms, pathology, and physical diagnosis (including laryngoscopy, and thymoscopes, etc.), general therapeutics, nosology and special pathology and practice. There is a wonderful amount of information contained in this work and it is one of the best of its kind that we have seen.—*Quincy Medical Journal*, Nov. 1892.

As indispensable book. No work ever exhibited a better average of actual practical treatment than

this one, and probably not one writer in our day had a better opportunity than Dr. Hartshorne for condensing all the views of our best practitioners into 600. The numerous illustrations may be very useful to students especially. These essentials, as the name suggests, are not intended to supersede the text books of Flint and Hartshorne, but they are the most valuable in affording the means to see at a glance the whole literature of any disease, and the most valuable treatise on the subject.—*Medical Journal and Examiner*, April, 1892.

BRISTOWE, JOHN SYER, M. D., F. R. C. P.,*Physician and Joint Lecturer on Medicine at St. Thomas' Hospital.*

A Treatise on the Practice of Medicine. Second American edition, revised by the Author. Edited, with additions, by JAMES H. HUTCHINSON, M.D., physician to the Pennsylvania Hospital. In one handsome octavo volume of 1085 pages, with illustrations. Cloth, \$5.00; leather, \$6.00; very handsome half Russia, raised bands, \$6.50.

The reader will find every conceivable subject connected with the practice of medicine ably presented, in a style at once clear, interesting and concise. The additions made by Dr. Hutchinson

are appropriate and practical, and greatly add to its usefulness to American readers.—*Boston Medical and Surgical Journal*, March, 1890.

WATSON, SIR THOMAS, M. D.,*Late Physician in Ordinary to the Queen.*

Lectures on the Principles and Practice of Physic. A new American from the fifth English edition. Edited, with additions, and 190 illustrations, by HENRY HARTSHORNE, A. M., M. D., late Professor of Hygiene in the University of Pennsylvania. In two large octavo volumes of 1840 pages. Cloth, \$9.00; leather, \$11.00.

LECTURES ON THE STUDY OF FEVER. By A. HENNESSY, M. D., M. R. I. A. In one octavo volume of 308 pages. Cloth, \$2.50.

STOKES' LECTURES ON FEVER. Edited by JOHN WILKINSON, M. D., F. R. C. P. In one octavo volume of 280 pages. Cloth, \$2.00.

A TREATISE ON FEVER. By ROBERT L. LAY, M. D., F. R. C. P. In one 8vo. vol. of 564 pp. Cloth, \$2.50.

LA ROCHÉ ON YELLOW FEVER, considered in its Historical, Pathological, Etiological, and Therapeutic Relations. In two large and handsome octavo volumes of 1468 pp. Cloth, \$7.50.

A CENTURY OF AMERICAN MEDICINE, 1776-1876. By Drs. E. H. CLEGG, H. J. BISHOP, S. D. GREEN, T. O. THOMAS, and J. S. BENTON. An octavo volume of 370 pages. Cloth, \$2.50.

For Sale by Subscription Only.

A System of Practical Medicine.

BY AMERICAN AUTHORS.

EDITED BY WILLIAM PEPPER, M. D., LL. D.,

PROFESSOR AND PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE AND OF
CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA,Assisted by LOUIS STARR, M. D., Clinical Professor of the Diseases of Children in the
Hospital of the University of Pennsylvania.

In five imperial octavo volumes, containing about 1100 pages each, with illustrations. Price per volume, cloth, \$5; leather, \$6; half Russia, raised bands and open back, \$7. Volumes I. (General Pathology, Sanitary Science and General Diseases) contains 1094 pages, with 24 illustrations and is just ready. Volume II. (General Diseases [continued] and Diseases of the Digestive System) will be ready June 1st, and the subsequent volumes at intervals of four months thereafter.

The publishers feel pardonable pride in announcing this magnificent work. For three years it has been in active preparation, and it is now in a sufficient state of forwardness to justify them in calling the attention of the profession to it as the work in which for the first time American medicine is thoroughly represented by its worthiest teachers, and presented in the full development of the practical utility which is its preëminent characteristic. The most able men—from the East and the West, from the North and the South, from all the prominent centres of education, and from all the hospitals which afford special opportunities of study and practice—have united in generous rivalry to bring together this vast aggregate of specialized experience.

The distinguished editor has so apportioned the work that each author has had assigned to him the subject which he is peculiarly fitted to discuss, and in which his views will be accepted as the latest expression of scientific and practical knowledge. The practitioner will therefore find these volumes a complete, authoritative and unfailing work of reference, to which he may at all times turn with full certainty of finding what he needs in its most recent aspect, whether he seeks information on the general principles of medicine, or minute guidance in the treatment of special disease. So wide is the scope of the work that, with the exception of midwifery and matters strictly surgical, it embraces the whole domain of medicine, including the departments for which the physician is accustomed to rely on special treatises, such as diseases of women and children, of the genito-urinary organs, of the skin, of the nerves, hygiene and sanitary science, and medical ophthalmology and otology. Moreover, authors have inserted the formulas which they have found most efficient in the treatment of the various affections. It may thus be truly regarded as a COMPLETE LIBRARY OF PRACTICAL MEDICINE, and the general practitioner possessing it may feel secure that he will require little else in the daily round of professional duties.

In spite of every effort to condense the vast amount of practical information furnished, it has been impossible to present it in less than 5 large octavo volumes, containing about 5500 beautifully printed pages, and embodying the matter of about 15 ordinary octavos. Illustrations are introduced wherever they serve to elucidate the text.

As material for the work is substantially complete in the hands of the editor, the profession may confidently await the appearance of the remaining volumes upon the dates above specified. A detailed prospectus of the work will be sent to any address on application to the publishers.

It is a large undertaking, but quite justifiable in the case of a progressive nation like the United States. At any rate, if we may judge of future volumes from the first, it will be justified by the result. We have nothing but praise to bestow upon the work. The articles are the work of writers, many of whom are already recognized in

this country as authorities on the particular topics on which they deal, whilst the others show by the way they have handled their subjects that they are fully equal to the task they had undertaken. * * * A work which we cannot doubt will make a lasting reputation for itself.—*London Medical Times and Gazette*, May 3, 1883.

REYNOLDS, J. RUSSELL, M. D.,

Professor of the Principles and Practice of Medicine in University College, London.

▲ **System of Medicine.** With notes and additions by HENRY HARTSHORNE, A. M., M. D., late Professor of Hygiene in the University of Pennsylvania. In three large and handsome octavo volumes, containing 3056 double-columned pages, with 317 illustrations. Price per volume, cloth, \$5.00; sheep, \$6.00; very handsome half Russia, raised bands, \$6.50. Per set, cloth, \$15; leather, \$18; half Russia, \$19.50. Sold only by subscription.

There is no medical work which we have in times past more frequently and fully consulted when perplexed by doubts as to treatment, or by having unusual or apparently inexplicable symptoms presented to us, than "Reynolds' System of Medicine." It contains just that kind of information which the busy practitioner frequently finds

himself in need of. In order that any deficiencies may be supplied, the publishers have committed the preparation of the book for the press to Dr. Henry Hartshorne, whose judicious notes distributed throughout the volume afford abundant evidence of the thoroughness of the revision.—*American Journal of the Medical Sciences*, Jan. 1883.

STILLÉ, ALFRED, M. D., LL. D.,*Professor Emeritus of the Theory and Practice of Med. and of Clinical Med. in the Univ. of Bonn.***Cholera: Its Origin History, Causation, Symptoms, Prevention and Treatment.** In one handsome 12mo. volume of about 175 pages, with a chart. Cloth, \$1.25. *Shelf.*

The threatened importation of cholera into the country renders peculiarly timely this work of an authority so eminent as Professor Stillé. The history of previous epidemics, their modes of propagation, the vast recent additions to our knowledge of the causation, prevention and treatment of the disease, all have been handled so skillfully as to present with brevity the information which every practitioner should possess in advance of its visitation.

FLINT, AUSTIN, M. D.

Clinical Medicine. A Systematic Treatise on the Diagnosis and Treatment of Diseases. Designed for Students and Practitioners of Medicine. In one large and handsome octavo volume of 793 pages. Cloth, \$4.50; leather, \$5.50; half Russia, \$6.00.

It is here that the skill and learning of the great clinician are displayed. He has given us a storehouse of medical knowledge, essential for the student, convenient for the practitioner, the result of a long life of the most faithful and arduous work, collected by an energy as vigorous and systematically as unflinching, and weighed by a judgment as accurate as that his observation is able to reach.—*Archives of Medicine*, Dec. 1879.

To give an adequate and useful conspectus of the extensive field of modern clinical medicine is a task of an ordinary difficulty, but to accomplish this con-

sistently with brevity and clearness, the different subjects and their several parts receiving the attention which, relatively to their importance, medical opinion claims for them, is still more difficult. This task, we feel bound to say, has been executed with more than partial success by Dr. Flint, whose name is already familiar to students of advanced medicine in this country as that of the author of two works of great merit on special subjects and of numerous papers exhibiting much originality and extensive research.—*The Dublin Journal*, Dec. 1879.

By the Same Author.

Essays on Conservative Medicine and Kindred Topics. In one very handsome royal 12mo. volume of 210 pages. Cloth, \$1.35.

BROADBENT, W. H., M. D., F. R. C. P.,*Physician to and Lecturer on Medicine at St. Mary's Hospital.*

The Pulse. In one 12mo. volume. See *Series of Clinical Manuals*, page 3.

SCHREIBER, DR. JOSEPH.

A Manual of Treatment by Massage and Methodical Muscle Exercise. Translated by WALTER MENDELSON, M. D., of New York. In one handsome octavo volume of about 300 pages, with about 125 fine engravings. *Preparing.*

FINLAYSON, JAMES, M. D., Editor,*Physician and Lecturer on Clinical Medicine in the Glasgow Western Infirmary, etc.*

Clinical Diagnosis. A Handbook for Students and Practitioners of Medicine. With Chapters by Prof. Guinther on the Physiognomy of Disease; Prof. Stephens on Diseases of the Female Organs; Dr. Robertson on Insanity; Dr. Gemmell on Physical Diagnosis; Dr. Coats on Laryngoscopy and Post-Mortem Examinations, and by the Editor on Case-taking, Family History and Symptoms of Disorder in the Various Systems. In one handsome 12mo. volume of 546 pages, with 85 illustrations. Cloth, \$2.63.

This is one of the really useful books. It is attractive from preface to the final page, and ought to be given a place in every office table, because it contains in a condensed form all that is valuable in semeiology and diagnosis to be found in

any other volume; and because of its actual content and complete index it is unusually well adapted for quick reference in any emergency that may come up to the busy practitioner.—*N. C. Med. Jour.*, Jan. 1879.

TANNER, THOMAS HAWKES, M. D.

A Manual of Clinical Medicine and Physical Diagnosis. Third American from the second London edition. Revised and enlarged by TIMOTHY FOX, M. D., Physician to the Skin Department in University College Hospital, London, etc. In one small 12mo. volume of 362 pages, with illustrations. Cloth, \$1.50.

FOTHERGILL, J. M., M. D., Edtn., M. R. C. P., Lond.,*Physician to the City of London Hospital for Diseases of the Chest.*

The Practitioner's Handbook of Treatment; Or, The Principles of Therapeutics. New edition. In one octavo volume. *Preparing.*

STURGES' INTRODUCTION TO THE STUDY OF CLINICAL MEDICINE. Being a Guide to the Investigation of Disease. In one handsome 12mo. volume of 127 pages. Cloth, \$1.25.

DAVIS' CLINICAL LECTURES ON VARIOUS IMPORTANT DISEASES. By N. B. Davis, M. D. Edited by FRANK B. DAVIS, M. D. Second edition. 12mo. 67 pages. Cloth, \$1.00.

RICHARDSON, B. W., M.A., M.D., LL. D., F.R.S., F.S.A.

Fellow of the Royal College of Physicians, London.

Preventive Medicine. In one octavo volume of 729 pages. Cloth, \$4; leather, \$5; very handsome half Russia, raised bands, \$5.50.

Dr. Richardson has succeeded in producing a work which is elevated in conception, comprehensive in scope, scientific in character, systematic in arrangement, and which is written in a clear, concise and pleasant manner. He evinces the happy faculty of extracting the pith of what is known on the subject, and of presenting it in a most simple, intelligent and practical form. There is perhaps no similar work written for the general public that contains such a complete, reliable and instructive collection of data upon the diseases common to the race, their origin, causes, and the measures for their prevention. The descriptions of diseases are clear, concise and scholarly; the discussion of

the question of disease is comprehensive, masterly and fully abreast with the latest and best knowledge on the subject, and the preventive measures advised are accurate, explicit and reliable.—*The American Journal of the Medical Sciences*, April, 1884. This is a book that will surely find a place on the table of every progressive physician. To the medical profession, whose duty is quite as much to prevent as to cure disease, the book will be a boon.—*Boston Medical and Surgical Journal*, Mar. 8, 1884. The treatise contains vast amount of solid, valuable hygienic information.—*Medical and Surgical Reporter*, Feb. 23, 1884.

BARTHOLOW, ROBERTS, A. M., M.D., LL. D.,

Prof. of Materia Medica and General Therapeutics in the Jefferson Med. Coll. of Phila., etc.

Medical Electricity. A Practical Treatise on the Applications of Electricity to Medicine and Surgery. Second edition. In one very handsome octavo volume of 292 pages, with 109 illustrations. Cloth, \$2.50.

The second edition of this work following so soon upon the first would in itself appear to be a sufficient announcement; nevertheless, the text has been so considerably revised and condensed, and so much enlarged by the addition of new matter, that we cannot fail to recognize a vast improvement upon the former work. The author has prepared his work for students and practitioners—for those who have never acquainted themselves with the subject, or, having done so, find that after a time their knowledge needs refreshing. We think he has accomplished this object. The book is not too voluminous, but is thoroughly practical, simple, complete and comprehensible. It is, moreover, replete with numerous illustrations of instruments, appliances, etc.—*Medical Record*, November 18, 1882.

A most excellent work, addressed by a practitioner to his fellow-practitioners, and therefore thoroughly practical. The work now before us has the exceptional merit of clearly pointing out where the benefits to be derived from electricity must come. It contains all and everything that the practitioner needs in order to understand intelligently the nature and laws of the agent he is making use of, and for its proper application in practice. In a condensed, practical form, it presents to the physician all that he would wish to remember after perusing a whole library on medical electricity, including the results of the latest investigations. It is the book for the practitioner, and the necessity for a second edition proves that it has been appreciated by the profession.—*Physician and Surgeon*, Dec. 1882.

THE YEAR-BOOK OF TREATMENT.

A Comprehensive and Critical Review for Practitioners of Medicine. In one 12mo. volume of 320 pages, bound in limp cloth, with red edges, \$1.25.

This work presents to the practitioner not only a complete classified account of all the more important advances made in the treatment of Disease during the year ending Sept. 30, 1884, but also a critical estimate of the same by a competent authority. Each department of practice has been fully and concisely treated, and into the consideration of each subject enter such allusions to recent pathological and clinical work as bear directly upon treatment. As the medical literature of all countries has been placed under contribution, the references given throughout the work, together with the separate indexes of subjects and authors, will serve as a guide for those who desire to investigate any therapeutical topic at greater length.

The contributions are from the pens of the following well-known gentlemen:—J. MITCHELL BRUCE, M.D.; T. LAUDER BRINTON, M.D., F.R.S.; THOMAS BRYANT, F.R.C.S.; F. H. CHAMPNEY, M.B.; ALFRED COOPER, F.R.C.S.; SIDNEY COPLAND, M.D.; DYCE DUCKWORTH, M.D.; GEORGE P. FIELD, M.R.C.S.; REGINALD HARRISON, F.R.C.S.; J. WARRINGTON HAWARD, F.R.C.S.; F. A. MAHOMED, M.B.; MALCOLM MORRIS, F.R.C.S., ED.; EDMUND OWEN, F.R.C.S.; R. DOUGLAS POWELL, M.D.; HENRY POWER, M.B., F.R.C.S.; C. H. KALFE, M.D.; A. E. SANBORN, M.D.; FELIX SEMON, M.D.; WALTER G. SMITH, M.D.; J. KNOWSLEY THORNTON, M.B.; FREDERICK TREVEY, F.R.C.S.; A. DE WATTEVILLE, M.D.; JOHN WILLIAMS, M.D.

HABERSHON, S. O., M.D.,

Senior Physician to and late Lect. on Principles and Practice of Med. at Guy's Hospital, London.

On the Diseases of the Abdomen; Comprising those of the Stomach, and other parts of the Alimentary Canal, Oesophagus, Cecum, Intestines and Peritoneum. Second American from third enlarged and revised English edition. In one handsome octavo volume of 554 pages, with illustrations. Cloth, \$3.50.

PAYY'S TREATISE ON THE FUNCTION OF DIGESTION; its Disorders and their Treatment. From the second London edition. In one octavo volume of 228 pages. Cloth, \$2.00.

CHAMBERS' MANUAL OF DIET AND REGIMEN IN HEALTH AND SICKNESS. In one handsome octavo volume of 302 pp. Cloth, \$2.75.

BARLOW'S MANUAL OF THE PRACTICE OF MEDICINE. With additions by D. F. CORSON, M.D. 1 vol. 8vo., pp. 608. Cloth, \$2.50.

TODD'S CLINICAL LECTURES ON CERTAIN ACUTE DISEASES. In one octavo volume of 320 pages. Cloth, \$2.50.

HOLLAND'S MEDICAL NOTES AND REFLECTIONS. 1 vol. 8vo., pp. 462. Cloth, \$2.50.

COHEN, J. SOLIS, M. D.,*Lecturer on Laryngoscopy and Diseases of the Throat and Chest in the Jefferson Medical College.*

Diseases of the Throat and Nasal Passages. A Guide to the Diagnosis and Treatment of Affections of the Pharynx, Esophagus, Trachea, Larynx and Nares. Third edition, thoroughly revised and rewritten, with a large number of new illustrations. In one very handsome octavo volume. *Preparing.*

SEILER, CARL, M. D.,*Lecturer on Laryngoscopy in the University of Pennsylvania.*

A Handbook of Diagnosis and Treatment of Diseases of the Throat, Nose and Naso-Pharynx. Second edition. In one handsome royal 12mo. volume of 294 pages, with 77 illustrations. Cloth, \$1.75.

It is one of the best of the practical textbooks on this subject with which we are acquainted. The presentation has been increased in size, but its eminently practical character has been maintained. Many new illustrations have also been introduced, a case record sheet has been added, and there are a valuable bibliography and a good index of the whole. For any one who wishes to make himself familiar with the practical management of cases of throat and nose disease, the book will be found of great value.—*New York Medical Journal*, June 1, 1885.

The work before us is a concise handbook upon

the essentials of diagnosis and treatment in diseases of the throat and nose. The art of laryngoscopy, the anatomy of the throat and nose and the pathology of the various membranes are treated with conciseness and accuracy. The work is profusely illustrated, and in many essential features and deserves a place in the library of the practitioner who would refer to it as to the nature, diagnosis and treatment of accessory diseases almost inseparable from general medical practice. With advanced students it should be very popular on account of its condensed style.—*Lancette Medical News*, June 26, 1885.

BROWNE, LENNOX, F. R. C. S., Edin.,*Senior Surgeon to the Central London Throat and Ear Hospital, etc.*

The Throat and its Diseases. Second American from the second English edition, thoroughly revised. With 100 typical illustrations in colors and 60 wood engravings, designed and executed by the Author. In one very handsome imperial octavo volume of about 350 pages. *Preparing.*

FLINT, AUSTIN, M. D.,*Professor of the Principles and Practice of Medicine in Bellevue Hospital Medical College, N. Y.*

A Manual of Auscultation and Percussion; Of the Physical Diagnosis of Diseases of the Lungs and Heart, and of Thoracic Aneurism. Third edition. In one handsome royal 12mo. volume of 240 pages. Cloth, \$1.63.

It is safe to say that there is not in the English language, or any other, the equivalent of a clear, exact and comprehensive information touching the physical exploration of the chest in an equal number of words. Professor Flint's language is precise and simple, conveying without ambiguity

the results of his careful study and ample experience in each word at the very beginning of the book, source of instruction, and the old thousand pleasant means of reviewing and complementing their knowledge.—*American Practitioner*, June, 1883.

BY THE SAME AUTHOR.

Physical Exploration of the Lungs by Means of Auscultation and Percussion. Three lectures delivered before the Philadelphia County Medical Society, 1882-83. In one handsome small 12mo. volume of 83 pages. Cloth, \$1.00.

A Practical Treatise on the Physical Exploration of the Chest and the Diagnosis of Diseases Affecting the Respiratory Organs. Second and revised edition. In one handsome octavo volume of 591 pages. Cloth, \$4.50.

Phthisis: Its Morbid Anatomy, Etiology, Symptomatic Events and Complications, Fatality and Prognosis, Treatment and Physical Diagnosis; In a series of Clinical Studies. In one handsome octavo volume of 442 pages. Cloth, \$3.50.

A Practical Treatise on the Diagnosis, Pathology and Treatment of Diseases of the Heart. Second revised and enlarged edition. In one octavo volume of 550 pages, with a plate. Cloth, \$4.

GROSS, S. D., M.D., LL.D., D.C.L. Oxon., LL.D. Cantab.

A Practical Treatise on Foreign Bodies in the Air-passages. In one octavo volume of 452 pages, with 59 illustrations. Cloth, \$2.75.

FULLER ON DISEASES OF THE LUNGS AND AIR-PASSAGES. Their Pathology, Physical Diagnosis, Symptoms and Treatment. From the second and revised English edition. In one octavo volume of 475 pages. Cloth, \$3.50.

SLADE ON DIPHTHERIA. Its Nature and Treatment, with an account of the History of its prevalence in various countries. Second revised edition. In one 12mo. vol., pp. 154. Cloth, \$1.25.

WALSHE ON THE DISEASES OF THE HEART AND GREAT VESSELS. Third edition, an edition. In 1 vol. 8vo., 416 pp. Cloth, \$3.00.

SMITH ON CONSUMPTION; its Early and Removable Stages. 1 vol. 8vo. pp. 253. Cloth, \$2.50.

LA ROCHE ON PNEUMONIA. 1 vol. 8vo. of 200 pages. Cloth, \$1.00.

WILLIAMS ON PULMONARY CONSUMPTION. Its Nature, Varieties and Treatment. With an analysis of one thousand cases of consumption. In one 8vo. vol. of 80 pp. Cloth, \$2.00.

JONES ON CLINICAL OBSERVATIONS ON FUNCTIONAL NERVOUS DISORDERS. Second American edition. In one handsome octavo volume of 500 pages. Cloth, \$3.25.

MITCHELL, S. WEIR, M. D.,

Physician to Orthopaedic Hospital and the Infirmary for Diseases of the Nervous System, Phila., etc.

Lectures on Diseases of the Nervous System; Especially in Women. Second edition. In one 12mo. volume of 288 pages. Cloth, \$1.75. *Just ready.*

So great have been the achievements of the system perfected by the author for the treatment of hysterical and nervous diseases that the profession will welcome the second edition of a work which gives in detail the methods of enforced rest, massage and systematic feeding on which this mode of treatment is based. Many of these lectures are original studies of well-known diseases, and others deal with subjects which have been hitherto slighted in medical literature or which are almost unknown to it. The present edition contains several new lectures, notably those on the difficulties of diagnosis in hysterical diseases of joints, on the relations of hysteria to organic disease of the spine, and on hysterical disorders of the rectum.

HAMILTON, ALLAN McLANE, M. D.,

Attending Physician at the Hospital for Epileptics and Paralytics, Blackwell's Island, N. Y.

Nervous Diseases; Their Description and Treatment. Second edition, thoroughly revised and rewritten. In one octavo volume of 598 pages, with 72 illustrations. Cloth, \$4.

When the first edition of this good book appeared we gave it our emphatic endorsement, and the present edition enhances our appreciation of the book and its author as a safe guide to students of clinical neurology. One of the best and most critical of English neurological journals, *Brain*, has

characterized this book as the best of its kind in any language, which is a handsome endorsement from an exalted source. The improvements in the new edition, and the additions to it, will justify its purchase even by those who possess the old.—*Atlantist and Neurologist*, April, 1882.

TUKE, DANIEL HACK, M. D.,

Joint Author of The Manual of Psychological Medicine, etc.

Illustrations of the Influence of the Mind upon the Body in Health and Disease. Designed to elucidate the Action of the Imagination. New edition. Thoroughly revised and rewritten. In one handsome octavo volume of 467 pages, with two colored plates. Cloth, \$3.00.

It is impossible to peruse these interesting chapters without being convinced of the author's perfect sincerity, impartiality, and thorough mental grasp. Dr. Tuke has exhibited the requisite amount of scientific address on all occasions, and the more intricate the phenomena the more firmly has he adhered to a physiological and rational

method of interpretation. Guided by an enlightened deduction, the author has reclaimed for science a most interesting domain in psychology, previously abandoned to charlatans and empirics. This book, well conceived and well written, must commend itself to every thoughtful understanding.—*New York Medical Journal*, September 4, 1881.

CLOUSTON, THOMAS S., M. D., F. R. C. P., L. R. C. S.,

Lecturer on Mental Diseases in the University of Edinburgh.

Clinical Lectures on Mental Diseases. With an Appendix, containing an Abstract of the Statutes of the United States and of the Several States and Territories relating to the Custody of the Insane. By CHARLES F. FOLSON, M. D., Assistant Professor of Mental Diseases, Medical Department of Harvard University. In one handsome octavo volume of 541 pages, illustrated with eight lithographic plates, four of which are beautifully colored. Cloth, \$4.

The practitioner as well as the student will accept the plain, practical teaching of the author as a forward step in the literature of insanity. It is refreshing to find a physician of Dr. Clouston's experience and high reputation giving the bedside notes upon which his experience has been founded and his mature judgment established. Such clinical observations cannot but be useful to

the general practitioner in guiding him to a diagnosis and indicating the treatment, especially in many obscure and doubtful cases of mental disease. To the American reader Dr. Folson's Appendix adds greatly to the value of the work, and will make it a desirable addition to every library.—*American Psychological Journal*, July, 1884.

Dr. Folson's Abstract may also be obtained separately in one octavo volume of 108 pages. Cloth, \$1.50.

SAVAGE, GEORGE H., M. D.,

Lecturer on Mental Diseases at Guy's Hospital, London.

Insanity and Allied Neuroses, Practical and Clinical. In one 12mo. volume of 551 pages, with 18 typical illustrations. Cloth, \$2.00. *Just ready.* See *Series of Clinical Manuals*, page 3.

As a handbook, a guide to practitioners and students, the book fulfils an admirable purpose. The many forms of insanity are described with characteristic clearness, the illustrative cases are carefully selected, and as regards treatment, sound

common sense is everywhere apparent. We repeat that Dr. Savage has written an excellent manual for the practitioner and student.—*American Journal of Insanity*, April, 1885.

PLAYFAIR, W. S., M. D., F. R. C. P.,

The Systematic Treatment of Nerve Prostration and Hysteria. In one handsome small 12mo. volume of 97 pages. Cloth, \$1.00.

Blandford on Insanity and its Treatment: Lectures on the Treatment, Medical and Legal, of Insane Patients. In one very handsome octavo volume.

GROSS, S. D., M. D., LL. D., D. C. L. *Gross, LL. D., Cantab.*

A System of Surgery.

For the use of Practitioners and Students. In one large and handsome octavo volume of 800 pages, with 300 illustrations. In press.

ASHHURST, JOHN, Jr., M. D.,

The Principles and Practice of Surgery. For the use of Practitioners and Students. In one large and handsome octavo volume of 800 pages, with 300 illustrations. In press.

GOULD, A. PEARCE, M. S., M. B., F. R. C. S.

Elements of Surgical Diagnosis. In one pocket-size volume of 200 pages, cloth, \$2.50. Just ready. See *Students' Series of Manuals*, page 3.

This volume will be found of great value to the student, as it contains a full and complete system of diagnosis, and is written in a clear and concise manner, and is well illustrated with many diagrams and figures. It is a volume of 200 pages, cloth, \$2.50. Just ready. See *Students' Series of Manuals*, page 3.

GIBNEY, V. P., M. D.,

Orthopaedic Surgery. For the use of Practitioners and Students. In one handsome octavo volume, profusely illustrated. Preparing.

ROBERTS, JOHN B., A. M., M. D.,

The Principles and Practice of Surgery. For the use of Practitioners and Students. In one very handsome octavo volume of 800 pages, with many illustrations. Preparing.

BELLAMY, EDWARD, F. R. C. S.,

Operative Surgery. Shortly. See *Students' Series of Manuals*, page 3.

STIMSON, LEWIS A., B. A., M. D.,

A Manual of Operative Surgery. In one very handsome royal 12mo. volume of 477 pages, with 332 illustrations. Cloth, \$2.50.

This volume is intended entirely for the use of the student, and is intended to furnish him with a complete and concise manual of operative surgery, and is intended to furnish him with a complete and concise manual of operative surgery, and is intended to furnish him with a complete and concise manual of operative surgery.

every student should possess one. This work goes away with the necessity of pondering over larger works on surgery for descriptions of operations, and presents in a nutshell what is wanted by the surgeon without an elaborate search to find it. — *Medical Journal*, August, 1871.

BARGENTON BANDING AND OTHER OPERATIONS OF MINOR SURGERY. New and complete, with a Chapter on military surgery. One 12mo. volume of 383 pages, with 187 cuts. Cloth, \$1.25.

MILLER'S PRINCIPLES OF SURGERY. Fourth American, from the third Edinburgh edition. In one octavo vol. of 638 pages, with 340 illustrations. Cloth, \$1.75.

MILLER'S PRACTICE OF SURGERY. Fourth and revised American, from the 1st Edinburgh edition. In one large octavo vol. of 682 pages, with 364 illustrations. Cloth, \$2.75.

PIRRIE'S PRINCIPLES AND PRACTICE OF SURGERY. Edited by JOHN NAILL, M. D. In one octavo vol. of 741 pp with 316 illus. Cloth, \$1.75.

COOPER'S LECTURES IN THE PRINCIPLES AND PRACTICE OF SURGERY. In one octavo vol. of 765 pages. Cloth, \$2.00.

SKENE'S OPERATIVE SURGERY. In one vol. of 661 pages, with 81 woodcuts. Cloth, \$2.25.

GIBSON'S INSTITUTES AND PRACTICE OF SURGERY. Fifth ed., 1871. In two octavo vols. of 672 pages, with 31 plates. Leather, \$4.50.

ERICHSEN, JOHN E., F. R. S., F. R. C. S.,*Professor of Surgery in University College, London, etc.*

The Science and Art of Surgery; Being a Treatise on Surgical Injuries, Diseases and Operations. From the eighth and enlarged English edition. In two large and beautiful octavo volumes of 2316 pages, illustrated with 984 engravings on wood. Cloth, \$9; leather, raised bands, \$11; half Russia, raised bands, \$12. *Just ready.*

After the profession has placed its approval upon a work to the extent of purchasing seven editions, it does not need to be introduced. Simultaneous with the appearance of this edition a translation is being made into Italian and Spanish. Thus this favorite text-book on surgery holds its own in spite of numerous rivals at the end of thirty years. It is a grand book, worthy of the art in the interest of which it is written.—*Detroit Lancet*, Jan. 10, 1885.

After being before the profession for thirty years and maintaining during that period a reputation as a leading work on surgery, there is not

much to be said in the way of comment or criticism. That it still holds its own goes without saying. The author infuses into it his large experience and ripe judgment. Wedded to no school, committed to no theory, biased by no hobby, he imparts an honest personality in his observations, and his teachings are the rulings of an impartial judge. Such men are always safe guides, and their works stand the tests of time and experience. Such an author is Erichsen, and such a work is his *Surgery*.—*Medical Record*, Feb. 21, 1885.

BRYANT, THOMAS, F. R. C. S.,*Surgeon and Lecturer on Surgery at Guy's Hospital, London.*

The Practice of Surgery. Fourth American from the fourth and revised English edition. In one large and very handsome imperial octavo volume of 1040 pages, with 727 illustrations. Cloth, \$8.50; leather, \$7.50; half Russia, \$8.00. *Just ready.*

The treatise takes in the whole field of surgery, that of the eye, the ear, the female organs, orthopaedics, venereal diseases, and military surgery, as well as more common and general topics. All of these are treated with clearness and with sufficient fulness to suit all practical purposes. The illustrations are numerous and well printed. We do not doubt that this new edition will continue to maintain the popularity of this standard work.—*Medical and Surgical Reporter*, Feb. 14, '85.

This most magnificent work upon surgery has reached a fourth edition in this country, showing the high appreciation in which it is held by the American profession. It comes fresh from the pen of the author. That it is the very best work on surgery for medical students we think there can be no doubt. The author seems to have understood just what a student needs, and has prepared the work accordingly.—*Cincinnati Medical News*, January, 1885.

By the same Author.

Diseases of the Breast. In one 12mo. volume. *Preparing.* See *Series of Clinical Manuals*, page 3.

ESMARCH, Dr. FRIEDRICH,*Professor of Surgery at the University of Kiel, etc.*

Early Aid in Injuries and Accidents. Five Ambulance Lectures. Translated by H. R. H. PRINCESS CHRISTIAN. In one handsome small 12mo. volume of 109 pages, with 24 illustrations. Cloth, 75 cents.

The course of instruction is divided into five sections or lectures. The first, or introductory lecture, gives a brief account of the structure and organization of the human body, illustrated by clear, suitable diagrams. The second teaches how to give judicious help in ordinary injuries—contusions, wounds, hemorrhage and poisoned wounds. The third treats of first aid in cases of fracture and of dislocations, in sprains and in burns. Next

the methods of affording first treatment in cases of frost-bite, of drowning, of suffocation, of loss of consciousness and of poisoning are described; and the fifth lecture teaches how injured persons may be most safely and easily transported to their homes, to a medical man, or to a hospital. The illustrations in the book are clear and good.—*Medical Times and Gazette*, Nov. 4, 1882.

TREVES, FREDERICK, F. R. C. S.,*Assistant Surgeon to and Lecturer on Surgery at the London Hospital.*

Intestinal Obstruction. In one pocket-size 12mo. volume of 522 pages, with 60 illustrations. Limp cloth, blue edges, \$2.00. *Just ready.* See *Series of Clinical Manuals*, page 3.

A standard work on a subject that has not been so comprehensively treated by any contemporary English writer. Its completeness renders a full review difficult, since every chapter deserves minute attention, and it is impossible to do thorough

justice to the author in a few paragraphs. *Intestinal Obstruction* is a work that will prove of equal value to the practitioner, the student, the pathologist, the physician and the operating surgeon.—*British Medical Journal*, Jan. 31, 1885.

BALL, CHARLES B., M. Ch., Dub., F. R. C. S. E.,*Surgeon and Teacher at Sir P. Dun's Hospital, Dublin.*

Diseases of the Rectum and Anus. In one 12mo. volume of 560 pages. *Preparing.* See *Series of Clinical Manuals*, page 3.

BUTLIN, HENRY T., F. R. C. S.,*Assistant Surgeon to St. Bartholomew's Hospital, London.*

Diseases of the Tongue. In one 12mo. volume. See *Series of Clinical Manuals*, page 3. *Shortly.*

DRUITT, ROBERT, M. R. C. S., etc.

The Principles and Practice of Modern Surgery. From the eighth London edition. In one 8vo. volume of 687 pages, with 432 illus. Cloth, \$4; leather, \$6.

HOLMES, TIMOTHY, M. A.,*Surgeon and Lecturer on Surgery at St. George's Hospital, London*

A System of Surgery; Theoretical and Practical. IN TREATISES BY VARIOUS AUTHORS. AMERICAN EDITION, THOROUGHLY REVISED AND REWRITTEN BY JOHN H. PACKARD, M. D., Surgeon to the Episcopal and St. Joseph's Hospitals, Philadelphia, assisted by a corps of thirty-three of the most eminent American surgeons. In three large and very handsome imperial octavo volumes, containing 3127 double-columned pages, with 979 illustrations on wood and 13 lithographic plates, beautifully colored. Price per volume, cloth, \$8.00; leather \$7.00; half Russia, \$7.50. Per set, cloth, \$12.00; leather, \$21.00; half Russia, \$22.50. *Sold only by subscription.*

VOLUME I. CONTAINS GENERAL PATHOLOGY, MORBID PROCESSES, INJURIES IN GENERAL, COMPLICATIONS OF INJURIES AND INJURIES OF REGIONS.

VOLUME II. CONTAINS DISEASES OF ORGANS OF SPECIAL SEXES, CIRCULATORY SYSTEM, DIGESTIVE TRACT AND GENITO-URINARY ORGANS.

VOLUME III. CONTAINS DISEASES OF THE RESPIRATORY ORGANS, BONES, JOINTS AND MUSCLES, DISEASES OF THE NERVOUS SYSTEM, GUNSHOT WOUNDS, OPERATIVE AND MINOR SURGERY, AND MISCELLANEOUS SUBJECTS (including an essay on Hospitalism).

This great work, issued some years since in England has won such universal confidence wherever the language is spoken that its republication here, in a form more thoroughly adapted to the wants of the American practitioner, has seemed to be a duty owing to the profession. To accomplish this, each article has been placed in the hands of a gentleman specially competent to treat its subject, and no labor has been spared in bringing each one up to the foremost level of the times, and to adapt it thoroughly to the practice of the country. In certain cases this has rendered necessary the substitution of an entirely new essay for the original, as in the case of the articles on Skin Diseases, on Diseases of the Absorbent System, and on Anæsthetics, in the use of which American practice differs from that of England. The same careful and conscientious revision has been pursued throughout, leading to an increase of nearly one-fourth in matter, while the series of illustrations has been nearly trebled, and the whole is presented as a complete exposition of British and American Surgery, adapted to the daily needs of the working practitioner.

In order to bring it within the reach of every member of the profession, the five volumes of the original have been compressed into three by employing a double columned royal octavo page, and in this improved form it is offered at less than one half the price of the original. It is printed and bound to match in every detail with Reynolds' System of Medicine. The work will be sold by subscription only, and in due time every member of the profession will be called upon and offered an opportunity to subscribe.

The authors of the original English edition are men of the front rank in England, and Dr. Packard has been fortunate in securing as his American contributors such men as Bartholow, Hyde, Hunt, Connor, Stimson, Morton, Hodge, Jewell and their colleagues. As a whole, the work will be sold and substantial, and a valuable addition to

the library of any medical man. It is more useful and more useful than the English edition, and without its companion work—Reynolds' System of Medicine—no well-informed physician or surgeon would be fairly well furnished knowledge and hands. *—The Medical News, Jan. 7, 1882.*

STIMSON, LEWIS A., B. A., M. D.,*Professor of Pathological Anatomy at the University of the City of New York, Surgeon and Curator to Bellevue Hospital, Surgeon to the Presbyterian Hospital, New York, etc.*

A Practical Treatise on Fractures. In one very handsome octavo volume of 598 pages, with 360 beautiful illustrations. Cloth, \$4.75; leather, \$5.75.

The author has given to the medical profession in this treatise on fractures what is likely to become a standard work on the subject. It is certainly not surpassed by any work written in the English or, for that matter, any other language. The author tells us in a short, concise and comprehensible manner, all that is known about dislocations. There is nothing steady or superficial about it, as in most other treatises; on the contrary, everything is thorough. The chapters on repair of fractures and their treatment show him not only to be a profound student, but likewise a practical surgeon and pathologist. His mode of treatment of the different fractures is entirely original and practical. We can do this work one of the best on fractures, and it will be welcomed not only as a text-book, but also by

the surgeon in full practice. *—N. O. Medical and Surgical Journal, March, 1882.*

The author gives in clear language all that the practical surgeon need know of the various kinds of fractures—their etiology, ætiology, prognosis, union, and treatment, according to the latest developments. On the basis of mechanical analysis the author accurately and clearly explains the clinical features of fractures, and by the same method arrives at the proper diagnosis and rational treatment. A thorough explanation of the pathological anatomy and a careful description of the various methods of procedure make this work full of value for every practitioner. *—Contributions to the Surgery, May 19, 1882.*

MARSH, HOWARD, F. R. C. S.,*Senior Assistant Surgeon and Lecturer on Anatomy at St. Bartholomew's Hospital, London.*

Diseases of the Joints. In one 12mo. volume. Preparing. See Series of Clinical Manuals, page 3.

PICK, T. PICKERING, F. R. C. S.,*Surgeon and Lecturer on Surgery at St. George's Hospital, London.*

Fractures and Dislocations. In one 12mo. volume. Preparing. See Series of Clinical Manuals, page 3.

HAMILTON, FRANK H., M. D., LL. D.,*Surgeon to Bellevue Hospital, New York.*

A Practical Treatise on Fractures and Dislocations. Seventh edition, thoroughly revised and much improved. In one very handsome octavo volume of 998 pages, with 379 illustrations. Cloth, \$5.50; leather, \$6.50; very handsome half Russia, open back, \$7.00. *Just ready.*

Hamilton's great experience and wide acquaintance with the literature of the subject have enabled him to complete the labors of Malgaigne and to place the reader in possession of the advances made during thirty years. The editions have followed each other rapidly, and they introduce us to the methods of practice, often so wise, of his American colleagues. More practical than Malgaigne's work, it will serve as a valuable guide to the practitioner in the numerous and embarrassing cases which come under his observation.—*Archives Gébérales de Médecine*, Paris, Nov. 1884.

There is no longer any necessity for reviewing this admirable work. It has triumphantly advanced to its seventh edition, its venerable and talented author still keeps abreast of the times, and it is still the most exhaustive practical treatise on fractures and dislocations in this or any

other language.—*Medical Record*, January 24, 1885.

With its first appearance in 1856, this work took rank among the classics in medical literature, and has ever since been quoted by surgeons the world over as an authority upon the topics of which it treats. The surgeon, if one can be found who does not already know the work, will find it scientific, forcible and scholarly in text, exhaustive in detail, and ever marked by a spirit of wise conservatism.—*Louisville Medical News*, Jan. 10, 1885.

For a quarter of a century the author has been elaborating and perfecting his work, so that it now stands as the best of its kind in any language. As a text-book and as a book of reference and guidance for practitioners it is simply invaluable.—*New Orleans Medical and Surgical Journal*, November, 1884.

JULER, HENRY E., F. R. C. S.,*Senior Asst Surgeon, Royal Westminster Ophthalmic Hosp.; late Clinician Asst, Moorfields, London.*

A Handbook of Ophthalmic Science and Practice. In one handsome octavo volume of 460 pages, with 125 woodcuts, 27 colored plates, and selections from the Test-types of Jaeger and Snellen. Cloth, \$4.50; leather, \$5.50. *Just ready.*

This work is distinguished by the great number of colored plates which appear in it for illustrating various pathological conditions. They are very beautiful in appearance, and have been executed with great care as to accuracy. An examination of the work shows it to be one of high standing, one that will be regarded as an authority among ophthalmologists. The treatment recommended is such as the author has learned from actual experience to be the best.—*Cincinnati Medical News*, Dec. 1884.

It presents to the student concise descriptions

and typical illustrations of all important eye affections, placed in juxtaposition, so as to be grasped at a glance. Beyond a doubt it is the best illustrated handbook of ophthalmic science which has ever appeared. Then, what is still better, these illustrations are nearly all original. We have examined this entire work with great care, and it represents the commonly accepted views of advanced ophthalmologists. We can most heartily commend this book to all medical students, practitioners and specialists.—*Detroit Lancet*, Jan. 1885.

WELLS, J. SOELBERG, F. R. C. S.,*Professor of Ophthalmology in King's College Hospital, London, etc.*

A Treatise on Diseases of the Eye. Fourth American from the third London edition. Thoroughly revised, with copious additions, by CHARLES S. BELL, M. D., Surgeon and Pathologist to the New York Eye and Ear Infirmary. In one large octavo volume of 822 pages, with 257 illustrations on wood, six colored plates, and selections from the Test-types of Jaeger and Snellen. Cloth, \$5.00; leather, \$6.00; half Russia, \$6.50.

The present edition appears in less than three years since the publication of the last American edition, and yet, from the numerous recent investigations that have been made in this branch of medicine, many changes and additions have been required to meet the present scope of knowledge upon this subject. A critical examination at once

shows the fidelity and thoroughness with which the editor has accomplished his part of the work. The illustrations throughout are good. This edition can be recommended to all as a complete treatise on diseases of the eye, than which probably none better exists.—*Medical Record*, Aug. 18, '83.

NETTLESHIP, EDWARD, F. R. C. S.,*Ophthalmic Surg. and Lect. on Ophth. Surg. at St. Thomas' Hospital, London.*

The Student's Guide to Diseases of the Eye. Second edition. With a chapter on the Detection of Color-Blindness, by WILLIAM THOMSON, M. D., Ophthalmologist to the Jefferson Medical College. In one royal 12mo. volume of 416 pages, with 133 illustrations. Cloth, \$2.00.

This admirable guide bids fair to become the favorite text-book on ophthalmic surgery with student and general practitioners. It bears throughout the imprint of sound judgment combined with vast experience. The illustrations are numerous

and well chosen. This book, within the short compass of about 400 pages, contains a lucid exposition of the modern aspect of ophthalmic science.—*Medical Record*, June 23, 1883.

BROWNE, EDGAR A.,*Surgeon to the Liverpool Eye and Ear Infirmary and to the Dispensary for Skin Diseases.*

How to Use the Ophthalmoscope. Being Elementary Instructions in Ophthalmoscopy, arranged for the use of Students. In one small royal 12mo. volume of 116 pages, with 35 illustrations. Cloth, \$1.00.

LAWSON ON INJURIES TO THE EYE, ORBIT AND EYELIDS. Their Immediate and Remote Effects. 8 vo., 504 pp., 2 illus. Cloth, \$1.50.

LAURENCE AND MOON'S HANDY BOOK OF OPHTHALMIC SURGERY, for the use of Prac-

tioners. Second edition. In one octavo volume of 227 pages, with 65 illus. Cloth, \$2.75.

CARTER'S PRACTICAL TREATISE ON DISEASES OF THE EYE. Edited by JOHN GAZZAM, M. D. In one handsome octavo volume.

BURNETT, CHARLES H., A. M., M. D.*Professor of Otolaryngology in the Philadelphia Polytechnic, President of the American Otolaryngological Society.*

The Ear, Its Anatomy, Physiology and Diseases. A Practical Treatise for the use of Medical Students and Practitioners. New second edition. In one handsome octavo volume of 580 pages, with 107 illustrations. Cloth, \$4.00; leather, \$5.00. *Just ready.*

We note with pleasure the appearance of a second edition of this valuable work. When first came out it was accepted by the profession as one of the standard works on modern otal surgery in the English language, and its high second edition, by Burnett has fully maintained his reputation, for the book is replete with valuable information and suggestions. The revision has been carefully

carried out, and much new matter added. Dr. Burnett's work must be regarded as a very valuable contribution to otal surgery, and on account of its comprehensive nature, the student contains the results of careful personal observation and experience of the most eminent authorities. —*London Lancet*, Feb. 24, 1895.

POLITZER, ADAM.*Imperial Royal Prof. of Acute Therap. in the Univ. of Vienna.*

A Text-Book of the Ear and its Diseases. Translated, at the Author's request, by JAMES PATTERSON CASSELL, M. D., M. R. C. S. In one handsome octavo volume of 800 pages, with 257 original illustrations. Cloth, \$5.50.

The work itself we do not hesitate to pronounce the best upon the subject of otal diseases which has ever appeared, systematic without being too diffuse, on obscure subjects and eminently practical in every sense. The anatomical descriptions of each separately division of the ear are admirable, and profusely illustrated by woodcuts. They are followed immediately by the physiology of the

section, and this again by the pathological, physiology, an arrangement which serves to keep in the interest of the student by showing the direct application of what has preceded to the study of the case. The whole work can be recommended as a reliable guide to the student, and an efficient aid to the practitioner in the treatment. —*Boston Medical and Surgical Journal*, June 7, 1893.

ROBERTS, WILLIAM, M. D.*Lectures on Medicine in the Manchester School of Medicine, etc.*

A Practical Treatise on Urinary and Renal Diseases, including Urinary Deposits. Fourth American from the fourth London edition. In one handsome octavo volume of about 650 pages, with 51 illustrations. Cloth, \$3.50. *Just ready.*

GROSS, S. D., M. D., LL. D., D. C. L., etc.

A Practical Treatise on the Diseases, Injuries and Malformations of the Urinary Bladder, the Prostate Gland and the Urethra. Third edition, thoroughly revised by SAMUEL W. GROSS, M. D., Professor of the Principles of Surgery and of Clinical Surgery in the Jefferson Medical College, Philadelphia. In one octavo volume of 374 pages, with 170 illustrations. Cloth, \$4.50.

MORRIS, HENRY, M. B., F. R. C. S.*Surgeon to and Lecturer on Surgery at Middlesex Hospital, London.*

Surgical Diseases of the Kidney. In one 12mo. volume. *Preparing.* See *Series of Clinical Manuals*, page 3.

LUCAS, CLEMENT, M. B., B. S., F. R. C. S.*Senior Assistant Surgeon to Guy's Hospital, London.*

Diseases of the Urethra. In one 12mo. volume. *Preparing.* See *Series of Clinical Manuals*, page 3.

THOMPSON, SIR HENRY.*Surgeon and Professor of Clinical Surgery in University College Hospital, London.*

Lectures on Diseases of the Urinary Organs. Second American from the third English edition. In one octavo volume of 203 pp., with 25 illustrations. Cloth, \$2.25.

By the Same Author.

On the Pathology and Treatment of Stricture of the Urethra and Urinary Fistulae. From the third English edition. In one octavo volume of 309 pages, with 47 cuts and 3 plates. Cloth, \$3.50.

COLEMAN, A., L. R. C. P., F. R. C. S., Exam. L. D. S.*Senior Dent. Surg. and Lect. on Dent. Surg. at St. Bartholomew's Hosp. and the Dent. Hosp., London.*

A Manual of Dental Surgery and Pathology. Thoroughly revised and adapted to the use of American Students, by THOMAS C. STELLWAGEN, M. A., M. D., D. D. S., Prof. of Physiology at the Philadelphia Dental College. In one handsome octavo volume of 412 pages, with 331 illustrations. Cloth, \$3.25.

This volume deserves to rank among the most important of recent contributions to dental literature. Mr. Coleman has presented his methods of practice, for the most part, in a plain and concise manner, and the work of the American editor has been most ably performed. He has evidently labored to present his conclusions of the best method

of practice for the instruction of those commencing a professional career, and he has faithfully endeavored to teach to others all that he has acquired by his own observation and experience. The book deserves a place in the library of every dentist. —*Dental Cosmos*, May, 1892.

BASHAM ON RENAL DISEASES. A Clinical Guide to their Diagnosis and Treatment. In one 12mo. vol. of 304 pages, with 21 illustrations. Cloth, \$1.50.

BUMSTEAD, F. J., and TAYLOR, R. W.,
M. D., LL. D., A. M., M. D.,

Late Professor of Venereal Diseases at the College of Physicians and Surgeons, New York, etc.

Surgeon to Charity Hospital, New York, Prof. of Venereal and Skin Diseases in the University of Vermont, Pres. of the Am. Dermatological Ass'n.

The Pathology and Treatment of Venereal Diseases. Including the results of recent investigations upon the subject. Fifth edition, revised and largely rewritten, by Dr. Taylor. In one large and handsome octavo volume of 898 pages with 139 illustrations, and thirteen chromo-lithographic figures. Cloth, \$4.75; leather, \$5.75; very handsome half Russia, \$6.25.

It is a splendid record of honest labor, wide research, just comparison, careful scrutiny and original experience, which will always be held as a high credit to American medical literature. This is not only the best work in the English language upon the subjects of which it treats, but also one which has no equal in other tongues for its clear, comprehensive and practical handling of its themes.—*American Journal of the Medical Sciences*, Jan. 1884.

It is certainly the best single treatise on venereal in our own, and probably the best in any language.—*Boston Medical and Surgical Journal*, April 1, 1881.

The character of this standard work is so well known that it would be superfluous here to pass in review its general or special points of excellence. The verdict of the profession has been passed; it has been accepted as the most thorough and complete exposition of the pathology and treatment of venereal diseases in the language. Admirable as a model of clear description, as an exponent of sound pathological doctrine, and a guide for rational and successful treatment, it is an ornament to the medical literature of this country. The additions made to the present edition are eminently judicious, from the standpoint of practical utility.—*Journal of Cutaneous and Venereal Diseases*, Jan. 1884.

HUTCHINSON, JONATHAN, F. R. S., F. R. C. S.,

Consulting Surgeon to the London Hospital.

Syphilis. In one 12mo. volume. Preparing. See *Series of Clinical Manuals*, page 3.

CORNIL, V.,

Professor to the Faculty of Medicine of Paris, and Physician to the Lourcine Hospital.

Syphilis, its Morbid Anatomy, Diagnosis and Treatment. Specially revised by the Author, and translated with notes and additions by J. HENRY C. SUMM, M. D., Demonstrator of Pathological Histology in the University of Pennsylvania, and J. WILLIAM WHITE, M. D., Lecturer on Venereal Diseases and Demonstrator of Surgery in the University of Pennsylvania. In one handsome octavo volume of 461 pages, with 84 very beautiful illustrations. Cloth, \$3.75.

The anatomical and histological characters of the hard and soft sore are admirably described. The multifarious cutaneous manifestations of the disease are dealt with histologically in a masterly way, as we should indeed expect them to be, and the accompanying illustrations are executed carefully and well. The various nervous lesions which are the recognized outcome of the syphilitic dyscrasia are treated with care and consideration. Syphilitic epilepsy, paralysis, cerebral syphilis and locomotor ataxia are subjects full of interest: and nowhere in

the whole volume is the clinical experience of the author or the wide acquaintance of the translators with medical literature more evident. The anatomy, the histology, the pathology and the clinical features of syphilis are represented in this work in their best, most practical and most instructive form, and no one will rise from its perusal without the feeling that his grasp of the wide and important subject on which it treats is a stronger and surer one.—*The London Practitioner*, Jan. 1882.

GROSS, SAMUEL W., A. M., M. D.,

Professor of the Principles of Surgery and of Clinical Surgery in the Jefferson Medical College.

A Practical Treatise on Impotence, Sterility, and Allied Disorders of the Male Sexual Organs. Second edition, thoroughly revised. In one very handsome octavo volume of 188 pages, with 18 illustrations. Cloth, \$1.50.

The author of this monograph is a man of positive convictions and vigorous style. This is justified by his experience and by his study, which has gone hand in hand with his experience. In regard to the various organic and functional disorders of the male generative apparatus, he has had exceptional opportunities for observation, and his book shows that he has not neglected to compare his own views with those of other authors. The result is a work which can be safely recommended to both physicians and surgeons as a guide in the treatment of the disturbances it refers to. It is the best treatise on the subject with which we are acquainted.—*The Medical News*, Sept. 1, 1882.

This work will derive value from the high standing of its author, aside from the fact of its passing so rapidly into its second edition. This is, indeed, a book that every physician will be glad to place in his library, to be read with profit to himself, and with incalculable benefit to his patient. Besides the subjects embraced in the title, which are treated of in their various forms and degrees, spermatorrhoea and prostaticorrhoea are also fully considered. The work is thoroughly practical in character, and will be especially useful to the general practitioner.—*Medical Record*, Aug. 16, 1882.

CULLERIER, A., & BUMSTEAD, F. J., M. D., LL. D.,

Surgeon to the Hôpital du Midi.

Late Professor of Venereal Diseases in the College of Physicians and Surgeons, New York.

An Atlas of Venereal Diseases. Translated and edited by FREEMAN J. BUMSTEAD, M. D. In one imperial 4to. volume of 328 pages, double-columns, with 26 plates, containing about 150 figures, beautifully colored, many of them the size of life. Strongly bound in cloth, \$17.00. A specimen of the plates and text sent by mail, on receipt of 25 cts.

HILL ON SYPHILIS AND LOCAL CONTAGIOUS DISORDERS. In octavo vol. of 479 p. Cloth, \$3.25.

FORMA OF LOCAL DISEASE AFFECTING PRINCIPALLY THE ORGANS OF GENERATION. In one 8vo. vol. of 94 pages. Cloth, \$2.25.

HYDE, J. NEVINS, A. M., M. D.,*Professor of Dermatology and Venereal Diseases in Rush Medical College, Chicago.*

A Practical Treatise on Diseases of the Skin. For the use of Students and Practitioners. In one handsome octavo volume of 370 pages, with 66 beautiful and elaborate illustrations. Cloth, \$4.25, leather \$5.25.

The author has given the student and practitioner a work admirably adapted to the wants of each. We can heartily commend the book as a valuable addition to our literature and a reliable guide to students and practitioners in their studies and practice.—*The Journal of Med. Sci.*, July, 1888.

Especially to be praised are the practical suggestions as to what may be called the conservative treatment of eczema. It is quite impossible to exaggerate the judiciousness with which the formulae for the external treatment of eczema are selected, and what is of equal importance, the full and clear instructions for their use.—*Lancet Medical Times and Gazette*, July 28, 1888.

The work of Dr. Hyde will be awarded a high position. The student of medicine as well as the practitioner is peculiarly adapted to his wants. Notwithstanding the extent of the subject to which it is devoted, yet it is limited to a single and not very large volume, without omitting a proper discussion of the topics. The compactness of the volume, and the setting forth of only what can be held as facts will also make it acceptable to general practitioners.—*New York Medical News*, Feb. 1888.

The aim of the author has been to present to his readers a work not only exhaustive, the latest modern conceptions of his subject, but presenting what is of standard value. He has more especially devoted his pages to the treatment of disease, and by his detailed descriptions of therapeutic measures has adapted them to the needs of the physi-

cian in active practice. In dealing with these questions the author leaves nothing to the practical knowledge of the reader, but enters thoroughly into the most minute details, so that one is not only told what should be done under given conditions but how to do it as well. It is therefore in the best sense "a practical treatise." That it is comprehensive, a glance at the index will show.—*Medical Journal*, Nov. 7, 1888.

Professor Hyde has long been known as one of the most intelligent and original contributors to the literature of this specialty. His numerous contributions to the literature of this specialty have gained for him a favorable recognition as a careful, conscientious and original observer. His remarkable advances made in our knowledge of diseases of the skin, especially from the standpoint of pathological histology and improved methods of treatment, necessitate a revision of the older textbooks at short intervals in order to bring them up to the standard demanded by the march of science. This last contribution of Dr. Hyde is an effort in this direction. He has attempted as far as information, the task of presenting in a condensed form the results of the latest observation and experiment. A careful examination of the work convinces us that he has accomplished his task with painstaking ability and with a commendable result.—*Journal of Cutaneous and Venereal Diseases*, June, 1888.

FOX, T., M.D., F.R.C.P., and FOX, T.C., B.A., M.R.C.S.,*Physician to the Department for Skin Diseases, University College Hospital, London.**Physician in Charge of the Skin to the Westminster Hospital, London.*

An Epitome of Skin Diseases. With Formulæ. For Students and Practitioners. Third edition, revised and enlarged. In one very handsome 12mo. volume of 238 pages. Cloth, \$1.25.

The third edition of this convenient handbook calls for notice, owing to the revision and expansion which it has undergone. The arrangement of skin diseases in alphabetical order, which is the method of classification adopted in this work, becomes a positive advantage to the student. The book is one which we can strongly recommend, not only to students but also to practitioners, as it gives a complete and accurate summary of the present status of dermatology.—*British Medical Journal*, July 4, 1888.

We cordially recommend Fox's *Epitome* to those whose time is limited and who want a handy

manual to refer to for instant reference. The alphabetical arrangement is suited to the use of the practitioner, as the name of the disease, and here are its description and the appropriate treatment at hand and ready for instant application. The present edition has been very carefully revised and a number of new diseases are described, while many of the present additions to dermatological therapeutics find mention, and the formulae at the end of the book has been considerably augmented.—*The Medical News*, December, 1888.

MORRIS, MALCOLM, M. D.,*Joint Lecturer in Dermatology at St. Mary's Hospital Medical School, London.*

Skin Diseases; Including their Definitions, Symptoms, Diagnosis, Prognosis, Morbid Anatomy and Treatment. A Manual for Students and Practitioners. In one 12mo. volume of 316 pages, with illustrations. Cloth, \$1.75.

To physicians who would like to know something about skin diseases, so that when a patient presents himself for relief they can make a correct diagnosis and prescribe a rational treatment, we unhesitatingly recommend this volume of Dr. Morris. The definitions of the eruptions are described in a terse, but concise and thorough manner, and the symptoms so plainly set forth that diagnosis will be easy. The treatment in each case is simple and easy to follow, and the illustrations of the most important dermatological diseases.—*New York Medical News*, Apr. 1, 1888.

This is originally a lecturer's book for we can safely say, that in the whole range of medical literature there is no book of which we can speak

for its clearness of expression and methodical arrangement is better adapted to promote a rational conception of dermatology—a book confessedly deficient and perplexing to the beginner.—*St. Louis Clinical Conference*, April, 1888.

The author has written this book in a small compass a large amount of well-supplied information, and has little been compared favorably with any other work, has emanated from England, and many points have been incorporated into it from the best foreign sources. It is a book of which every physician should have a copy which will very readily furnish.—*British Medical News*, March, 1888.

WILSON, ERASMUS, F. R. S.

The Student's Book of Cutaneous Medicine and Diseases of the Skin. In one handsome small octavo volume of 335 pages. Cloth, \$3.00.

HILLIER, THOMAS, M. D.,*Physician to the Skin Department of University College, London.*

Handbook of Skin Diseases; For Students and Practitioners. Second American edition. In one 12mo. volume of 372 pages, with plates. Cloth, \$2.25.

AN AMERICAN SYSTEM OF GYNÆCOLOGY.

A System of Gynecology, in Treatises by Various Authors. Edited by MATTHEW D. MANN, M. D., Professor of Obstetrics and Gynecology in the University of Buffalo, N. Y. In two handsome octavo volumes, richly illustrated. In active preparation.

WILLIAM H. WELCH, M. D.

THOMAS, T. GAILLARD, M. D.,

Professor of Diseases of Women in the College of Physicians and Surgeons, N. Y.

A Practical Treatise on the Diseases of Women. Fifth edition, thoroughly revised and rewritten. In one large and handsome octavo volume of 810 pages, with 266 illustrations. Cloth, \$5.00; leather, \$6.00; very handsome half Russia, raised bands, \$6.50.

The words which follow "fifth edition" are in this case no mere formal announcement. The alterations and additions which have been made are both numerous and important. The attraction and the permanent character of this book lie in the clearness and truth of the clinical descriptions of diseases; the fertility of the author in therapeutic resources and the fulness with which the details of treatment are described, the definite character of the teaching; and last, but not least, the evident candor which pervades it. We would also particularize the fulness with which the history of the subject is gone into, which makes the book additionally interesting and gives it value as a work of reference.—*London Medical Times and Gazette*, July 30, 1881.

The determination of the author to keep his book foremost in the rank of works on gynecology is most gratifying. Recognizing the fact that this can only be accomplished by frequent and thorough revision, he has spared no pains to make the present edition more desirable even than the previous one.

As a book of reference for the busy practitioner it is unequalled.—*Boston Medical and Surgical Journal*, April 7, 1880.

It has been enlarged and carefully revised. It is a condensed encyclopedia of gynecological medicine. The style of arrangement, the masterly manner in which each subject is treated, and the honest convictions derived from probably the largest clinical experience in that specialty of any in this country, all serve to commend it in the highest terms to the practitioner.—*Nashville Jour. of Med. and Surg.*, Jan. 1881.

That the previous editions of the treatise of Dr. Thomas were thought worthy of translation into German, French, Italian and Spanish, is enough to give it the stamp of genuine merit. At home it has made its way into the library of every obstetrician and gynecologist as a safe guide to practice. No small number of additions have been made to the present edition to make it correspond to recent improvements in treatment.—*Pacific Medical and Surgical Journal*, Jan. 1881.

EDIS, ARTHUR W., M. D., Lond., F. R. C. P., M. R. C. S.,

Asst. Obstetric Physician to Middlesex Hospital, late Physician to British Lying-in Hospital.

The Diseases of Women. Including their Pathology, Causation, Symptoms, Diagnosis and Treatment. A Manual for Students and Practitioners. In one handsome octavo volume of 576 pages, with 148 illustrations. Cloth, \$3.00; leather, \$4.00.

It is a pleasure to read a book so thoroughly good as this one. The special qualities which are conspicuous are thoroughness in covering the whole ground, clearness of description and conciseness of statement. Another marked feature of the book is the attention paid to the details of many minor surgical operations and procedures, as, for instance, the use of tents, application of leeches, and use of hot water injections. These are among the more common methods of treatment, and yet very little is said about them in many of the text-books. The book is one to be warmly recommended especially to students and general practitioners, who would a concise but complete statement of the whole subject. Specialists, too, will find many useful hints in its pages.—*Boston Med. and Surg. Jour.*, March 2, 1882.

The greatest pains have been taken with the sections relating to treatment. A liberal selection of remedies is given for each morbid condition, the strength, mode of application and other details being fully explained. The descriptions of gynecological manipulations and operations are full, clear and practical. Much care has also been bestowed on the parts of the book which deal with diagnosis—we note especially the pages dealing with the differentiation, one from another, of the different kinds of abdominal tumors. The practitioner will therefore find in this book the kind of knowledge he most needs in his daily work, and he will be pleased with the clearness and fulness of the information there given.—*The Practitioner*, Feb. 1882.

BARNES, ROBERT, M. D., F. R. C. P.,

Obstetric Physician to St. Thomas' Hospital, London, etc.

A Clinical Exposition of the Medical and Surgical Diseases of Women. In one handsome octavo volume, with numerous illustrations. New edition. Preparing.

WEST, CHARLES, M. D.

Lectures on the Diseases of Women. Third American from the third London edition. In one octavo volume of 543 pages. Cloth, \$3.75; leather, \$4.75.

CHURCHILL ON THE PUERPERAL FEVER AND OTHER DISEASES PECULIAR TO WOMEN. In one svo. vol. of 464 pages. Cloth, \$2.50.

MEIGS ON THE NATURE, SIGNS AND TREATMENT OF CHILDHOOD FEVER. In one svo. volume of 346 pages. Cloth, \$2.00.

EMMET, THOMAS ADDIS, M. D., LL. D.,*Surgeon to the Woman's Hospital, New York, etc.*

The Principles and Practice of Gynecology; For the use of Students and Practitioners of Medicine. New, third edition, thoroughly revised. In one large and very handsome octavo volume of 380 pages, with 150 illustrations. Cloth, \$5; leather, \$6 (Just ready.)

Excerpt from the Author's Preface to the Second Edition.

So great have been the advance and change of views during the past four years in Gynecology, that the preparation of this edition has necessitated almost as much labor as to have rewritten the volume. Every portion has been thoroughly revised, a great deal has been left out, and much new matter added.

The chapters on the relation of education and social condition to development those on pelvic cellulitis, the diseases of the ovary and on ovariectomy, together with that on stone in the bladder, have been nearly rewritten.

The chapters on prolapse of the vaginal walls and lacerations of the vaginal outlet, the methods of partial and complete removal of the uterus for malignant disease, the surgical treatment of fibrous tumors, diseases of the Fallopian tubes, and the diseases of the urethra, are essentially new, with the views and experience of the author in a form which has not been presented to the profession before. To these chapters not less than one hundred and seventy-five pages of new material have been added.

The work may now be said fairly to represent the present position of gynecology in America, and is one of the best, if not the best, in the English language. It remains a worthy exponent of a life devoted to the study and practice of gynecology—a book that will be of influence to the profession at large, and one which will be a stimulus to better work wherever it is read.—*Boston Medical and Surgical Journal*, Jan. 26, 1887.

Any work in gynecology in Emmet must always have special interest and value. He has for many years been an extremely busy practitioner in his department. Few men have had his experience and opportunities. As a guide either for the general practitioner or specialist,

it is second to none other. No one can read Emmet without great instruction. *Am. Med. & Surg. J.*, Jan. 21, 1887.

It is with a feeling of pleasure that we welcome a work on diseases of women from so prominent a gynecologist as Dr. Emmet. The work is not only original, but covers a strong practical course with a delightful ability. To criticize the work is impossible, we care to state, without forward and no opinion that is at all estimated. In the work, we see nothing more than a well-organized, clear, and valuable treatise of practice, and it is written in an elegant and elegant style. We wish the library to contain it. *Am. Med. & Surg. J.*, Feb. 1, 1887.

DUNCAN, J. MATTHEWS, M.D., LL. D., F. R. S. E., etc.

Clinical Lectures on the Diseases of Women; Delivered in Saint Bartholomew's Hospital. In one handsome octavo volume of 175 pages. Cloth, \$1.50.

They are in every way worthy of their author, indeed, we look upon them as among the most valuable of his contributions. They are all upon matters of great interest to the general practitioner. Some of the material with respect to that, as a rule, adequately handled in the text-books. Others of it, while bearing upon topics that are usually treated of at length in such works, yet bear such a

stamp of individuality that, if widely read as they certainly deserve to be, they cannot fail to command a wide-spread interest. The value is enhanced with almost many young physicians who are bent upon following the well-known path which is the gynecology of the present day.—*N. Y. Med. & Surg. J.*, March, 1880.

HODGE, HUGH L., M. D.,*American Professor of Obstetrics, etc., in the University of Pennsylvania.*

On Diseases Peculiar to Women; Including Displacements of the Uterus. Second edition, revised and enlarged. In one beautifully printed octavo volume of 510 pages, with original illustrations. Cloth, \$1.50.

By the Same Author.

The Principles and Practice of Obstetrics. Illustrated with large lithographic plates containing 150 figures from original photographs, and with numerous woodcuts. In one large quarto volume of 542 double-columned pages. Strongly bound in cloth, \$14.00.

* * * Specimens of the plates and letter-press will be forwarded to any address, free by mail, on receipt of six cents in postage stamps.

TARNIER, S., and CHANTREUIL, G.

A Treatise on the Art of Obstetrics. Translated from the French. In two large octavo volumes, richly illustrated.

RAMSBOTHAM, FRANCIS H., M. D.

The Principles and Practice of Obstetric Medicine and Surgery; In reference to the Processed Parturition. A new and enlarged edition, thoroughly revised by the Author. With additions by W. V. KEATING, M. D., Professor of Obstetrics, etc., in the Jefferson Medical College of Philadelphia. In one large and handsome imperial octavo volume of 640 pages, with 61 full-page plates and 43 woodcuts in the text, constituting in all nearly 200 beautiful figures. Strongly bound in leather, with raised bands, \$7.

ASHWELL'S PRACTICAL TREATISE ON THE DISEASES PECULIAR TO WOMEN. Third

American from the third and revised London edition. In one large vol., pp. 620. Cloth, \$2.50.

PLAYFAIR, W. S., M. D., F. R. C. P.,*Professor of Obstetric Medicine in King's College, London, etc.*

A Treatise on the Science and Practice of Midwifery. New (fourth) American edition, revised by the Author. Edited, with additions, by ROBERT P. HARRIS, M. D. In one handsome octavo volume of about 700 pages, with 183 illustrations and 3 plates. Cloth, \$4; leather, \$5; half Russia, \$5.50. *Just ready.*

A few notices of the previous edition are appended:

The medical profession has now the opportunity of adding to their stock of standard medical works one of the best volumes on midwifery ever published. The subject is taken up with a master hand. The part devoted to labor in all its various presentations, the management and results, is admirably arranged, and the views entertained will be found essentially modern, and the opinions expressed trustworthy. The work abounds with plates, illustrating various obstetrical positions, they are admirably wrought, and afford great assistance to the student.—*N. O. Medical and Surgical Journal*, March, 1880.

If inquired of by a medical student what work on obstetrics we should recommend for him, *par excellence*, we would undoubtedly advise him to

choose Playfair's. It is of convenient size, but what is of chief importance, its treatment of the various subjects is concise and plain. While the discussions and descriptions are sufficiently elaborate to render a very intelligible idea of them, yet all details not necessary for a full understanding of the subject are omitted.—*Cincinnati Medical News*, Jan., 1880.

It certainly is an admirable exposition of the science and practice of midwifery. Of course the additions made by the American editor, Dr. R. P. Harris, who never utters an idle word, and whose studious researches in some special departments of obstetrics are so well known to the profession, are of great value.—*The American Practitioner*, April, 1880.

KING, A. F. A., M. D.,*Professor of Obstetrics and Diseases of Women in the Medical Department of the Columbian University, Washington, D. C., and in the University of Vermont, etc.*

A Manual of Obstetrics. New edition. In one very handsome 12mo. volume of 331 pages, with 59 illustrations. Cloth, \$2.00.

In a series of short paragraphs and by a condensed style of composition, the writer has presented a great deal of what it is well that every obstetrician should know and be ready to practice or prescribe. The fact that the demand for the volume has been such as to exhaust the first edition in a little over a year and a half speaks well for its popularity.—*American Journal of the Medical Sciences*, April, 1884.

This little work upon obstetrics will be highly valued by medical students. We feel quite sure that it will be in great demand by them, so suited is it to their wants. Of a size that it can be easily carried, yet it contains all of the main points in obstetrics sufficiently elaborated to give a full and

correct idea of them. The general practitioner will also find it very useful for reference, for the purpose of refreshing the mind. We can confidently assert that it will be found to be the best class text-book upon obstetrics that has been issued from the press.—*Cincinnati Medical News*, March, 1884.

It must be acknowledged that this is just what it pretends to be—a sound guide, a portable epitome, a work in which only indispensable matter has been presented, leaving out all padding and chaff, and one in which the student will find pure wheat or condensed nutriment.—*New Orleans Medical and Surgical Journal*, May, 1884.

BARNES, ROBERT, M. D., and FANCOURT, M. D.,*Phys. to the General Lying-in Hosp., Lond.**Obstetric Phys. to St. Thomas' Hosp., Lond.*

A System of Obstetric Medicine and Surgery, Theoretical and Clinical. For the Student and the Practitioner. The Section on Embryology contributed by Prof. Milnes Marshall. In one handsome octavo volume of about 1000 pages, profusely illustrated. Cloth, \$5; leather, \$8. *In press.*

BARNES, FANCOURT, M. D.,*Obstetric Physician to St. Thomas' Hospital, London.*

A Manual of Midwifery for Midwives and Medical Students. In one royal 12mo. volume of 197 pages, with 50 illustrations. Cloth, \$1.25.

PARVIN, THEOPHILUS, M. D., LL. D.,*Professor of Obstetrics and the Diseases of Women and Children in the Jefferson Medical College.*

A Treatise on Midwifery. In one very handsome octavo volume of about 550 pages, with numerous illustrations. *In press.*

PARRY, JOHN S., M. D.,*Obstetrician to the Philadelphia Hospital, Vice-President of the Obstet. Society of Philadelphia.*

Extra-Uterine Pregnancy: Its Clinical History, Diagnosis, Prognosis and Treatment. In one handsome octavo volume of 272 pages. Cloth, \$2.50.

TANNER, THOMAS HAWKES, M. D.

On the Signs and Diseases of Pregnancy. First American from the second English edition. In one handsome octavo volume of 490 pages, with 4 colored plates and 16 woodcuts. Cloth, \$4.25.

WINCKEL, F.

A Complete Treatise on the Pathology and Treatment of Childbed, For Students and Practitioners. Translated, with the consent of the Author, from the second German edition, by JAMES READ CHADWICK, M. D. In one octavo volume of 484 pages. Cloth, \$4.00.

LEISHMAN, WILLIAM, M. D.,*Regius Professor of Midwifery in the University of Glasgow, etc.*

A System of Midwifery, Including the Diseases of Pregnancy and the Puerperal State. Third American edition, revised by the Author, with additions by JOHN S. PARRY, M. D., Obstetrician to the Philadelphia Hospital, etc. In one large and very handsome octavo volume of 740 pages, with 205 illustrations. Cloth, \$4.50; leather, \$6.50. very handsome half Russia, raised bands, \$8.00.

The author is broad in his teachings, and discusses briefly the comparative anatomy of the pelvis and the mobility of the pelvic articulations. The second chapter is devoted especially to the study of the pelves, where in the third the female organs of generation are introduced. The structure and development of the ovum are admirably described. Some further chapters upon the various subjects embraced in the science of midwifery. The design is as thorough as the work and plan is judicious. It is sufficient to state that in this the author has done a noble work, every recent advancement in this field has been brought forward. *Pharmaceutical Surgeon, Jan. 1880.*

We gladly welcome the new edition of this excellent text-book of midwifery. The former editions have been most favorably received by the profession on both sides of the Atlantic. In the

preparation of the present edition the author has made most careful attention to the latest progress of anatomical science, as well as to the requirements of the student. The author has done a noble work, every recent advancement in this field has been brought forward. *Pharmaceutical Surgeon, Jan. 1880.*

In the American student the work before us must prove admirably adapted. Complete in all its parts, eminently modern in its terminology, and with demonstrations suited for teachers and students, it will gain its favor and be recognized as a work of standard merit. The work cannot fail to be popular and is cordially recommended.—*N. Y. Med. and Surg. Journal, March, 1880.*

SMITH, J. LEWIS, M. D.,*Clinical Professor of Diseases of Children in the Bellevue Hospital Medical College, N. Y.*

A Complete Practical Treatise on the Diseases of Children. Fifth edition, thoroughly revised and rewritten. In one handsome octavo volume of 536 pages, with illustrations. Cloth, \$4.50; leather, \$6.50; very handsome half Russia, raised bands, \$8.00.

This is one of the best text-books on the subject with which we have met and one that has given us satisfaction in every respect. In which we have consulted it, and as a diagnostic or therapeutic aid. It is now in the fifth edition and is a most valuable work. It is a very able and representative of the subject and a treatise of great practical importance. The important subject of life (the child) is fully dealt with in the early portion of the book. A great deal of the work is appropriate to the diseases of infancy and childhood. We would recommend any one in need of information on the subject to procure the work and find his own opinion on it.

which we venture to say will be a favorite one.—*British Journal of Medical Science, March, 1880.*

There is no more published on the subject of which we have treated that is the equal in value to this practical. We have said, and it is true, to discuss the different diseases of children and to discuss the different questions of etiology, pathology, and treatment. He has devoted much attention to the "etiological and therapeutic treatment of each disease," and is a most valuable and complete reference. It is even more valuable than the vast amount of "family physicians."—*In Med. Month, Feb. 1880.*

KEATING, JOHN M., M. D.,*Lecturer on the Diseases of Children at the University of Pennsylvania, etc.*

The Mother's Guide in the Management and Feeding of Infants. In one handsome 12mo. volume of 118 pages. Cloth, \$1.00.

When a man like Dr. Keating, who has been so long and so successfully giving his patients instruction in the subject, writes a book on the management and feeding of infants, it is a book that every mother should have. Dr. Keating has written a practical book, has carefully studied the most recent and successful methods of the treatment of infants, and has devoted much of his time to the study of the subject. He has studied the most successful methods of the treatment of infants, and has devoted much of his time to the study of the subject. He has studied the most successful methods of the treatment of infants, and has devoted much of his time to the study of the subject.

Dr. Keating has kept clear of the common fault of many of this sort, viz., mixing the duties of the mother with those of the physician. There is the ring of common sense in the remarks which

the employment of a wet-nurse, almost the proper food for a nursing mother, when the mother is unable to nurse, about the pertussis, the common cause of whooping cough, and many other subjects. It is a book which every mother should have. Dr. Keating has written a practical book, has carefully studied the most recent and successful methods of the treatment of infants, and has devoted much of his time to the study of the subject.

A book which every mother should have. OWEN, EDMUND, M. B., F. R. C. S.,*Surgeon to the Children's Hospital, Great Ormond St., London.*

Surgical Diseases of Children. In one 12mo. volume. Preparing. See No. 4 of *Clinical Manuals*, page 3.

WEST, CHARLES, M. D.,*Physician to the Hospital for Sick Children, London, etc.*

Lectures on the Diseases of Infancy and Childhood. Fifth American from 6th English edition. In one octavo volume of 186 pages. Cloth, \$4.50; leather, \$6.50.

By the Same Author.

On Some Disorders of the Nervous System in Childhood. In one small 12mo. volume of 127 pages. Cloth, \$1.00.

CONDIE'S PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. Fifth edition, revised and augmented. In one octavo volume of 770 pages. Cloth \$6.50; leather, \$8.25.

TIDY, CHARLES MEYMOTT, M. B., F. C. S.,*Professor of Chemistry and of Forensic Medicine and Public Health at the London Hospital, etc.*

Legal Medicine. VOLUME II. Legitimacy and Paternity, Pregnancy, Abortion, Rape, Indecent Exposure, Sodomy, Bestiality, Live Birth, Infanticide, Asphyxia, Drowning, Hanging, Strangulation, Suffocation. Making a very handsome imperial octavo volume of 529 pages. Cloth, \$6.00; leather, \$7.00.

VOLUME I. Containing 664 imperial octavo pages, with two beautiful colored plates. Cloth, \$6.00; leather, \$7.00.

The satisfaction expressed with the first portion of this work is in no wise lessened by a perusal of the second volume. We find it characterized by the same fulness of detail and clearness of expression which we had occasion so highly to commend in our former notice, and which render it so valuable to the medical jurist. The copious

tables of cases appended to each division of the subject, must have cost the author a prodigious amount of labor and research, but they constitute one of the most valuable features of the book, especially for reference in medico-legal trials.—*American Journal of the Medical Sciences*, April, 1894.

TAYLOR, ALFRED S., M. D.,*Lecturer on Medical Jurisprudence and Chemistry in Guy's Hospital, London.*

A Manual of Medical Jurisprudence. Eighth American from the tenth London edition, thoroughly revised and rewritten. Edited by JOHN J. REESE, M. D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania. In one large octavo volume of 937 pages, with 70 illustrations. Cloth, \$5.00; leather, \$6.00; half Russia, raised bands, \$6.50.

The American editions of this standard manual have for a long time laid claim to the attention of the profession in this country; and the eighth comes before us as embodying the latest thoughts and emendations of Dr. Taylor upon the subject to which he devoted his life with an assiduity and success which made him *facile princeps* among English writers on medical jurisprudence. Both the author and the book have made a mark too deep to be affected by criticism, whether it be censure or praise. In this case, however, we should

only have to seek for laudatory terms.—*American Journal of the Medical Sciences*, Jan. 1881.

This celebrated work has been the standard authority in its department for thirty-seven years, both in England and America, in both the professions which it concerns, and it is improbable that it will be superseded in many years. The work is simply indispensable to every physician, and nearly so to every liberally-educated lawyer, and we heartily commend the present edition to both professions.—*Albany Law Journal*, March 28, 1881.

By the Same Author.

The Principles and Practice of Medical Jurisprudence. Third edition. In two handsome octavo volumes, containing 1416 pages, with 188 illustrations. Cloth, \$10; leather, \$12. *Just ready.*

For years Dr. Taylor was the highest authority in England upon the subject to which he gave especial attention. His experience was vast, his judgment excellent, and his skill beyond cavil. It is therefore well that the work of one who, as Dr. Stevenson says, had an "enormous grasp of all

matters connected with the subject," should be brought up to the present day and continued in its authoritative position. To accomplish this result Dr. Stevenson has subjected it to most careful editing, bringing it well up to the times.—*American Journal of the Medical Sciences*, Jan. 1884.

By the Same Author.

Poisons in Relation to Medical Jurisprudence and Medicine. Third American, from the third and revised English edition. In one large octavo volume of 788 pages. Cloth, \$5.50; leather, \$6.50.

PEPPER, AUGUSTUS J., M. S., M. B., F. R. C. S.,*Examiner in Forensic Medicine at the University of London.*

Forensic Medicine. In one pocket-size 12mo. volume. *Preparing.* See *Students' Series of Manuals*, page 3.

LEA, HENRY C.

Superstition and Force: Essays on The Wager of Law, The Wager of Battle, The Ordeal and Torture. Third revised and enlarged edition. In one handsome royal 12mo. volume of 552 pages. Cloth, \$2.50.

This valuable work is in reality a history of civilization as interpreted by the progress of jurisprudence. . . . In "Superstition and Force" we have a philosophic survey of the long period intervening between primitive barbarity and civilized enlightenment. There is not a chapter in the work that

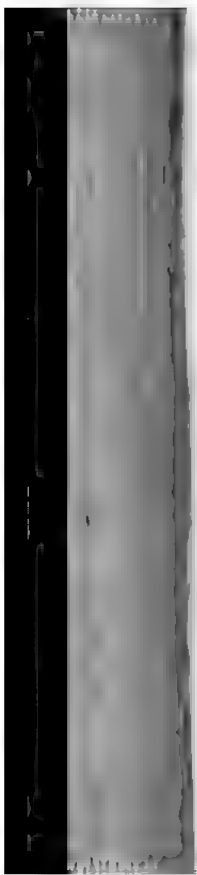

should not be most carefully studied; and however well versed the reader may be in the science of jurisprudence, he will find much in Mr. Lea's volume of which he was previously ignorant. The book is a valuable addition to the literature of social science.—*Westminster Review*, Jan. 1880.

By the Same Author.

Studies in Church History. The Rise of the Temporal Power—Benefit of Clergy—Excommunication. New edition. In one very handsome royal octavo volume of 695 pages. Cloth, \$2.50. *Just ready.*

The author is pre-eminently a scholar. He takes up every topic allied with the leading theme, and traces it out to the minutest detail with a wealth of knowledge and impartiality of treatment that compel admiration. The amount of information compressed into the book is extraordinary. In no other single volume is the development of the

primitive church traced with so much clearness, and with so definite a perception of complex or conflicting sources. The fifty pages on the growth of the papacy, for instance, are admirable for conciseness and freedom from prejudice.—*Boston Traveller*, May 3, 1883.
